Introduction Performance development in sprint running relies on small groups of athletes working closely with experienced coaches. Direct observation of technique is usually followed by verbal feedback. Video recordings are used sometimes to supplement feedback, and intermittent performance measures, from competitions, and from training data (e.g. 'flying 30s'), are used to monitor progress. Most enhancements arising from technology are provided in one-off sessions, or in the presence of third party specialists. The purpose of this paper is to outline the development and deployment of a self-contained computerised system to support athletics coaching and per-

formance, in which athletes and coaches have become part of a ubiquitous computing network. Methods The primary component of the system is a novel light gate system (Pisa Light Gates, or PLG, Cheng et al, 2010a), used to provide split times and split velocities for multiple athletes running at the same time. PLG comprises banks of photocell beams integrated into an athletics-training arena and operated by coaches from a web enabled hand-held wireless device (i.e. iPod touch). PLG logs split times automatically via an integrated gumstix computer, enabling immediate display to the coach via the hand-held device, and if required, on a large trackside screen. PLG provides a high level of flexibility for data retrieval: the coaches can view the data immediately or interrogate it confidentially via an SQL database using a password protected web interface to review their athletes, or in consultation with an individual sprinter (Cheng et al, 2010b). System evaluation has comprised validity checking of the novel timing beam configuration; and coach and athlete feedback on the operation and use of the data. Results Beam break times were evaluated against criterion 3D kinematic data (CODA) and found to agree to <10 ms. Interview responses from coaches and athletes have been overwhelmingly positive with the flexibility offered by the controller receiving universal acclaim. Discussion The lack of setup time, the ease of use and the ability to time multiple athletes simultaneously have made PLG ideal for its purposes. Importantly the system has been found not to interfere with the coaching process, but rather to enhance it; not to interfere with the athlete's performance but to enrich it; and finally to be easy to control via familiar every day mobile wireless technology. ## BETTER TIMES: MONITORING PERFORMANCE IN SWIMMING

SANDERS, R., MCCABE, C., MACHTSIRAS, G., THOW, J., EINARSSON, I.  
UNIVERSITY OF EDINBURGH

BETTER TIMES: MONITORING PERFORMANCE IN SWIMMING Sanders, R.1, McCabe, C.2, Machtsiras, G.1, Thow, J.1, Einarsson, I. 3 1: CARE, The University of Edinburgh (Edinburgh, Scotland), 2: University of Abertay (Dundee, Scotland), 3: University of Iceland (Reykjavik, Iceland) Introduction The extent to which feedback is valued by swimming coaches is related to how quickly the feedback is available. At the Centre for Aquatics Research and Education (CARE) methods have been developed with the aid of recent technology to return information to swimmers and coaches with quick turnaround times. The purpose of this paper is to describe the methods currently used at CARE to provide information to coaches and swimmers aimed at improving the performance of the swimmer. Methods The following protocols have been developed for providing feedback to swimming coaches and swimmers: 1. Video recording of mid-pool, starts, and turns, using above and below water cameras. The recordings are replayed on a plasma screen on poolside in normal, slow, and stopped motion. Advice of coaches and biomechanists can then be tried immediately by the swimmer and changes observed again in the same session. 2. Simple quantitative analysis is performed using the video data obtained from several camera views. Dartfish software is used to enhance the effectiveness and attractiveness of the reports. In addition to the typical 'race analysis' variables, two-dimensional angles and body positions are quantified enabling assessment of posture and technique. Discussion of the results with coaches, physiotherapists, strength and conditioning specialists, and the CARE biomechanists leads to informed interventions to improve performance. 3. A new method of quantifying glide performance in starts and turns (Naemi, and Sanders, 2008) has been further developed to yield coach friendly software that enables fast feedback (Naemi et al., under review). The efficacy of the system to improve start performance has been established by (Thow et al., under review). 4. Feedback regarding muscle activity could be instructive with respect to teaching a swimmer to relax muscles when they are not required to generate force. However, EMG is rarely used to provide feedback to coaches and swimmers. This is due to the difficulty of collecting EMG from swimmers while swimming. Waterproofing is normally problematic and the time required to prepare the swimmers is excessive. Additionally there is a problem in moving the recording system and the EMG electrode leads with the moving swimmer. However, recent technological advances have enabled the development of a wireless system that is easily waterproofed and quick to set up. References Thow J, Machtsiras G, Sanders RH. ## MONITORING SPORTS PERFORMANCE IN VARIOUS SETTINGS – THE MOBILE MOTION ADVISOR

BACA, A.  
ISW AT THE UNIVERSITY OF VIENNA

Introduction The intention of mobile motion assistance is to support athletes (leisure time and elite sport) in their training. A mobile device gathers performance parameter values on the spot and sends them to a server component for further analyses. The classification of the data and generation of (immediate) feedback is based on expert knowledge. Methods A prototype system for monitoring, transmitting and processing sports performance data for the purpose of providing feedback has been developed (cf. Baca et al., 2010). During training, athletes are equipped with a mobile device and wireless sensors communicating via the ANT protocol in order to acquire biomechanical, physiological and other sports specific performance parameters. The measured data is buffered locally and forwarded via Internet to a server. The server provides experts with remote data access, analysis and (partly automated) feedback routines. In this way, experts are able to analyse the athlete's performance and return individual feedback messages from remote locations. Results and Discussion Three use cases comprising application fields of the MMA have already been realised (Preuschl et al., 2010). Our first implementations concern running and mountain biking, two endurance sports. Furthermore, selected weight training machines have been equipped with sensor and communication technology for giving feedback during resistance exercises. The prototype installations of the MMA have been set up for use during physical education activities. Interactive communication technology is thus provided to teachers and students. Characteristic parameters of the performances of a whole class can be supervised continuously. In this way the teachers are able to monitor performance and activity data of a large number of students and may give the students individual feedback. #### ANAEROBIC THRESHOLD DETERMINATION IN HEALTHY MALES: CAN NIRS HELP?

BELLOTTI, C., DE ROIA, G., CALABRIA, E., POGLIAGHI, S.

UNIVERSITY OF VERONA

**PURPOSE:** Muscle O<sub>2</sub> extraction (i.e. deoxyHb), as measured non-invasively by near-infrared spectroscopy (NIRS), increases linearly during an incremental cycling exercise, showing a modified slope (deflection point) at 50-70% of VO<sub>2</sub>max. A possible coincidence of this deflection point with anaerobic threshold (AT) has been suggested, yet not univocally demonstrated, by previous studies using different NIRS systems/parameters and AT indexes. We tested the hypothesis that AT can be accurately determined based on quantitative measures of deoxyHb. We compared the NIRS-derived AT (NIRSAT, determined by double linear function fitting) to the first ventilatory threshold (VT1) defined by Wasserman method. **METHODS:** 77 healthy men (age 55±17 yrs - range 20-80; VO<sub>2</sub>max 35.0±9.6 mL•Kg<sup>-1</sup>•min<sup>-1</sup> - range 17-60) performed an incremental test to exhaustion on a cycle ergometer (Sport Excalibur, Lode, The Netherlands). Cardiorespiratory variables were measured BbB using a metabolic cart (Quark b2, Cosmed, Italy). DeoxyHb was monitored non-invasively on the right vastus lateralis with a quantitative, continuous-wave, single-distance NIRS (OxiplexTS, ISS, USA). The possible coincidence of VO<sub>2</sub> and HR values at NIRSAT and at VT1 was tested by: i) paired Student's t-test; ii) Pearson product moment correlation and iii) Bland Altman analysis. **RESULTS:** VO<sub>2</sub> and HR at VT1 were 1917±484 mL•min<sup>-1</sup> (70±8 % VO<sub>2</sub>max) and 124±16 bpm (77±7 % HRmax) respectively. Muscle O<sub>2</sub> extraction increased as a function of exercise intensity up to a deflection point, NIRSAT, at which VO<sub>2</sub> was 1991±533 mL•min<sup>-1</sup> (73±11 %VO<sub>2</sub>max) and HR was 128±19 bpm (80±9 % HRmax). For both VO<sub>2</sub> and HR, the difference from VT1 values was statistically significant (p<0.05), yet practically very small (<4%, i.e. below the minimum detectable difference). VO<sub>2</sub> and HR data at NIRSAT were highly correlated with values at VT1 (0.9 and 0.8 respectively). The Bland Altman analysis confirmed a significant yet very small bias for VO<sub>2</sub> and HR (3.8 mL•Kg<sup>-1</sup>•min<sup>-1</sup> and 4 bpm, respectively) and a small imprecision (0.4 mL•Kg<sup>-1</sup>•min<sup>-1</sup> and 11 bpm respectively). **CONCLUSIONS:** In a large and heterogeneous group of healthy males, a change in muscle O<sub>2</sub> extraction was consistently demonstrated at a VO<sub>2</sub> and HR that are highly correlated and substantially coincident with the values measured at VT1, during an incremental cycling exercise. Therefore, our data confirm the hypothesis that the anaerobic threshold can be accurately determined with a NIRS. Along with the non-invasiveness, NIRS offers the advantage of the independence from irregularity of breathing pattern that can heavily affect ventilatory-based techniques.

#### ULTRASOUND MEASUREMENTS OF MUSCLE STRUCTURAL CHANGES RELATED TO ASYMMETRY IN POWER PRODUCTION DURING GAIT IN CHILDREN WITH CEREBRAL PALSY

BÖHM, B.1, OBERHOFFER, R.1, BRAND, A.2, BÖHM, H.2

1 TECHNISCHE UNIVERSITÄT MÜNCHEN, GERMANY; 2 ORTHOPAEDIC HOSPITAL FOR CHILDREN, BEHANDLUNGSZENTRUM ASCHAU, GERMANY

**Introduction** The muscle is a highly adaptive tissue; it responds rapidly to mechanical stress, hormonal activity and changes in the amount and magnitude of activity. The potential for adaptation in muscle derives from the rapid turnover of proteins in the muscle cell [1]. It has been shown in hemiplegic patients that muscle volume was significantly reduced at the involved leg and biarticular muscles were predominantly affected [2]. However it is not known whether structural changes in the muscle tendon unit are directly related to pathological function during gait. Therefore the aim of this study was to measure asymmetry in muscle structure in children with cerebral palsy and to relate those to asymmetries in power production during gait. **Methods** Sixteen children with cerebral palsy GMFCS I and II with asymmetric as well as symmetric involvement of the legs were gait analyzed using an eight camera Vicon system. Muscle structures (tendon, aponeuroses and fiber lengths, as well as angle of pennation) of m. gastrocnemius were determined using ultrasonography (Siemens Andara, 7.5 MHz probe). During the sonography the patients were seated on a chair and the ankle joint was passively moved by the examiner from maximal plantar to maximal dorsiflexion, while the joint angle and position of the ultrasound probe was monitored with the Vicon camera system. Concentric ankle joint energy at push-off was correlated with the muscle structure at average ankle joint angle during stance phase of gait. **Results** Significant correlations with mechanical joint energy at push off were shown for asymmetry in tendon and aponeurosis length (R=-0.56, p=0.003) and the asymmetry in fiber length (R=-0.50, p=0.04). The tendon-aponeurosis and the fiber lengths were on average 4% and 6% shorter at the involved leg. **Discussion** Asymmetries in muscle fiber and tendon-aponeurosis lengths show clinically significant correlation to power production during gait. Consequently impairment during gait can be directly related to structural changes in the muscle tendon unit. For that reason sport therapy might therefore be focused on the structures responsible for asymmetries in power production during gait. **Literature** [1] Ponten et al. 2008, J. #### THE EFFECT OF USING A PORTABLE GAS ANALYSIS SYSTEM ON ENERGY EXPENDITURE DURING SUBMAXIMAL EXERCISE

SPARKS, S.A., BAILEY, T., CHANDLER, P., ORME, D.

EDGE HILL UNIVERSITY AND UNIVERSITY OF CUMBRIA

**Introduction:** The use of portable gas analysis has become widespread in physiological research and training over the last decade. The versatility of such systems allows them to be used in a wide variety of settings, and during a multitude of exercise modes. Despite their extensive use, few studies have investigated the possible additional effects of their carriage on the very physiological responses they are designed to measure (Sparks and Orme 2009). No studies have evaluated the effects of carrying a portable gas analyser during long duration submaximal exercise. The aim of this study was to evaluate the effects of gas analyser carriage over a prolonged period at a variety of submaximal speeds during treadmill exercise. **Method:** Ten male participants of mean (±SD) age 30.8(5.1) y, body mass 79.6(6.9) kg, and height 1.81(0.1) m, completed six randomly ordered laboratory treadmill tests at three different speeds (4, 8 and 12 km/h) for 40 minutes under two conditions. The experimental trials required participants to complete the exercise bout whilst either wearing a portable (P) respiratory gas analysis system (Metamax 3B, Cortex, Germany) in a harness on the chest, or a control trial (L) where the weight of the gas analyser was supported by a harness adjacent to the treadmill. Throughout each exercise trial, respiratory gases, heart rate (HR) and rating of perceived exertion (RPE) were measured. Respiratory gases were used to calculate energy expenditure (EE) via

indirect calorimetry (Frayn 1983). All data were analysed using a General Linear Model ANOVA with Repeated Measures, significance was accepted at  $p < 0.05$ . Results: Total EE was elevated with increased speed ( $p < 0.001$ ). Significantly higher EE occurred during the P trial than during the L trial ( $p = 0.01$ ) only at 12 km/h ( $855.3 \pm 104.3$  and  $801.5 \pm 82.2$  kcal respectively), but not at either of the other speeds ( $220.1 \pm 31.7$ ,  $207.8 \pm 25.8$  and  $569.9 \pm 91.8$ ,  $568.7 \pm 58.6$  kcal for the 4 and 8 km/h speeds in the L and P trials respectively). VO<sub>2</sub> ( $p = 0.03$ ), and breathing rate ( $p = 0.006$ ) were also only elevated in the P trial at 12 km/h. Conclusion: Running at speeds of 12 km/h whilst carrying a portable gas analysis system elevate the energy demands of the activity. Additional EE is caused by an increased oxygen demand and this is met by an increase in breathing rate. The use of portable gas analysis systems may have an adverse impact on the performance of prolonged running due to the increased EE demands. References: Frayn, K. N., (1983), J. Appl. Phys., 55: 628-634. Sparks, S.A., and Orme, D., (2009). Proceedings of the 14th Annual Congress of the ECSS, Oslo, Norway, (24th-27th June 2009, PP-PH08, 354).

## A COMPARISON OF METHODS FOR QUANTIFYING TRAINING LOAD: RELATIONSHIPS BETWEEN MODELLED AND ACTUAL TRAINING RESPONSES

COUTTS, A.J.1, WALLACE, L.K.1, SLATTERY, K.M.1,2

1: UTS (SYDNEY, AUSTRALIA), 2: NSWIS (SYDNEY, AUSTRALIA)

Introduction Training load (TL) can be described as either the external (i.e. the training completed by the athlete) or internal (i.e. the athlete's response to external TL) stimulus applied to athletes. At present, it is not known which of the TL measures relate best to the training outcomes (i.e. performance, fitness and fatigue). To assess the validity of each of these TL measures, we compared the relationships between predicted and actual performance, fitness and fatigue with both internal and external TL using a mathematical model. Methods A modeling post facto longitudinal research design was used to compare the performance, fitness and fatigue responses in 7 trained runners (age:  $35.8 \pm 9.1$  yr, VO<sub>2</sub>max:  $52.8 \pm 4.1$  ml/kg/min) during a 15 wk period. Each runner completed between 5-10 sessions per week, which were measured via a Polar RS800 heart rate (HR) monitor with foot pod and also perception of effort. The dose for each training session was then calculated using the session-RPE method, Banisters TRIMP and the Training Stress Score (TSS). Weekly running performance (1500-m time trial), fitness (submaximal HR tests) and fatigue (Profile of Mood States) were measured. Busso's [1] model was applied to the training data from each runner using each of the three TL input measures to predict performance, fitness and fatigue. Pearson's correlation assessed the relationships between modelled and the actual weekly performance, fitness and fatigue measures within each runner. Significance was  $p < 0.05$ . Results The 15 wks of training improved 1500-m performance by  $5.4 \pm 2.6\%$ . Modelled performance significantly correlated with actual performance in each subject, with average relationships ( $r$  values) being  $0.74 \pm 0.16$ ,  $0.53 \pm 0.24$  and  $0.18 \pm 0.22$  for the TSS, session-RPE and TRIMP input methods, respectively. Similarly, there were moderate correlations between modelled and actual fitness measures (%HRmax) for the TSS ( $-0.54 \pm 0.28$ ), session-RPE ( $-0.48 \pm 0.26$ ) and TRIMP ( $-0.48 \pm 0.31$ ) methods. Actual and predicted fatigue were not correlated with any input method ( $P < 0.05$ ). Discussion These findings show that the TSS and session-RPE methods are appropriate for quantifying TL when using a systems model to examine training responses in endurance runners. In contrast, care should be taken in using the HR-based to quantify TL. Our findings also show that submaximal HR may be a valid simple fitness test for assessing fitness changes in endurance runners. However, the lack of relationship between the actual and predicted fatigue suggests that the fatigue component of the POMS is insensitive to small changes in trained athletes. References Busso, T. (2003). Med Sci Sports Exercise, 2003. 35: 1188-95

## VALIDITY OF THE BIOHARNESS MONITORING SYSTEM

JOHNSTONE, J.1, FORD, P.A.2, HUGHES, G.1, WATSON, T.1, GARRETT, A.T.1

1: UNIVERSITY OF HERTFORDSHIRE 2: BRITISH OLYMPIC ASSOCIATION

Introduction: The Bioharness monitoring system may provide physiological information on sporting performance by recording multiple data streams simultaneously during activity. There is limited information on the precision of the Bioharness against established criterion measures. Therefore, this study assessed the validity of the Bioharness monitoring system. Methods: 23 healthy males (age  $21.5 \pm 2.8$  yrs, body mass  $71.4 \pm 7.9$  kg, height  $1.79 \pm 0.07$  m) participated. Heart rate (HR), Breathing Frequency (BF) and Accelerometry (ACC) precision were assessed during a discontinuous incremental (0-12 km.h<sup>-1</sup>) treadmill protocol ( $n = 13$ ). Infra-red skin temperature (ST) was assessed during a 45 minute sub-maximal cycle ergometer test ( $n = 10$ ) on two separate occasions with environmental temperature controlled at  $\sim 20^\circ\text{C}$  and  $\sim 30^\circ\text{C}$ . Posture (P) was assessed by securing devices to a tilt table which were moved through 160° at 10° intervals. Reference precision of measurement devices were; HR: Polar T31 (Polar Electro), BF: Spirometer (Cortex Metalyser), ACC: Oxygen expenditure (Cortex Metalyser), ST: Skin thermistors and data logger (Grant Instruments), P: Goniometer (Leighton Flexometer). Results: There was a strong relationship between predicted and criterion measure for HR ( $r = 0.99$ ,  $p < 0.01$ ), BF ( $r = 0.94$ ,  $p < 0.01$ ), ACC ( $r = 0.97$ ,  $p < 0.01$ ) and P ( $r = 0.99$ ,  $p < 0.01$ ). Limits of Agreement (LOA) identified absolute differences in HR (mean difference  $\pm 95\%$  LOA;  $-0.63 \pm 9.88$  b.min<sup>-1</sup>), BF ( $-0.84 \pm 7.56$  b.min<sup>-1</sup>), P ( $0.06 \pm 2.62^\circ$ ). Less precision was observed with increasing treadmill velocity. LOA increasing at 12 km.h<sup>-1</sup> for HR ( $-1.64 \pm 11.07$  b.min<sup>-1</sup>;  $r = 0.96$ ,  $p < 0.01$ ) and BF ( $1.27 \pm 8.26$  b.min<sup>-1</sup>;  $r = 0.77$ ,  $p < 0.01$ ) respectively. ST established a moderate relationship between the predicted and criterion measure ( $-0.22 \pm 1.98^\circ\text{C}$ ;  $r = 0.76$ ,  $p < 0.01$ ) which was not enhanced when data was analysed specific to the thermal environment (Thermo-neutral  $0.03 \pm 2.93^\circ\text{C}$ ;  $r = 0.43$ ,  $p < 0.01$ ; Hot  $-0.49 \pm 1.44^\circ\text{C}$ ;  $r = 0.75$ ,  $p < 0.01$ ). Discussion: Data suggest that the Bioharness is a valid multivariable monitoring device within ambulatory laboratory testing. Weaker precision of ST data could be linked to the positioning of infra red device relative to the skin surface. High treadmill velocity resulted in increasing errors for HR and BF which could be attributed to EMG and movement artefacts. Comparatively consistent performance of ACC and P may be due to these variables being related to well developed piezoelectric technology, the data from which is not reliant on contact with the skin. Bioharness devices provided by Zephyr Technology

## EFFECT OF ADIPOSE TISSUE THICKNESS ON NIRS-DERIVED PARAMETERS DURING INCREMENTAL EXERCISE

MARWOOD, S.

LIVERPOOL HOPE UNIVERSITY

Marwood, S.1, Roche, D.1, Garrard, M.1,2, Unnithan, V.B.1,3. 1: Sport & Exercise Science Research Team, Liverpool Hope University 2: Physical Activity, Sport & Exercise Science, Leeds Metropolitan University 3: Sport & Exercise Science, Staffordshire University Introduction Adipose tissue thickness (ATT) has the capacity to blunt the signal derived from near-infrared spectroscopy (NIRS) at the site of interrogation. However this has not previously been examined during large muscle mass exercise and a wide range of exercise intensities. Methods 14 healthy male adolescents undertook 2 incremental cycle-exercise tests to the limit of tolerance, starting at 40W with 40W incre-

ments. At rest and during the final 30s of each completed 4min stage, concentrations of tissue total haemoglobin (THb), oxyhaemoglobin (HbO<sub>2</sub>) and deoxyhaemoglobin (HHb) were measured via NIRS (Oxiplex TS) at the vastus lateralis, and pulmonary oxygen uptake (VO<sub>2</sub>) was determined breath-by-breath. Prior to exercise, ATT was determined at the site of interrogation via ultrasound (Bodymetrix BX2000). Individual mean responses of NIRS data during the two trials were correlated with ATT using a bivariate (Pearson) correlation. Results Absolute values of [THb], [HbO<sub>2</sub>] and [Hb] were strongly, inversely correlated ( $P < 0.01$ ) with ATT at rest ( $r = -0.91, -0.88, -0.84$ , respectively). As exercise intensity increased from 40W to 240W, these strong correlations remained for [THb] and [Hb] (range of  $r$ : [THb]  $r = -0.85$  to  $-0.90$ ; [HHb]  $-0.87$  to  $-0.92$ ), but weakened progressively for [HbO<sub>2</sub>] (though remaining significant; range of  $r$ :  $-0.85$  to  $-0.59$ ,  $P < 0.05$ ). When the NIRS data were expressed as the change from rest (deltaNIRS) there were no significant relationships between ATT and [THb], [HbO<sub>2</sub>] and [Hb] at 40W ( $r = -0.46, -0.16, -0.34$ ). As exercise intensity increased however, there was a progressive increase in the strength of the relationship for [HbO<sub>2</sub>] and [Hb] but not for [THb], ( $r = 0.71, -0.90, -0.39$ , respectively at 240W). This pattern of relationship between NIRS / deltaNIRS data and ATT remained when the NIRS data were corrected for VO<sub>2</sub> / deltaVO<sub>2</sub>. Discussion The strong relationship between absolute NIRS-derived data and ATT indicates a reduction in the interrogative depth of NIR light as ATT increases. Comparisons of absolute NIRS-derived data between separate groups should therefore be treated with caution, particularly if differences exist in the ATT. Recalculating the [HbO<sub>2</sub>] and [HHb] data as the change from rest reduced the impact of ATT at low, but not high, exercise intensities, indicating a blunting of the maximal detectable oxy- and deoxygenation with increasing ATT. If source-detector distance is fixed (and relatively small), it may be prudent to consider only those subjects with the lowest ATT as participants in a study.

#### AEROBIC FITNESS AND BRAIN HEALTH IN PREADOLESCENT CHILDREN

KAMIJO, K.1.2, PONTIFEX, M.B.2, O'LEARY, K.C.2, SCUDDER, M.R.2, WU, C.2, CASTELLI, D.M.3, HILLMAN, C.H.2

1: JSPS (TOKYO, JAPAN), 2: UNIVERSITY OF ILLINOIS AT URBANA-CHAMPAIGN (USA), 3: UNIVERSITY OF TEXAS AT AUSTIN (USA)

**Introduction** Today, children in industrialized nations have become more sedentary and less fit, which is related to increases in the prevalence of obesity and several chronic diseases such as cardiovascular diseases and type-2 diabetes. Recent neuroelectric studies using event-related brain potentials (ERPs) in our laboratory have suggested that aerobic fitness is associated with not only chronic diseases prevention, but also brain health and cognition in preadolescent children (Hillman et al., 2005, 2009; Pontifex et al., in press). However, these ERP studies have mainly employed cross-sectional designs. This study aimed to better establish a causal link between aerobic fitness and changes in brain health and cognition in preadolescent children using a randomized control design. **Methods** Previously sedentary children, aged 7-9 years, participated in a 9-month randomized control trial in which they were assigned to either an after-school physical activity program or a waitlist control group. Participants performed tasks, which manipulated cognitive control requirements including inhibition, working memory, and cognitive flexibility. During these tasks, task performance and ERPs such as the P3 component and contingent negative variation (CNV) were assessed. **Results** Overall, increases in aerobic fitness resulting from the physical activity intervention led to improvements in task performance, larger P3 amplitudes, and larger CNV amplitudes, with no such effect observed for the waitlist control group. Further, disproportionately greater effects of the physical activity intervention were observed during task conditions requiring the upregulation of cognitive control. **Discussion** These findings suggest that regular physical activity leading to increases in aerobic fitness results in more effective attentional allocation (larger P3) and cognitive preparation (larger CNV), which in turn may underlie the production of superior task performance. The disproportionate effect of the physical activity intervention based on the cognitive control requirements imply that physical activity may improve the effectiveness of neural networks including the prefrontal cortex, which show protracted maturation. This study suggests that regular physical activity is associated with brain health and cognition and may assume a crucial role of cognitive development in preadolescent children. **References** Hillman CH, Buck SM, Themanson JR, Pontifex MB, Castelli DM. #### IN VIVO AND IN VITRO ANALYSES OF EXERCISE-INDUCIBLE FACTORS TO ACTIVATE LIPOLYSIS IN ADIPOCYTES

HASHIMOTO, T.

RITSUMEIKAN UNIVERSITY

Physiological strategies such as exercise training (ET) aimed toward fat loss by active lipolysis in adipocytes and fatty acid (FA) oxidation in muscles (i.e. fat mobilization) have become of great therapeutic interest against metabolic disorders. However, molecular mechanisms underlying augmented capacity of active lipolysis induced by ET are not clear. Lipid-associated proteins (LAP) such as perilipin (PLIN), hormone sensitive lipase (HSL), adipose triglyceride lipase (ATGL) and its co-activator CGI-58, are supposed to play important roles in regulating fat storage and mobilization, by interacting with each other. Additionally, it is possible that the mitochondria have a pivotal role in not only oxidative capacity in muscles but also lipolysis in white adipose tissue, because deficiency of mitochondrial respiration decreased lipolysis. **PURPOSE:** In this study, we examined the effects of ET on the expressions of LAP and mitochondria-related proteins in diet-induced obese (DIO) rats. Furthermore, we assessed putative factors induced by ET to activate lipolysis in differentiated 3T3-L1 adipocytes. **METHODS:** DIO Wistar male rats (20 wk) were divided into sedentary control group (SED, n=7) and exercise training group (EX, n=7). Treadmill running (30 m/min, 1 hr/day, 5 days/wk) was conducted for 6 wk in EX. Epididymal fat (Epi) was dissected and used for protein analyses. 3T3-L1 adipocytes were incubated with media containing 10  $\mu$ M H<sub>2</sub>O<sub>2</sub>, 10 mM lactate, 5 mM caffeine, 2 mM AICAR, or 100  $\mu$ M SNAP (NO donor) for 16 hr, or 1 mM H<sub>2</sub>O<sub>2</sub> for 15 min, followed by the incubation with normal media for up to 24 hr total. Protein expressions were analyzed by Western blotting. Lipolytic activity was biochemically analyzed by glycerol and FA release into media in response to  $\beta$ -adrenergic stimulation in 3T3-L1 cells. **RESULTS:** Epi decreased by 20% in EX as compared to SED. The expression of PLIN, HSL, ATGL, and CGI-58 in EX Epi increased 1.8~2.7 fold as compared to SED. The expression of PPAR $\gamma$  coactivator-1 $\alpha$  (PGC-1 $\alpha$ ) and cytochrome c oxidase (COX) in EX Epi increased 4.0 and 1.9 fold as compared to SED, respectively. In 3T3-L1 cells, the expression of HSL and CGI-58 in any condition (e.g. lactate) increased more than 1.5 fold as compared to control. Furthermore, lactate or caffeine increased 2.3 or 2.2 fold in PGC-1 $\alpha$  expression, respectively, and 10  $\mu$ M or 1 mM H<sub>2</sub>O<sub>2</sub> increased 1.8 or 2.1 fold in COX expression, respectively, as compared to control. Glycerol release was significantly increased by lactate, caffeine, or SNAP incubation. FA release was significantly increased by 1 mM H<sub>2</sub>O<sub>2</sub>, caffeine, or AICAR incubation. **CONCLUSION:** The results suggest the beneficial effects of ET on fat loss through the increases in LAP and mitochondrial biogenesis. Furthermore, it is plausible that ROS, lactate, calcium signaling, AMPK, and NO are potential exercise-inducible factors to activate lipolysis in adipocytes.

**SIGNIFICANCE OF NON-EXERCISE ACTIVITY THERMOGENESIS ON BODY WEIGHT REGULATION**

OHKAWARA, K.

NATIONAL INSTITUTE OF HEALTH AND NUTRITION

It is reported that well-controlled supervised exercise intervention resulted in individual variability for the amount of body fat reduction (Donnelly et al., 2005). This phenomenon may be caused from decreasing physical activity and increasing energy intake after exercise. Nonexercise activity thermogenesis (NEAT) may be associated with compensation of energy expenditure (EE) through a day, and also be an important factor to body weight regulation (Levine et al., 1999). However, the amount of NEAT is difficult to measure in free-living conditions. Study 1: Physical activity level (PAL) was measured in eleven adult men by different protocols in 24-hour calorimeter stays: high-frequency moderate-activity day (M-day) and high-frequency vigorous-activity day (V-day) (Ohkawara et al., 2008). On the other hand, forty-one adults measured PAL in daily living conditions using doubly-labelled water method. In both experiments, step counts per day were also measured by an accelerometer. Study 2: 1) Twenty one Japanese obese men performed 90-min exercise sessions on 3 days per week for 12 weeks. 2) Hundred twenty nine Japanese obese women participated in a randomized controlled trial aimed at studying the effects of group-based support on weight loss. Total physical activity (PA) was measured using a triaxial accelerometer, which automatically classifies time associated with household and locomotive activities (Ohkawara et al., 2010). Study 1: PAL and step counts were  $1.82 \pm 0.14$  and  $29588 \pm 1126$  steps/d (M-day), and  $1.74 \pm 0.15$  and  $23755 \pm 1038$  steps/d (V-day), respectively. In daily living conditions, PAL and step counts were  $1.73 \pm 0.15$  and  $10022 \pm 2605$  steps/d. Study 2: In the exercise intervention, the amount of household activity remained unchanged but locomotive activity significantly increased in nonexercise days through the intervention period. There was a significant negative association between the change in PA during nonexercise days and the change in body weight. In group-based support intervention, there was a significant negative association between the change in body weight and the change in amount of above moderate-intensity locomotive activity and between the change in body weight and the change in amount of low-intensity household activity. The results from study 1 suggest that nonlocomotive activities substantially contribute to maintain higher PAL in daily living in both of sex. The results from study 2 suggest that 1) increased total PA induced by locomotive activity contributes to weight reduction in men, and 2) both of low-intensity household and moderate-intensity locomotive activities contribute to weight reduction in women. Therefore, NEAT could play an important role in body weight regulation. References Donnelly JE et al. (2005). *Exerc Sport Sci Rev*, 33, 169-174. Levine JA et al. **Invited symposia****IS-BN05 Neuroscience of imitation and observational learning****PHYSICAL AND OBSERVATIONAL LEARNING IN THE HUMAN BRAIN AND BEHAVIOUR**

CROSS, E.1, HAMILTON, A.F.C.2, GRAFTON, S.T.3

(1) RADBOLD UNIVERSITY NIJMEGEN, THE NETHERLANDS; (2) UNIVERSITY OF NOTTINGHAM, UK; (3) UNIVERSITY OF CALIFORNIA SANTA BARBARA

**Introduction** When learning any new skill, from dancing the tango to rock climbing, we benefit from physical practice, but watching others perform or learn the same skill can also positively impact new skill acquisition (Hodges et al., 2007). More recently, neuroscientists have turned their attention to the neural underpinnings of physical and observational learning, to explore points of overlap and divergence between both approaches (Cross et al., 2009; Frey and Gerry, 2006). In one such study, we demonstrated that specific components of the human mirror neuron system (MNS; brain regions active during action execution and observation), are modulated in a similar manner by physical and observational learning of simple dance sequences (Cross et al., 2009). In the present study, we aimed to extend these findings by exploring the brain and behavioural components of observational learning of knot tying from non-expert models. **Methods** Participants were assigned a training partner, and practiced tying one group of knots ("tied" condition), and watched their partner tie different knots ("watched" condition) across 5 days. fMRI was obtained prior to and immediately following the week of training while participants performed a knot-matching task. **Results** Functional MRI data indicated that after training, the same parietal and premotor components of the MNS responded when viewing images of knots from the tied and watched conditions compared to knots that were untrained. Activity in these areas represents the neural overlap of observing and physically embodying an action. This is further supported by behavioral data from a post-scanning test where participants tied knots from all three training groups. **Discussion** The neuroimaging data demonstrate the emergence of action resonance processes based on observational learning without concurrent physical practice. These findings also lend further support to the notion that the MNS is modulated by physical and observational practice in a similar manner. Moreover, learning by observing a non-expert model appears to be beneficial in a similar way as learning from an expert model. Cross ES, Kraemer DJ, Hamilton AF, Kelley WM, Grafton ST. **DIFFERENT PROCESSES UNDERPIN MOTOR LEARNING FROM PHYSICAL PRACTICE AND ACTION-OBSERVATION**

HAYES, S.

LIVERPOOL JOHN MOORES UNIVERSITY

Different processes underpin motor learning from physical practice and action-observation Hayes, S. J., 1 Andrew, M., Elliott, D., 1, 2 and Bennett, S. J. 1 Liverpool John Moores University; 2 McMaster University **Introduction** It has recently been suggested that a lack of motor reafterence during action-observation leads to different learning effects compared to physical practice, and indicates the underpinning processes are different (Ong & Hodges, 2010). However, to further examine the contribution of motor reafterence in action-observation, it is necessary to determine whether there is transfer having practiced or observed a task to the same or opposite effector, and the same or different spatial-sequence. Data from intermanual transfer experiments show transfer to an untrained effector is related to cross-communication between the two hemispheres via supplementary motor area (SMA; Perez et al., 2007). The information processed in SMA is sensory motor reafterence. We predict that transfer to a different spatial-sequence with an opposite effector that recruits homo-

logous muscle groups will be possible after physical practice, but not action-observation because no sensory motor reafference is available during the intervention. Method Thirty-three participants provided consent and were divided into 3 groups: physical practice (PP;  $n=11$ ), action-observation (AO;  $n=11$ ) and control (CTL;  $n=11$ ). After a pre-test (5 trials), the PP group were yoked to AO group, and acted as models whilst practising (60 trials) a spatial-sequence task with their right hand. The CTL group observed a blank screen. All participants performed a post-test (5 trials) and three transfer tests (3 x 5 trials). Transfer 1 involved the right effector and different spatial-sequence (non-homologous muscles); Transfer 2 involved the left effector and same spatial-sequence (non-homologous muscles); Transfer 3 involved the left effector and different spatial-sequence (homologous muscles). Results Compared to controls, PP and AO were more accurate at learning relative ( $p<0.05$ ) and absolute ( $p<0.05$ ) timing. The transfer data for absolute timing revealed that PP and AO were more accurate than CTL in Transfer 1, 2 and 3 ( $p<0.05$ ). For relative timing, PP and AO were more accurate than CTL in Transfer 1. There was no difference between the groups in Transfer 2 ( $p>0.05$ ), whereas in Transfer 3 the PP were more accurate than AO and CTL ( $p<0.05$ ). Discussion These data demonstrate that observational learning facilitates the acquisition and transfer of relative and absolute timing. Yet, intermanual transfer to a condition that recruits homologous muscles is only possible after physical practice. These findings suggest that action-observation recruits similar, but not exact, motor processes as those engaged in physical practice. The role of the mirror system is undoubtedly part of observational learning (Cross et al. 2009), but the reduced role of SMA in action-observation (Zentgraf et al., 2005) attenuates the necessary neural processing that support intermanual transfer.

### THE INFLUENCE OF GOALS ON IMITATION IN ADULTS WITH AUTISM

GOWEN, E., WILD, K., POLIAKOFF, E.  
MANCHESTER UNIVERSITY

Symposium: Neuroscience of imitation and observational learning (Speaker 3) The influence of goals on imitation in adults with autism Gowen.E1, Wild.K1 and Poliakoff.E2 1 Faculty of Life Sciences, University of Manchester; 2 Psychological Sciences, University of Manchester Introduction Voluntary imitation refers to the situation where we intentionally copy another person's actions and is thought to rely on mirror neurons that are active during both observation and execution of an action. Evidence indicates that imitation is affected by the presence or absence of goals (Bekkering et al., 2000). The dual route theory proposes that goal-less actions are imitated via a direct route which maps visual information onto one's own motor system, whereas actions that contain goals are processed via an indirect route that uses stored representations (Rumiati & Tessari, 2002). As imitation and mirror neurons are thought to be important for social understanding it has been proposed that autistic people who are characterised by difficulties with social cognition may have a mirror neuron deficit. In such a case, one would expect autistic individuals to show impaired imitation. However, recent evidence suggests that impairments may only be present during imitation of goal-less actions, suggesting a specific deficit of the direct pathway (Hamilton et al., 2007). Methods The current work took a quantitative approach to investigate whether autistic people were more impaired at imitation of goal-less compared to goal directed actions. Sixteen adult autistic and matched control participants imitated hand actions of different speeds while their own hand movements were recorded using Polhemus tracking equipment. Imitation ability was compared between goal-less and goal directed conditions. Results In contrast to the control group, the autistic group failed to modulate the speed of their movements in the goal-less imitation condition. However, performance was similar for both groups in the goal directed condition, suggesting a selective impairment of goal-less imitation. Discussion These findings highlight that not all aspects of imitation are impaired in autistic individuals, but that imitation of goal-less actions via the direct route of imitation is more affected. This work, together with other recent findings (Hamilton et al., 2007; Dinstein et al., 2010) suggests that the role of mirror neurons in autism needs further refinement. ### THE ROLE OF PREFRONTAL CORTEX IN IMITATION AND OBSERVATIONAL LEARNING

VOGT, S., HIGUCHI, S.  
LANCASTER UNIVERSITY

In Symposium: Neuroscience of imitation and observational learning (Speaker 4) Introduction Learning a new skill from a model is not easy. Although the metaphor of an action mirroring system in the human brain might suggest otherwise, imitation learning likely shares aspects with other forms of motor learning (Vogt & Thomaschke, 2007). In previous work (Vogt et al., 2007), we have studied the brain regions involved in the learning of novel hand postures (guitar chords). In addition to the parieto-frontal 'mirror' system (PFMC, Rizzolatti & Sinigaglia, 2010), we found the dorsolateral prefrontal cortex (DLPFC) activated, which is typically involved in the early stages of motor learning. This indicates that the PFMC is not sufficient for learning novel skills and that higher-order, supervisory processes are involved in imitation learning. The main hypotheses of the present study were (1) that DLPFC would be involved in imitation learning in a 'fast' imitation task with minimal requirements to maintain information in working memory, and (2) that learning by observing-only also involves both the DLPFC and PFMC, and not only the PFMC as suggested by earlier studies (Frey & Gerry, 2006; Cross et al., 2009). Methods These were similar to the methods in Vogt et al. (2007), except that we used a 3 Tesla Siemens scanner and a substantially faster paradigm where participants responded to action pictures within the 3 s presentation period. They had practised one set of chords by observation+execution (OEP), and another set by observation-only (OP). In addition, our study is the first to contrast activations during both observation and imitation of actions that had been previously practised by either OP and OEP. Results During imitative execution, the DLPFC and PFMC were strongly activated after the first practice session, confirming hypothesis 1. Further, OP-actions were associated with stronger activations than OEP-actions, which reflected that the OP actions were less well practised and were performed more slowly than the OEP actions. During action observation, only the PFMC plus occipital cortex were activated. However, a correlation analysis across subjects between the functional activations and the benefit that each participant obtained by OP indicated that left inferior parietal cortex (Frey & Gerry, 2006) and bilateral DLPFC were significantly correlated with the behavioural data, confirming hypothesis 2. Discussion The results confirm our hypotheses. However, we only found marginal differences between OEP and OP actions during action observation, which is likely due to the common OP-component in both practice conditions. References Cross E. ### IS-SH06 Migration and Ethnicity in Physical Activity and Sport

#### BORDER CROSSINGS: MAKING SENSE OF MIGRATION AND SPORT

MAGUIRE, J.

LOUGHBOROUGH UNIVERSITY

Several dimensions and issues characterize the study of migration and sport. These include: first, which sports are most involved, why have they been so affected and what structural or cultural changes have thus occurred in those sports and in the societies in which they are located?; second, what are the patterns of global movement and how and why have they developed in this manner?; third, what has been the impact of and on fans in their own migration as 'tourists' or as part of a diaspora, and their perception of the sports they consume; fourth, what has been the impact on 'host' and 'donor' countries more broadly?; fifth, why do 'professional' athletes become labour migrants, how is this process contoured and shaped and what do they experience along their journey; sixth, in what ways does such migration reflect the movement of highly skilled workers more generally; and seventh, what implications are there for sport policy and for the domestic and foreign policies of nation-states more broadly? With the deregulation of the global economy, the blurring of national sovereignty and boundaries, the emergence of 'world class' firms and the rebranding of sport production, the recruitment of elite talent has been deemed essential by the new breed of owners of sport franchises – wealthy entrepreneurs or heavily indebted consortia – from North America, the Middle East or Asia. This recruitment of talent has been viewed as necessary to enable the 'firm' to compete 'on the field' but also 'in the field' – to seek to win but also to enable the 'brand' to have world class status and marketability in the global economy. Hence the recruitment of the 'highly skilled'. Here, then, some observations and suggestions will be offered that illuminate this dimension of global sport and some possible lines of enquiry will be highlighted.

#### SPORT IN MIGRANT COMMUNITIES

PFISTER, G.

UNIVERSITY OF COPENHAGEN

Migrants from non-Western countries are under-represented among the physically active population, a fact which is often explained by religion. This general statement about physical culture in migrant communities obscures the diversity of life styles among migrants, which depend, among other things, on gender, age, social class and ethnic background. In this paper I will provide an overview of existing information about the sport (for all) participation of various migrant groups, using the situations in Denmark and Germany as examples. A focus will be placed on the interrelations between sporting activities and demographic variables, social and ecological environments, countries of origin and impacts of gendered body and movement cultures. Sources will be statistics of sports organisations, population surveys and scientific studies. A main focus will be on suggesting potential explanations for the various ways migrants deal with Western sporting habits and physical cultures. Pierre Bourdieu's approach to habitus and body capital, as well as Judith Whitehead's concept of physical literacy, will provide a theoretical frame for discussing and understanding the appropriation or rejection of Western body cultures by various migrant groups.

#### IDENTITY, DIASPORA AND RELIGION: INTERNATIONAL CASE STUDIES ON MUSLIM WOMEN IN SPORT

BENN, T.,

UNIVERSITY OF BIRMINGHAM

The aim of the presentation is to increase awareness of ways in which Muslim women manage their identity in terms of religion and sport participation. It matters because Muslim women are often perceived as the most marginalised and oppressed group in the sporting field (Hargreaves 2000). This can be related to traditional, cultural expectations of women as well as religious requirements for body modesty, which can affect preferences for dress codes and single sex environments for women's participation. Situations are particularly complex in diaspora communities where groups seek ways to sustain identities connected to cultural heritage, while trying to fit into the host society in which they form a minority group (Dagkas and Benn 2006). Using constructionist identity and body theories, a comparison of findings from empirical case studies on Muslim women and sport are explored. The outcomes indicate the need for greater knowledge, awareness and flexibility of teachers, coaches, researchers and policy-makers as they increasingly meet values and beliefs different to their own. Situation specific solutions and ways of bridging gaps between policy-makers and participants need to be pursued to improve the inclusion of Muslim women in sport. Currently two international approaches are being used to achieve the same goal for inclusion with regard to this issue: 'Accept and Respect' and 'Atlanta+'. They represent divergent paths based on different worldviews and illustrate the contested nature of universals regarding fundamental human rights to sport, gender equality and religion.

### OP-BN09 Vibration and Injury

#### RELATIONSHIPS BETWEEN FOOT TYPE AND DYNAMIC REARFOOT MOTION IN BAREFOOT AND SHOD GAIT

CHUTER, V., SMITH, R.

UNIVERSITY OF NEWCASTLE, UNIVERSITY OF SYDNEY

Background The Foot Posture Index (FPI) provides an easily applicable, validated method for quantifying static foot position and has recently been demonstrated to be a strong predictor of dynamic rearfoot motion in a barefoot condition (Redmond 2006, Chuter, 2010). Footwear has been demonstrated to alter foot mechanics during walking gait when compared with a barefoot condition (De Wit et al., 2000). This study aimed to compare the strength of relationship between dynamic rearfoot motion and FPI scores in shod and unshod gait. Methods Thirty-two participants were recruited with equal numbers of pronated and normal foot types as classified by FPI score. Three dimensional rearfoot motion in a barefoot and shod condition was collected for each of the participants and dynamic maximum

rearfoot eversion correlated with total FPI score across all participants and within the normal and pronated foot types. The capacity for the total FPI score to predict maximum frontal plane motion of the rearfoot in each condition was investigated. Results Overall, correlation between total FPI score and maximum rearfoot eversion in the barefoot condition was strongly positive ( $r=0.88$ ). Correlations performed on data subsets in the barefoot condition demonstrated a pronated foot type (FPI +5 to +9) and maximum rearfoot eversion angle (MaxEv) was more strongly positively correlated, ( $r=0.59$ ,  $p<0.05$ ), than the normal foot type and maximum rearfoot eversion ( $r=0.56$ ,  $p<0.05$ ). In the shod group, correlations between the FPI score and MaxEv during gait for all participants was 0.56 ( $p<0.05$ ). Correlation between FPI score and MaxEv in the pronated foot type was less strong compared with a normal foot type ( $r=0.49$   $p=0.05$  and  $r=0.56$ ,  $p<0.01$  respectively). Linear regression analysis demonstrated the FPI score had greater predictive capacity for MaxEv in the barefoot condition (adjusted  $r^2=0.80$ ,  $p<0.05$ ) compared with the shod condition (adjusted  $r^2=0.29$ ,  $p=NS$ ). Conclusions The results of this study suggest the FPI has good predictive ability for an aspect of dynamic rearfoot function in barefoot gait, allowing classification by functional foot type. However, the strength of relationship between FPI score and frontal plane rearfoot motion in shod gait is greatly reduced and this needs to be considered prior to application of this clinical assessment tool. Chuter, V. 2010. J Foot Ankle Res, 3 (9). De Wit, B., de Clercq, D. and Aerts, P. (2000). J of Biomech, 33: 269-78 Redmond, A.C., Crosbie, J., Ouvrier, R.A. (2006). Clin Biomech, 21(1): 89-98.

### NO LONG TERM EFFECTS OF PROPHYLACTIC ANKLE STABILIZERS!

ALT, W., STROHMAIER, K., HELLMANN, N., REULE, C.

UNIVERSITY OF STUTTGART

**Introduction** Effective prevention of sports injuries requires understanding of aetiology and risk factors and development and evaluation of preventive measures. The effectiveness of prophylactic ankle stabilizers (PAS), e.g. bracing or taping, has been proved statistically (Dizon et al. 2009). In biomechanical studies the neuromuscular and mechanical effects of PAS have been investigated (Alt et al., 1999). Little is known about long-term effects of PAS and sometimes atrophy effects are supposed. In this study we investigated long term neuromuscular effects of PAS in male players of team sports before and after 6 months. **Methods** 58 male athletes have been randomized assigned into an intervention (IG) or control group (CG). Athletes with history of ankle or knee injuries or regular usage of PAS during the last 6 months have been excluded. Athletes of the IG selected one of three different ankle stabilizers and were instructed to use it only during every training session and game for the next six months. Functional biomechanical testing included four conditions: treadmill (Zebris FDM-T, Germany) gait (5 km/h) and running (10 km/h); a series of drop jumps; static injury simulation by tilt platform; postural sway by single leg stance (GKS1000, Germany). Neuromuscular activation of lower leg muscles has been evaluated by surface EMG (Noraxon Telemyo 2400 T G2). All methods have been used and validated in previous studies. A pre-post ratio has been calculated. Injuries have been recorded by phone calls weekly. **Results** There was 50% fluctuation of subjects in both groups. Thus, a non-parametric test has been performed and revealed no significant difference between pre – post measurements for all four conditions. The pre-post ratio of neuromuscular activation patterns during gait & running, drop jumps, simulated ankle injury and single leg stance did not differ and was not different between groups. The absolute number of ankle injuries in the PAS group was 6 and 7 in the control group. However, four injured athletes of the IG did not use the ankle stabilizer during the injury and the remaining two suffered from severe contact injuries. **Discussion** Effects of long term use of PAS are still unclear and the rare findings are not consistent. In this study no neuromuscular effects during functional testing could be found after 6 months in a group of male team sport athletes. Hence, it might be suggested to use PAS in combination with additional sensorimotor training in order to compensate for the potential of other postulated negative effects. ### REAL AND SHAM WHOLE BODY MECHANICAL VIBRATION MODULATES SPINAL EXCITABILITY IN HEALTHY YOUNG ADULTS.

HORTOBÁGYI, T.1, GOMEZ, J.2, RIDER, P.2, LAMBERT, J.2, MUEFFELMAN, R.2, DEVITA, P.2

1: UNIVERSITY OF GRONINGEN, GRONINGEN, THE NETHERLANDS, 2: EAST CAROLINA UNIVERSITY, GREENVILLE, NC, USA

**REAL AND SHAM WHOLE BODY MECHANICAL VIBRATION (WBV) MODULATES SPINAL EXCITABILITY IN HEALTHY YOUNG ADULTS.** Hortobágyi, T.1, Gomez, J.2, Rider, P.2, Lambert, J.2, Mueffelman, R.2, DeVita, P.2 1: University of Groningen, Center for Human Movement Sciences, Groningen, The Netherlands, 2: East Carolina University, Department of Exercise and Sport Science, Greenville, NC, USA **Introduction** Several studies reported that neuromuscular function, including maximal voluntary muscle force (MVF) and power increase after acute and chronic bouts of WBV. These papers also suggested the hypothesis that increases in neuromuscular function after WBV may be due to increases in excitability of supraspinal and spinal reflexes. To test this hypothesis, we conducted two experiments with the purpose to determine the effects of WBV on supraspinal and spinal reflex excitability. **Methods** In Experiment 1 we examined the amplitude of voluntary (V) wave (stimulation at 120% of maximal compound action potential, Mmax) and spinal excitability (Hsuperimposed, Hsup, stimulation at 20% of Mmax) during MVFs before and 0, 2, 4, 6, 8, 10, 12, and 14 min after 5 bouts of 1-min-long real WBV at 30 Hz ( $n = 10$ ) by stimulating the tibial nerve. Experiment 2 examined spinal excitability (H reflex) at rest before and every 5 s during the 1-min-long rest interval after each of 5 bouts of 1-min-long real WBV at 30 Hz ( $n = 10$ ) and 50 Hz ( $n = 10$ ) and sham WBV at 30 Hz ( $n = 10$ ) and during the follow-up at 0, 2, 4, 6, 8, 10, 12, and 14 min after the 5th bout of WBV. Because subjects alternated position between standing (WBV) and lying (H reflex testing), we also evoked a small M wave in conjunction with the H reflexes to control for the potential movement of the electrode and were successful to have statistically similar M wave size across bouts of WBV ( $p = 0.384$ ). **Results** Experiment 1 revealed no changes in V wave and Hsup after WBV at 30 Hz. Experiment 2 revealed that WBV depressed H reflex amplitude relative to baseline 34% (30 Hz), 26% (50 Hz), and 18% (sham) in the rest intervals between 5 bouts of WBV (all  $p < 0.05$ ) and an overall ~15% depression was still present at the end of the 4, 1-min-long rest intervals between 5 bouts of WBV. Compared with sham, the depression was 21% ( $p<0.05$ ) and 11% more at 30 Hz. However, during the 14-min follow-up the reflex depression reversed to an overall ~15% facilitation in all three conditions (30 Hz, 50 Hz, sham). **Discussion** These data suggest that both real and sham WBV affect spinal excitability at rest but not during contraction. WBV's modulatory effects seem to be due to an additive effect of vibration and muscle stretch that is present in the ankle plantarflexors as participants stand on the platform with knees and ankles flexed during WBV. Future studies will have to determine if the cumulative post-vibration facilitation of spinal excitability contributes to acute and chronic increases in neuromuscular function.

## A SYSTEMATIC REVIEW OF THE EFFECTS OF ACUTE STATIC STRETCH ON MAXIMAL MUSCULAR PERFORMANCE

KAY, A.D.1, BLAZEVOICH, A.J.2

1: UON (NORTHAMPTON, UK), 2: ECU (PERTH, AUSTRALIA)

**Introduction** The benefits of pre-exercise muscle stretching have been recently questioned (Magnusson & Renström, 2006) following reports of significant post-stretch reductions in force and power production. However, methodological issues and equivocal research findings have prevented a clear consensus being reached. As no detailed systematic review exists, the literature describing responses to acute static muscle stretch was comprehensively examined. **Methods** Medline, ScienceDirect, SPORTDiscus, Swetswise and Zetoc were searched with recursive reference list checking. Selection criteria included: randomised, quasi-randomised and intervention-based trials published in peer reviewed journals examining an acute static stretch intervention on maximal muscular strength, power or speed performance published before 2011. **Results** The search revealed 2634 possible articles; one-hundred met the inclusion criteria. Study design was often poor, with many studies not imposing a control condition/group or providing appropriate reliability statistics (31%). There is no evidence that short-duration acute static stretch (<30 s) has a detrimental effect (pooled estimate = -0.5%), with there being overwhelming evidence that stretch durations of 30-45 s also imparted no significant effect (pooled estimate = -2.7%). A clear dose-response effect was evident between stretch duration and both the likelihood and magnitude of significant decrements, with a significant reduction being likely to occur with stretches >60 s. Maximal muscular strength, power and speed performances were similarly affected regardless of stretch duration, with similar trends apparent across lower limb muscle groups and contraction modes. **Discussion** There is strong evidence for a dose-response effect where the likelihood and magnitude of significant impairments exists for stretches ≥60 s, regardless of performance task, contraction mode or muscle group. However, the overwhelming evidence is that short-duration static stretch (≤45 s) does not detrimentally affect maximal muscle efforts (especially speed or power performance) and can be performed in a pre-exercise routine without compromising maximal muscle performance. The detrimental effects of static stretch are mainly limited to longer durations (≥60 s) that are not typically used during pre-exercise routines in clinical or athletic populations and, therefore, have limited practical relevance. No research exists describing the effects of <60 s static stretch on eccentric strength; given that muscle-strain injury risk is typically associated with eccentric muscle actions, this needs to be examined in the future. **References** Magnusson P, Renström P. (2006). *Eur J Sport Sci*, 6, 87-91.

### OP-PM16 Training and Testing: Individual Sports

#### ALTERATIONS IN LOWER EXTREMITY MUSCLE FUNCTION DURING SQUASH PLAY

KIRKLAND, M., CHRISTIE, C.

RHODES UNIVERSITY

**Introduction** Most of the research relating to squash has focused on cardiovascular load while less emphasis has been placed on the impact on the musculoskeletal system. Therefore, the focus of this investigation was to quantify the changes in muscle function as a result of repeated squash play. **Methods** Twelve sub-elite squash players who were free from injury were selected to participate. Each player was required to attend one experimental session, during which they performed an original laboratory-based squash-simulation protocol designed specifically for this investigation. The protocol was based on notational analysis for movement patterns and not shot selection. To ensure that players were adequately taxed during the protocol, heart rate was continuously monitored and blood lactate was measured immediately post protocol. Muscle function was quantified using the Cybex 6000 isokinetic dynamometer pre and post simulation. Concentric and eccentric peak torque and work were measured in the quadriceps and hamstrings of both legs at testing speeds of 60o.sec-1 and 180o.sec-1. **Results** Average heart rate ( $164.77 \pm 7.48$  bt.min-1) and blood lactate levels ( $10.73 \pm 5.27$  mmol.L-1) confirmed that all players were sufficiently taxed during the simulation. As a generalisation, the protocol resulted in an all round decrease in muscle function. Significant ( $p < 0.05$ ) decreases were found for concentric and eccentric strength of the quadriceps at 60o.sec-1; while significant differences were found for concentric and eccentric work for both quadriceps and hamstrings at both testing speeds. The slow testing speed produced a greater number of significant torque decrements, particularly in the quadriceps. For example, in the right leg, the concentric strength of the quadriceps decreased from  $228 (\pm 27.48)$  Nm at 60o.sec-1 (a 26Nm decrease). Conversely, the faster, functional speed caused a greater number of significant decrements in work, even though the largest decrement occurred at 60o.sec-1. Overall, a greater number of significant decreases were found for concentric strength and work as opposed to eccentric strength and peak torque respectively. **Discussion** Although more significant differences were found for concentric movements and work, there were similar mean decreases in strength and work for both concentric and eccentric motions; decreases of 7.75% and 9.25% for concentric strength and work respectively and 8.12% and 9.62% for eccentric strength and work respectively. It is therefore evident that risk of injury would be considerably increased in the latter stages of the game and that future research should establish the critical start of these changes. Further, training programmes should be designed considering these decrements in strength and work.

#### THE GROSS MECHANICAL EFFICIENCY OF SIMULATED SWIMMING FRONT CRAWL SWIMMING

SWAINE, I., ZAMPARO, P.

CANTERBURY CHRIST CHURCH UNIVERSITY

The gross mechanical Efficiency of simulated swimming front crawl swimming Swaine, I. 1, Zamparo, P. 2. 1: CCCU (Canterbury, UK), 2: University of Verona (Verona, Italy) **Introduction** Recently, a new swimming training machine has been used to simulate the front crawl, during which work rate of each limb can be quantified. This type of simulated swimming offers the opportunity to assess gross mechanical efficiency in a much simpler way than has been possible previously. The purpose of this study was to determine the gross mechanical efficiency of incremental whole-body simulated swimming on a new ergometer, using an energy balance approach (Zamparo et al., 2005). **Methods** Ten swimmers with a mean age of  $23.2 \pm 4.1$  (yrs), stature  $1.76 \pm 0.15$  (m) and body mass of  $71.7 \pm 2.9$  (kg) gave informed consent and participated in exercise testing on a novel simulated swimming ergometer. Whole-body simulated swimming commenced at 50 W and increased by 25 Watts per minute. Participants were asked to simulate the movement actions of front crawl swimming, against increasing air-dyne resistance, until volitional exhaustion. Throughout the incremental exercise test heart rate (HR), oxygen uptake (VO2), total power output (PO), stroke frequency (SF) and kick frequency (KF) were averaged and recorded at 30s intervals. Peak values for

HR (HRpeak), VO<sub>2</sub> (VO<sub>2</sub>peak) and PO (POpeak) were determined during the 30s prior to termination of exercise. The VO<sub>2</sub> and PO values at each minute of the incremental test were used to calculate Gross Mechanical Efficiency (ME<sub>gross</sub>). Internal mechanical work (W<sub>int</sub>) was calculated from kick and stroke frequencies. The gross mechanical efficiency was corrected by addition of W<sub>int</sub> values. Results External work of the whole front crawl (sum of arms and legs) ranged from about 50 to 350 W during incremental simulated swimming. The power output produced by the legs ranged from 18 to 180 W (35-50% of total external work). For the arms it ranged from 33 to 173 (65-49% of total external work). For the whole body (sum of arms and legs) internal work was estimated to range from 7 to 87 W. Metabolic power input ranged from 0.8 to 4.5 l.min<sup>-1</sup>. Values for corrected gross mechanical efficiency ranged from 0.21 to 0.28 with a general trend for increasing efficiency as exercise intensity increased. Discussion These values show that gross mechanical efficiency in swimmers, when performing simulated front crawl swimming on this new ergometer, is similar to the gross mechanical efficiency values reported for other sports such as running and cycling. It is much higher than the propelling efficiency values (5-9.5%) obtained for free swimming. References P. ## MAXIMAL AEROBIC CAPACITY AND EFFICIENCY IN WORLD CLASS SPRINT SKIERS USING THE DOUBLE POLING AND G3 SKATING TECHNIQUE

ETTEMA, G., SANDBAKK, Ø., LEIRDAL, S.

*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

Maximal aerobic capacity and efficiency in world class sprint skiers using the double poling and G3 skating technique Ettema G, Sandbakk Ø, Leirdal S Department of Human Movement Science, Norwegian University of Science and Technology (Trondheim, Norway) Introduction Cross-country skiing is a sport with two different main techniques: classical style and skating. Within those two categories there are several sub-categories exploiting mainly the lower extremities, the upper body or both simultaneously. The aim of the present study was to investigate if the use of different body compartments affects aerobic capacity and gross efficiency (GE) in world class sprint skiers. We therefore compared very different techniques, i.e., the G3 skating (whole body) and the classical double poling (mainly upper body) technique (DP). Methods Six world class sprint skiers performed a maximal aerobic test at 5 % incline in both G3 skating and the double poling. In addition, they performed a submaximal 4 min test at the same inclination at 16km/h. During All tests oxygen consumption was measured using a Jaeger Oxycon Pro (Jaeger, Germany). At the end of each test, heart rate (Polar, Kempele, Finland) and blood lactate (Lactate Pro, Arkray, Japan) was recorded. Work rate was calculated on basis of incline, speed, and rolling friction (Sandbakk et al., 2010). Metabolic rate was estimated on basis of oxygen consumption and lactate levels (Sandbakk et al., 2010). GE was defined as the ratio between the external work rate and the metabolic rate. G3 and DP were compared using the t-test for paired comparisons. Results VO<sub>2</sub>peak in G3 and DP differed significantly (G3: 70.8 vs DP: 63.5ml/kg/min). Also the maximal aerobic work rate differed significantly (402 vs 358W). Thus, 89 % of G3 work rate and VO<sub>2</sub>peak was achieved in DP. During the sub-maximal work rate, oxygen cost did not differ significantly between the two techniques (57.3 vs 55.8ml/kg/min). Blood lactate differed (4.3 vs 8.4mmol/l) as well as heart rate (174 vs 180bpm). GE did not differ between the two techniques (15.37 vs 15.05 %). Discussion World class skiers exploit around 90 % of their skating capacity when using the DP technique (both with respect to VO<sub>2</sub>max and maximal aerobic work rate). The cost of a given sub-maximal work does not seem to be affected by two very different techniques, giving an equal GE for both techniques at the same work rate. GE in both techniques compare with other weight-bearing activities (e.g., speed skating). This may be evidence that GE reflects a basic physiological property of human skeletal muscle, irrespective of technique details and muscle groups that are used. Still, the specifics of the physiological load (i.e., heart rate, lactate levels and energy sources) seem to be affected very clearly. ## REPEATED SPRINT VS HIGH-INTENSITY AEROBIC TRAINING IN TENNIS

FERNANDEZ-FERNANDEZ, J., ZIMEK, R., WIEVELHOVE, T., FERRAUTI, A.

*FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCES; RUHR-UNIVERSITÄT BOCHUM*

Introduction Tennis involves intermittent, high-intensity efforts interspersed with periods of low-intensity activity, during which active recovery (between points) and passive periods (between changeover breaks in play) take place, over an extended period of time (Fernandez-Fernandez et al., 2009). In this situation, tennis players need a mixture of different training systems (i.e., repeated sprint and interval training) for enhancing both the aerobic and anaerobic capacities, in order to achieve high levels of performance. Despite the growing effectiveness from the above-mentioned training strategies for team sports (Iaia et al., 2009), no studies have focused on the specific effects of different high intensity training programs in tennis players. The aim of this study was to compare the effects of a repeated-sprint training (RST) and a high-intensity aerobic interval training (HIT) and on different physical variables of tennis players. Methods 31 competitive male tennis (HIT (n = 11), RST (n = 12) or control group (CON, n = 9)) players took part in a training intervention of 6 weeks. Players completed baseline tests (e.g., VO<sub>2</sub>peak), a specific endurance field test (i.e., Hit and Turn test), 20 m sprint, CMJ, and a RSA test. HIT performed 3 x 90 s runs (90-95%HR<sub>max</sub>) separated by 180 s of active recovery (70%HR<sub>max</sub>), and 8 min of an on-court tennis game (i.e., 2:1 game) between sets. RST performed 3 x 10 shuttle sprints (22 m), separated by 20 s of passive recovery, and 8 min of an on-court tennis game (i.e., 2:1 game) between sets. Results Results showed significant time x intervention interactions for VO<sub>2</sub>peak, with a significant increase in the VO<sub>2</sub>peak level of 6.0% in HIT (p=0.008) and 4.9% in RST (p= 0.010), while no changes occurred in CON. HIT induced greater improvements in tennis-specific endurance (HIT: 28.9% vs RST: 14.5%; p<0.05) and RST led to a significant improvement in repeated sprint ability (i.e., reduction in the mean sprint time of 3.8%; p<0.05). Neither training strategy induced any effects on jumping and sprinting ability. Discussion The inclusion of either HIT or RST programs to normal tennis training sessions represents effective means to increase performance related physical fitness traits in high-level tennis players. It seems that RST represents a time-efficient stimulus for a simultaneous improvement of general and tennis-specific aerobic fitness as well for repeated sprint ability. From a practical point of view, a combination of different training strategies seems to be more effective since several physiological systems are involved during tennis. **Introduction** In response to the need to adjust training loads of sprinters in speed sessions, caused by great variability in the number of series that coaches use and ignorance about how many series realize, when to stop training or what tool to use to control optimally speed session training, was carried out this study, in which we tried to approach the relationship between the degree of load and the fatigue, measured through speed losses and jump capacity and for the metabolic stress. **Methods** Eighteen high level sprinters (age  $23.1 \pm 4.4$  yr, body mass  $73.7 \pm 4.6$  kg, height  $177.6 \pm 5.9$  cm; body fat  $9.6 \pm 2.9\%$ ) took part in the study. They realized sprints of 40, 60 and 80m made to the maximum speed possible up to lose 3% of the speed. It was carried out in three different sessions separated by a week. Before and after each run they made 3 "Countermovement jumps" (CMJ) and blood lactate and ammonia were measured each two repetitions performed. **Results** The losses produced in the successive sprints presented a high relation between the distances and reduction in CMJ height. In 40m this loss was equivalent to the speed loss, 3.1 % for 40m, but it increased 6.7 % in 60m and to 8.3 % in 80m. The fatigue, measured as a decrease in vertical jump's height, increases with distance traveled, and, is strongly correlated to lactate ( $r = 0.93$ ) and ammonia ( $r = 0.89$ ). **Discussion** The mechanical and metabolic response to repeated sprint at maximal intensity had been previously analyzed by Gorostiaga et al. (2010) which examined CMJ height loss following typical sprint-training workouts in 400m elite runners in distances between 60 and 300m although were not performed at maximal intensity. Our study focus on distances of 40, 60 and 80m performed at highest possible speed. Relationship between reduction in CMJ height and distances could be used as indicator of the degree of fatigue produced by various types of efforts, and therefore would be useful for the control and dose of training load. The metabolic stress developed during the effort can be estimated by controlling the CMJ because of the high correlation between CMJ and blood and ammonia concentrations. The high correlations found between mechanical (speed and CMJ height losses) and metabolic (lactate and ammonia) measures of fatigue support the validity of using CMJ to objectively quantify neuromuscular fatigue during sprint training. **References** Gorostiaga, E.M., Asiain, X., Izquierdo, M., et al. Vertical jump performance and blood ammonia and lactate levels during typical training sessions in elite 400-m runners. *J Strength Cond Res.* 2010;24(4):1138-49.

**PLYOMETRIC TRAINING EFFECTS IN DANCERS' JUMP TEST**

SANTANA, J.E., DIEHL, M., CAMPOS, M.H., MOURA, F.A., CUNHA, S.A.

CAMPINAS STATE UNIVERSITY

**PLYOMETRIC TRAINING EFFECTS IN DANCERS' DROP JUMP TEST** Santana, J. E.1; Diehl, M.1; Campos, M. H.2; Moura, F. A.1; Cunha, S. A.1 1: FEF-UNICAMP (Campinas, BR), 2: FEF-UFG (Goiânia, BR) **Introduction** A successful ballet dancer it is not only evaluated by a perfect execution of techniques during steps, but it's also taken in consideration its capacity of performing more complex steps. Mikhail Baryshnikov, i.e., is known by his high vertical jumps. However, dancers are not used to train muscular power (Wyon et al., 2006) to improve jumps performance. The aim of this study was to verify if ballet dancers trained in plyometry improve their performance in drop jump test compared to non-trained. **Methods** Were recruited 8 female ballet dancers from the Institute of Arts (Campinas State University). Four participants performed plyometric training for 8 weeks (mean of 662 jumps per week, loads raised progressively), composing the trained group (TG:  $56.9 \pm 5.9$  Kg,  $1.64 \pm 0.04$  m,  $19.2 \pm 1.5$  years). Others 4 participants composed the non-trained group (NT:  $54.8 \pm 6.7$  Kg,  $1.5 \pm 0.05$  m,  $21.7 \pm 0.9$  years) and remained daily activities. Each participant performed 3 drop jump trials to test training effect. The highs were obtained by kinematical analysis of a sacrum marker (2 digital cameras, 300Hz frequency). The marker position was obtained using Dynamic Posture® (Campos, 2010). Cameras' calibration and 3D reconstruction were performed by DLT (Abdel-Aziz e Karara, 1971). **Results** are expressed in medians (MED) and confidence intervals range (CIr), pre and post-training (PreT/PostT) (Mcgill et al., 1978). **Results** The TG presented no differences in their highs (MED 0.27cm, CIr from 0.24 to 0.30cm at PreT and 0.35cm, 0.29-0.40cm at PostT). The NT showed major values in PostT highs (0.35cm, 0.33-0.38cm) compared to PreT values (0.284 cm, 0.25-0.31cm). However, the values obtained PostT to NT raised with a mean of 27% from PreT and 10% to NT. **Discussion** NT may have increased the highs at PostT test due to demanding classes at their daily activities. TG showed no differences with the training, in which the low number of participants may explain this result. Nevertheless, plyometric training improved jump performance in 27%, suggesting that training benefited most muscular power to TG than NT, despite the results found to NT. This kind of training develops muscular power and is important to dancer fitness. **References** Abdel-Aziz, Y. I, et al. **Oral presentations****OP-PM24 Nutrition: Protein****ACUTE N-ACETYLCYSTEINE SUPPLEMENTATION ATTENUATES FATIGUE FOLLOWING REPEATED BOUTS OF INTERMITTENT EXERCISE**

COBLEY, J., MCGLORY, C., MORTON, J.P., CLOSE, G.L.

LIVERPOOL JOHN MOORES UNIVERSITY

**Introduction** - Reactive Oxygen Species (ROS) production during exercise may be key regulators of cellular adaptation and thus supplementation with antioxidants may be unwise (1). However, it is also known that ROS increase exercise-induced muscle damage and may be endogenous mediators of fatigue (2). In situations where performance/recovery is essential and adaptation is inconsequential, for example during a football tournament, antioxidant supplementation may be an effective means to maximise performance. This study investigated N-acetylcysteine (NAC) supplementation on Yo-Yo level one performance (YIRT-L1) following repeated-bouts of intermittent exercise. **Method** - Twelve males were randomly allocated into a supplement (NAC, 50mg/kg body weight, n=6) or a placebo group

(n=6). Following a one day loading phase subjects completed three testing sessions, on alternate days (Day 1, 3 and 5), consisting of a pre-exercise blood sample, an intermittent exercise protocol typical of team sports such as rugby/football, YIRT-L1 and a post-exercise blood sample. Results and Discussion – There was a significant difference in YIRT-L1 performance between the 2 groups ( $P<0.0005$ ) with the NAC group performing ~25% better on day 1 compared with the placebo group. Moreover, whereas the placebo group's performance deteriorated on day 3 and 5 (~10%) compared with day 1, the NAC group maintained their performance throughout the trial. Plasma creatine kinase values increased markedly over time ( $P=0.002$ ) in both groups, however CK values were significantly greater in the NAC group ( $P=0.029$ ). Conclusion - These data suggest that ROS are endogenous mediators of fatigue following intermittent exercise and NAC supplementation maintains performance. Furthermore, the intermittent exercise resulted in muscle damage on day 3 and 5, and although antioxidant supplementation did not attenuate this damage, supplementation with NAC did improve YIRT-1 performance on these test days. These data would suggest that athletes engaged in repeated intermittent exercise and not looking for training adaptations may benefit from NAC supplementation. References 1. ## STIMULATION OF MUSCLE ANABOLISM BY SIMULTANEOUS AND SEPARATE INGESTION OF ESSENTIAL AMINO ACIDS AND CARBOHYDRATE FOLLOWING RESISTANCE EXERCISE

WITARD, O.C., COCKE, T.L., FERRANDO, A.A., WOLFE, R.R., TIPTON, K.D.

UNIVERSITY OF STIRLING

Introduction: Given the delayed response of net muscle protein balance (NBAL) to carbohydrate (CHO) ingestion post exercise, we proposed that by postponing ingestion of amino acids relative to CHO, it may be possible to enhance the anabolic response of muscle to co-ingestion of amino acids and CHO. Hence, this study compared the post exercise response of NBAL to the combined (COMB) or separated (SEP) ingestion of essential amino acids (EAA) and CHO. Methods: Eight recreationally-trained subjects completed two trials in random order, COMB (drink one contained CHO plus EAA, drink two contained placebo) and SEP (drink one contained CHO, drink two contained EAA). In both conditions, drink one was administered 1 h following an acute exercise bout ( $10 \times 8$  repetitions of leg extension) and 1 h prior to drink two. A primed, continuous infusion of L-[ring- $^{13}C_6$ ]-phenylalanine was combined with collection of muscle biopsies and multiple femoral arterial and venous blood samples for determination of the response of muscle protein metabolism. Results: Elevated muscle protein synthesis rates were primarily responsible for the change from net release to net uptake of amino acids across the leg following post exercise EAA ingestion in both conditions. Arterial amino acid concentrations peaked 30-40 min after ingestion of the EAA-containing drink (COMB, drink one; SEP, drink two) in both conditions. No differences in arterial insulin concentrations were detected between COMB and SEP, nor did area under the curve (AUC) for phenylalanine delivery to the leg differ between COMB ( $162 \pm 23$   $\mu\text{mol}/\text{min}/100\text{mL}$  leg vol/6 h) and SEP ( $152 \pm 21$   $\mu\text{mol}/\text{min}/100\text{mL}$  leg vol/6 h). Likewise, mixed muscle protein fractional synthesis rates were similar between conditions (COMB:  $0.086 \pm 0.007$  %/h; SEP:  $0.089 \pm 0.009$  %/h). The response of phenylalanine NBAL following post exercise drink ingestion in COMB was biphasic, whereas only a single, albeit more marked, peak in NBAL was observed following drink two in SEP. As a result, phenylalanine exchange across the leg, determined 1 h following ingestion of EAA-containing drinks, was ~50% higher in SEP vs. COMB ( $P<0.05$ ). However, calculated over the total acute 6 h recovery period, phenylalanine exchange across the leg from the AUC of NBAL was not different between conditions (COMB:  $110 \pm 19$  mg phenylalanine/6 h vs. SEP:  $117 \pm 24$  mg phenylalanine/6 h). Conclusions: These data suggest that delayed ingestion of EAA 1 h following CHO does not augment the anabolic response of muscle to post exercise co-ingestion of EAA and CHO. Thus, separation of amino acid and CHO ingestion following resistance exercise is unnecessary for optimizing muscle anabolism. Funded by National Institutes of Health

## THE EFFECT OF PROTEIN SUPPLEMENTATION ON THE GAINS IN ELBOW FLEXOR MUSCLE STRENGTH AND SIZE WITH RESISTANCE TRAINING

ERSKINE, R.M., FLETCHER, G., HANSON, B., FOLLAND, J.P.

LOUGHBOROUGH UNIVERSITY

THE EFFECT OF PROTEIN SUPPLEMENTATION ON THE GAINS IN ELBOW FLEXOR MUSCLE STRENGTH AND SIZE WITH RESISTANCE TRAINING Erskine R.M., Fletcher G., Hanson B., Folland J.P. Loughborough University, UK Introduction It is thought that protein supplementation may enhance the gains in muscle strength and size that occur with resistance training (RT) but the scientific evidence is equivocal. Previous studies have been confounded by small sample sizes, imprecise measures of muscle size or no control of prior exercise or habitual protein intake. The purpose of this study was to comprehensively compare the changes in elbow flexor muscle size and strength in response to 12-wk of RT with or without protein supplementation. Methods Thirty-three previously untrained, healthy men (18-30 yr) completed an initial 3-wk RT period without nutritional supplementation and then 6-wk of no training. The initial RT period provided extensive familiarisation and facilitated neural adaptations that might confound muscular responses. Participants were then pair-matched for habitual protein intake and isometric strength response to the initial 3-wk RT and randomly assigned to protein (PRO; n = 17) or placebo (PLA; n = 16) supplementation groups. Participants subsequently completed 12-wk of supplemented RT during which they received a PRO (20g protein, 7g carbohydrate, 250ml H<sub>2</sub>O) or PLA (7g carbohydrate, 250ml H<sub>2</sub>O) supplement immediately before and after each training session in a double-blind manner. Elbow flexor training was performed 3 x per wk with unilateral and bilateral 'preacher curls' (2-3 sets of each exercise; 8-10 repetition maximum (RM)). Muscle strength (unilateral preacher curl 1-RM and isometric elbow flexion force at a joint angle of 120°) and size (1.5T magnetic resonance imaging of the dominant arm to measure total volume and sum of maximum anatomical cross-sectional areas (ACSA) of the biceps brachii, brachialis and brachioradialis muscles) were assessed before and after the 12-wk of supplemented RT. Results PRO and PLA demonstrated similar increases in elbow flexor muscle volume (PRO,  $17.0 \pm 7.1\%$  vs PLA,  $14.9 \pm 4.6\%$ ;  $P = 0.32$ ), ACSA (PRO,  $16.2 \pm 7.1\%$  vs PLA,  $15.6 \pm 4.4\%$ ;  $P = 0.80$ ), 1-RM lifting strength (PRO,  $41.8 \pm 21.2\%$  vs PLA,  $41.4 \pm 19.9\%$ ;  $P = 0.97$ ) and isometric force (PRO,  $12.0 \pm 9.9\%$  vs PLA,  $14.5 \pm 8.3\%$ ;  $P = 0.43$ ). Dietary protein intake during the 12-wk supplemented RT, including training and non-training days, was  $1.56 \pm 0.33$  and  $1.35 \pm 0.47\text{g}/\text{kg}/\text{d}$  for PRO and PLA, respectively ( $P = 0.12$ ). Discussion In the present study, protein supplementation did not augment the muscle strength and size changes that occurred after 12-wk RT. Future studies should investigate whether the adaptations to RT in different circumstances (e.g. whole body exercise, or previously well-trained participants) may be more responsive to protein supplementation. ## WHEY PROTEIN STIMULATES POSTPRANDIAL MUSCLE PROTEIN ACCRETION MORE EFFECTIVELY THAN CASEIN AND CASEIN HYDROLYSATE IN OLDER MEN

PENNINGS, B., SENDEN, J.M.G., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY

Background: Sarcopenia has been attributed to a diminished muscle protein synthetic response to food intake. Whey protein ingestion results in greater postprandial muscle protein accretion when compared with the ingestion of casein (1). The greater anabolic properties of whey versus casein have been attributed to its faster digestion and absorption kinetics (2). However, whey and casein also markedly differ in their amino acid composition. Recently, we observed that when intact casein is hydrolyzed, in vivo protein digestion and absorption kinetics can be modulated to resemble a fast protein while retaining its amino acid composition (3). This provides us with an important tool to define the characteristics responsible for the proposed anabolic properties of whey versus casein. Objective: To compare protein digestion and absorption kinetics and subsequent postprandial muscle protein accretion following ingestion of whey, casein, and casein hydrolysate in healthy, older adults. Design: A total of 48 older men were randomly assigned to ingest a meal-like amount (20 g) of intrinsically L-[1-13C]phenylalanine labeled whey (WHEY), casein (CAS), or casein hydrolysate (CASH). Protein ingestion was combined with continuous intravenous L-[ring-2H5] phenylalanine infusion to assess in vivo digestion and absorption kinetics of dietary protein and subsequent mixed muscle protein fractional synthetic rates (FSR). Results: The peak appearance rate of dietary protein-derived phenylalanine in the circulation was greater with WHEY and CASH when compared with CAS ( $P < 0.05$ ). FSR values, calculated from the ingested tracer, were higher following WHEY ( $0.15 \pm 0.02$  %/h) compared with CAS ( $0.08 \pm 0.01$  %/h;  $P < 0.01$ ) and CASH ( $0.10 \pm 0.01$  %/h;  $P < 0.05$ ) ingestion. FSR values showed a strong positive correlation with the postprandial increase in plasma leucine concentrations ( $r = 0.66$ ;  $P < 0.01$ ). Conclusions: Ingestion of 20 gram whey protein stimulates postprandial muscle protein accretion more effectively than the same amount of intact casein or casein hydrolysate in older men. The greater anabolic properties of whey versus casein are likely attributed to a combination of faster digestion and absorption kinetics as well as a greater leucine content. 1. ## SEVEN DAYS ORAL INGESTION OF PANTOTHENIC ACID AND CYSTEINE DOES NOT ALTER MUSCLE CO-ENZYME A CONTENT, EXERCISE METABOLISM OR EXERCISE PERFORMANCE IN HUMANS

WALL, B.T., STEPHENS, F.B., MARIMUTHU, K., CONSTANTIN-TEODOSIU, D., MACDONALD, I.A., GREENHAFF, P.L.

SCHOOL OF BIOMEDICAL SCIENCES, UNIVERSITY OF NOTTINGHAM, NOTTINGHAM, UK

Pantothenic acid and cysteine are precursors for co-enzyme A (CoA) biosynthesis and are routinely sold as nutritional supplements purported to improve endurance exercise performance, presumably by altering muscle fuel selection during exercise. Here we determined the effects of 7 days of pantothenic acid and cysteine ingestion on muscle total CoA (acetyl-CoA + free CoA) content, muscle fuel selection during prolonged sub-maximal exercise and endurance exercise performance in healthy volunteers. On 3 occasions, each separated by 3 wks, 8 healthy male volunteers (age  $22.9 \pm 1.4$  yr, BMI  $24.2 \pm 1.5$  kg.m<sup>2</sup>) performed 60 min cycling exercise at 75% VO<sub>2</sub>max followed by intermittent cycling to exhaustion (for a total exercise time of  $91.3 \pm 3$  min) at 75% VO<sub>2</sub>max, which was then followed by a 15 min work output cycling performance trial. On each occasion, muscle biopsies were obtained at rest, after 60 min of exercise and at the point of exhaustion (following intermittent exercise). Following the first experimental visit (baseline), a 2 wk recovery period was followed by 1 wk of volunteers ingesting either 3 g of placebo control (glucose polymer; CON) per day or 1.5 g of D-pantothenic acid and 1.5 g of L-cysteine (CP) per day in a randomised, counter-balanced, double blind manner. The order of supplementation was then reversed 1 week prior to the third experimental visit. Resting muscle total CoA content was not different between baseline, CON and CP visits;  $101.9 \pm 11.4$ ,  $88.0 \pm 9.0$  and  $82.8 \pm 11.7$   $\mu$ mol.kg<sup>-1</sup>, respectively. Muscle glycogen content was depleted by 60 min of exercise at 75% VO<sub>2</sub>max (to 29%, 35% and 37% [all  $P < 0.001$ ] of the resting value in baseline, CON and CP visits, respectively) and at exhaustion (to 12%, 16% and 11% of the resting value [all  $P < 0.001$ ] in baseline, CON and CP visits, respectively), but there was no difference in glycogen utilisation between treatment groups. Similarly, there was no difference in muscle lactate accumulation during exercise or the mean RER response during exercise when comparing treatment groups. Finally, work output during the performance trial was no different between CON and CP visits. The present study demonstrates that 7 days of dietary supplementation with pantothenic acid and cysteine does not elevate muscle total CoA content and does not alter muscle fuel selection or exercise performance during prolonged sub-maximal intensity exercise in humans.

## TRIGONELLINE CAN PREVENT SKELETAL MUSCLE LOSS

FRIEDEL, A., KURATLI, K., BRUNNER, H., WANG, Y., WYSS, C., ELSTE, V.

DSM NUTRITIONAL PRODUCTS LTD.

Introduction: Trigonelline is a natural derived niacin-related compound which can be found in many plants like e.g. fenugreek (*Trigonella foenum-graecum*), and coffee beans. It has been demonstrated to have several biological activities like preventing dental caries by preventing the bacteria *Streptococcus mutans* from adhering to teeth or to regenerate neurons which improved the memory in rats. In this study we tested the effects of Trigonelline in skeletal muscle cells in vitro and in vivo. Methods: C2C12 mouse myoblast cells were cultured under normal conditions (3 days, at 37°C, with 5% CO<sub>2</sub>, 10% Foetal Calf Serum until 100% confluency) and then differentiated with 2% FCS differentiation medium for 24h. The cells were then treated for 24h with 10 $\mu$ g/ml Trigonelline and the differentiation of the cells was determined using high content screening (as primary antibody alpha-myosin was used). In an established atrophy animal model (hindlimb unloading / tail suspension model) we tested whether the substance is able to prevent skeletal muscle loss. Ten weeks old female C57BL/6J mice (n=10) were treated by gavage for 3 weeks with Trigonelline (300 mg/kg bw/d). Control group (n=10) was only treated with gelatine. At the end of the study bodyweight, body composition (NMR, Bruker Minispec) and computer tomography (pQCT, Stratec) was determined and the skeletal muscle weight of the gastrocnemius, plantaris and soleus muscles were measured. Results: The in vitro data showed that Trigonelline at dose of 10 $\mu$ g/ml increased the differentiation of C2C12 mouse myoblasts, which led to elongation and fusion into multinucleated myocytes, as indicated by alpha-myosin marker staining. 45% more differentiation of the cells in the first experiment and respectively 37% in the second experiment were observed. In the in vivo test, the animals treated with Trigonelline at 300mg/kg bw/d dose showed less decline of lean body mass after 3 weeks of hind limb unloading compared to the control

group. The pQCT results showed tendencies to a higher total lower leg (by 4%) and muscle cross-sectional area. The weight of the gastrocnemius muscle was significantly higher compared to the not treated but suspended control group. We could observe an 11% increase of the gastrocnemius muscle weight. The in vivo results indicated that Trigonelline was able to reduce the decline of the skeletal muscle mass caused by inactivity. In Summary, Trigonelline was able to increase the differentiation of muscle cells to myotubes in-vitro and to reduce skeletal muscle loss in the in-vivo model. Conclusion: These results suggest that Trigonelline is able to increase the differentiation of C2C12 cells and to prevent skeletal muscle loss in the hindlimb unloading animal model, therefore, trigonelline, may act as a health ingredient to promote skeletal muscle health.

#### LONG-TERM EFFECTS OF LEISURE-TIME PHYSICAL ACTIVITY ON DEPRESSIVE SYMPTOMS IN EARLY MIDLIFE: THE CARDIOVASCULAR RISK IN YOUNG FINNS STUDY

YANG, X.1, TELAMA, R.2, HIRVENSAALO, M.2, HINTSANEN, M.3, HINTSA, T.3, PULKKI-RÄBACK, L.3, VIKARI, J.S.A.4, KELTIKAN-GAS-JÄRVINEN, L.3, RAITAKARI, O.T.4

1: LIKES (JYVÄSKYLÄ, FINLAND), 2: JYU (JYVÄSKYLÄ, FINLAND), 3: HYU (HELSINKI, FINLAND), 4: TYU (TURKU, FINLAND)

Introduction Research on the role of past and current leisure-time physical activity (LTPA) as correlates or predictors of depressive symptoms is scarce and there is a lack of prospective data that are able to show such association. The purpose of this study was to examine the effects of sustained participation in LTPA over 6 years on depressive symptoms among early-middle-aged men and women. Methods Participants were 1396 healthy adults (555 men and 841 women), aged 30 – 45 years in 2007, from the ongoing Cardiovascular Risk in Young Finns Study. LTPA was assessed using a self-report questionnaire completed in connection with a medical examination in 2001 and 2007. The participants were grouped into four categories according to tertiles of LTPA index at two phases: persistently active, increasingly active, decreasingly active and persistently inactive. Depressive symptoms were assessed by using a revised version of Beck's Depression Inventory in 2001 and 2007. Results LTPA and depressive symptoms correlated negatively at baseline and follow-up among men and women. The change in 6-year LTPA was inversely associated with depressive symptoms in both sexes in the final model when age, education, occupation, smoking and body mass index were entered simultaneously. Men and women who were persistently inactive were more likely to develop depressive symptoms (OR 1.94, 95% CI 1.04–3.61 for men and OR 2.84, 95% CI 1.63–4.95 for women) than those who were persistently active over 6 years. In women, the persistent inactivity and decreasing activity were associated with the depressive symptoms irrespective of the confounders, but was not any more significant when adjusted for the baseline depressive symptoms. In men, the association was explained by occupation. Discussion The major finding of the present study was that there is a significant relationship between LTPA and depressive symptoms in adults over 6 years which maybe bidirectional. These prospective findings give evidence of the effectiveness of long-term LTPA in the prevention of depressive symptoms in adulthood. Although the significance between LTPA and depressive symptoms disappeared when adjusted for the baseline depression, our findings suggest that not only current LTPA but also LTPA history, specifically persistent LTPA across the 6 years, may be important for the prevention of depressive symptoms in early midlife. Participation in regular physical activity during leisure may help middle-aged adults to cope with depressive symptoms. Another important finding was that the decreasing physical activity was related with depressive symptoms in women. A long-term LTPA may play a beneficial role in the development of psychological well-being and can be used as a means to prevent or reduce depressive symptoms, particularly in women.

#### ACTIVE MOTHERS GIVE BIRTH TO HEALTHIER CHILDREN

DELIA, S.

NATIONAL SPORTIV CENTER

ACTIVE MOTHERS GIVE BIRTH TO HEALTHIER CHILDREN Delia, S. Msc, Andersen, L.B Prof, Pano, G. Msc, Delia, B. PhD, Çuko, E. Msc Abstract Introduction PA is an important public health tool used in the treatment and prevention of various physical diseases, as well as in the pregnant women during pregnancy. In Albania, benefits of PA during pregnancy do not appear to be widely publicized, and some consider the theme a taboo. At birth, fetal weight is viewed as the crucial parameter that is directly related to the health and nutrition of the mother, and also as an important determination of the chances of the newborn to survive and experience healthy growth and development. Objectives First objective was to show whether there is a relationship between PA levels of pregnant women during pregnancy with baby birth weight. Second objective was to identify which factors influence the baby's weight at birth. Methods We analyzed the Maternity Hospital Statistical datas from January-February; May- June to October 2009. Women 18-45 years old (n =648) that have had the first pregnancy were eligible for this study. Both qualitative and quantitative research methodology was utilized in this study. Preliminary statistical methods as well as polychotomous logistic regression (PLR) analysis were conducted to investigate the relationship between baby's birth weight and mother's attributes which included employment status and type of employment which were taken as surrogates for mother's level of activity during pregnancy. Discussion Inactive mothers were more likely to give birth to unhealthy babies and active mothers gave birth to healthier babies. Analysis of dispersion results (i.e variance, risk), show that mothers who were inactive gave birth to babies whose birthweight was more varied than the birthweights of the babies delivered by active mothers. Obese and overweight mothers were more likely to give birth to overweight babies, while mothers experiencing normal delivery were less likely (OR = 1.88) to deliver overweight babies. Unemployed mothers were more likely (OR = 4.1) to deliver underweight babies while employed mothers were more likely (OR = 1/0.21) to deliver overweight babies. Results This study was important in shedding some light on how baby's weight at birth was influenced by some of the mother's attributes, especially physical activity. Healthy active women give birth to healthier babies who grow to be healthier children and adults, hence, a better and a healthier society. ### IMPACT OF THE USE OF AN ACTIVITY WATCH ON STAGES OF READINESS AND T2D-RISK VARIABLES

RING-DIMITRIOU, S.1, UNDEUTSCH, A.2, SCHWEIGERER, L.1, LAUKKANEN, R.3,4, PAULWEBER, B.2

1UNIVERSITY OF SALZBURG, 2PRIVATE MEDICAL UNIVERSITY SALZBURG, 3POLAR ELECTRO OY KEMPELE, 4 UNIVERSITY OF OULU

**INTRODUCTION** Recently, a new activity watch (AW200, Polar Electro Oy, Kempele, Finland) was introduced for energy expenditure assessments during activity sessions (Brugniaux et al. 2010). Because no study investigated the impact of such a device on physical activity behavior and T2D risk factors we investigated if subjects at high risk of T2D can improve in stages of readiness for PA, and T2D-risk factors during 6 mo intervention. **METHODS** 82 high-risk subjects (40-60 yrs) who participated in DE-PLAN (Diabetes Europe – Prevention using Lifestyle, physical Activity and Nutrition) were randomly assigned to an intense intervention (14 hrs lifestyle education, LSE) with and without AW200 (IG-AW, 18m/11f; IG, 10m/16f), as well as to a light intervention (LG, 2 hrs LSE; 10m/10f). After LSE the participants were contacted by a motivational letter every 6 wks. At baseline and after 6 mo stages of readiness were determined by one question according to Marcus et al. (1992). Body mass, height, waist, fasting glycosylated hemoglobin, fasting insulin and 2h-glucose were assessed at the same time. Pre-post differences were measured with non-parametric (Mann-WhitneyTest) and parametric tests (MANOVA). Group differences in stages of exercise readiness were tested with Kruskal-Wallis Test. Significance level was set  $p < .05$  and all tests were conducted separately for sex. **RESULTS** No group effects were found in all tested variables in both sexes. At baseline most of the subjects were in pre-contemplation and contemplation (>80%) stages, whereas after 6 mo more than 80% shifted to preparation and action stages. The change in exercise readiness was significant in males (IG-AW, IG;  $p < .001$ ), and in females (IG-AW,  $p = .001$ ; LG,  $p = .04$ ). No significant changes were found in T2D-risk factors. **DISCUSSION** Although the AW200 is a valid device to monitor energy expenditure it was not superior to the intense or light LSE to improve activity behavior. This is in accordance with Aittasalo et al. (2005) who found no impact of self-monitoring methods on exercise behavior after 6 months. Furthermore, the administered LSE was too weak to change T2D risk factors. However, our results indicate that mail contacts every 6 weeks additionally to 14 hourly sessions LSE improved exercise readiness. We conclude that a more intense intervention seems necessary to improve T2D risk factors in high-risk adults. **REFERENCES** Brugniaux JV, Niva A, Pulkkinen I., Laukkanen R, Richalet J-P, Pichon AP (2010). ### BODY MASS INDEX AND PHYSICAL FITNESS CHARACTERISTICS OF 6-10 YEAR OLD CHILDREN- A RURAL SPORT DEVELOPMENT INITIATIVE.

VAN GENT, M.

UNIVERSITY OF FORT HARE

Body Mass Index (BMI) and physical fitness characteristics of 6-10 year old children- A Rural Sport Development Initiative. M.M van Gent and L. Miza, University of Fort Hare, Alice, South Africa Introduction BMI is used in many studies to establish prevalence of overweight and obesity. However, studies among rural children in South Africa have revealed conflicting findings (Monyeki et al, 1999; Armstrong et al. 2006; UN 2006). This has serious implications for sport development in rural areas, thus the aim is to establish the prevalence of overweight and obesity among rural children, the differences in physical fitness among children according to BMI classification and the relationship between BMI and physical fitness characteristics. Method Sample consisted of 6-10 year old children ( $n=100$ ). Descriptive statistics were used to classify the children into three groups; normal weight ( $-1SD$  score to median), overweight ( $>+1SD$ ) and obesity ( $>+2SD$ ) (WHO, 2007). ANOVA was used to establish differences between groups (BMI classification) in terms of physical fitness. Correlation was established by using Pearson's correlation coefficient. Results There was 13% occurrence of obesity and 23% of overweight. Statistical differences between the BMI classification groups were found for 10m speed ( $p=0.03$ ) and 20m speed ( $p=0.04$ ). Obese 9 year olds outperformed the other groups in agility ( $10.5 \pm 0.83$ ), speed ( $2.28 \pm 0.44$ ) and muscle endurance ( $27 \pm 6.03$ ). In general the overweight group outperformed the other groups in terms of physical fitness characteristics. BMI correlated poorly with all physical fitness characteristics. Discussion It seems that overweight and obesity is increasing among rural children when using BMI as reference (Armstrong et al, 2006, UN 2006). However, BMI and physical fitness characteristics present poor correlation, thus BMI might possibly not be suitable for use in sport development programs as an indicator of fatness. Support previous finding of BMI being an indicator of heaviness rather than fatness (Monyeki et al, 1999) and that in rural settings BMI might possibly suggest muscle mass instead of fatness (Malina et al., 1998). ### DOES A CLASSROOM PHYSICAL ACTIVITY INTERVENTION HELP PRIMARY 6 CHILDREN ATTAIN THE RECOMMENDED 60 MINUTES OF PHYSICAL ACTIVITY EACH DAY?

DRUMMY, C., BRESLIN, G., DAVISON, G.W., MCKEE, D., MURPHY, M.H.

UNIVERSITY OF ULSTER

**Introduction** The school environment plays an important role in influencing physical activity behaviour, as it is a compulsory aspect of children's lives. Low cost classroom based physical activity breaks interspersed throughout the normal school day have the potential to increase the proportion of children who meet daily physical activity targets. **Methods** 91 children (47 intervention, 44 control) aged 9-10 years participated in a 12 week classroom physical activity intervention involving 3x5 minute high intensity exercise breaks spread across the day. Children wore an accelerometer for 7 days before and then again after the programme to ascertain moderate to vigorous physical activity (MVPA) levels. Height, weight and skin fold measurements were also taken at these time points. A 2x2 mixed design ANOVA was used to compare MVPA across group and time. Results An interaction effect was observed between time and group ( $F(2,89)=6.04, P=.016, \eta^2=.064$ ). Time spent in MVPA significantly changed from 58.8 ( $\pm 17.4$ ) to 66.31 ( $\pm 26.5$ ) minutes per day in the intervention group. There was no increase in daily activity in the control group. No significant differences were found for BMI or skin fold. Before the intervention 36.2% of children met the daily physical activity guidelines, this increased to 44.8% post intervention. **Conclusions** A low cost classroom based intervention of high intensity physical activity increased daily MVPA in primary school children to help them meet the current physical activity recommendations for health.

## CLUSTERED CARDIOMETABOLIC RISK AND CARDIORESPIRATORY FITNESS IN 10-11.9YR OLD SCHOOLCHILDREN: THE REACH Y6 PILOT STUDY

BODDY, L.M., THOMAS, N.E., FOWEATHER, L., GOBBI, R., GRAVES, L.E.F., HOPKINS, N., GREEN, D.J., STRATTON, G.

LIVERPOOL JOHN MOORES UNIVERSITY

CLUSTERED CARDIOMETABOLIC RISK AND CARDIORESPIRATORY FITNESS IN 10-11.9YR OLD SCHOOLCHILDREN: THE REACH Y6 PILOT STUDY Boddy, L.M.1-3, Thomas, N.E.4, Fowweather, L.1,2, Gobbi, R.1,3, Graves, L.E.F.1,2, Hopkins, N. 1,2, Green, D.J. 2,5, Stratton, G.1,2. 1: The REACH Group, 2: RISES, LJMU, UK, 3: ECL, LJMU, UK, 4: Swansea University, UK. 5: The University of Western Australia. Introduction Cardio-respiratory fitness [CRF] is a key component of health, and a number of studies have shown links between CRF and cardiometabolic risk in children (Andersen et al., 2008; Ekelund, et al., 2007). Cardiometabolic risk is often assessed using features of the metabolic syndrome, with few studies incorporating markers of systemic inflammation, circulating cytokines or non-invasive markers of cardiovascular structure and function into risk scores. The aim of this cross-sectional pilot study was to estimate clustered cardiometabolic risk and investigate the relationship between risk and CRF in 10-11.9yr old children. Methods Sixty-two (n = 28 boys) Year 6 (mean age 11.32yrs) schoolchildren took part in the study. Participants completed assessments of CRF (VO<sub>2</sub>peak), cardiovascular structure and function (blood pressure [BP], flow mediated dilation [FMD%], left ventricular mass index [LV mass index]), body composition (DEXA), and anthropometrics. Fasting blood samples were assayed for: high sensitivity C-reactive protein, adiponectin, insulin, glucose, high-density-lipoprotein cholesterol, low-density lipoprotein cholesterol, and triglycerides. Systolic BP, FMD%, LV mass index, trunk fat (kg) and blood markers were used to create a clustered risk score. Differences between the sexes were examined using analysis of variance. Participants were then assigned to a 'normal' or 'high' risk group, and differences in VO<sub>2</sub>peak were assessed by risk group controlling for sex and maturation using analysis of covariance. Logistic regression was completed to assess the odds of being at high risk if classified as unfit. Results Boys were; fitter, had higher HDL levels, and had lower; body fat, LV mass index, insulin and triglyceride levels than girls ( $p \leq 0.05$ ). There were no significant differences in clustered risk score between boys and girls. Participants in the 'at risk' group were less fit than those in the 'normal' risk group ( $p \leq 0.05$ ). The odds of being in the high risk group were 10.75 for those classified as unfit compared to the fit reference group. Discussion These findings provide more evidence that fitness is related to clustered cardiometabolic risk, and highlight the importance of promoting fitness in children. Future studies are required to assess the link between physical activity and clustered cardiometabolic risk in youth. References Andersen L., Sarhinha L, Froberg K, Riddoch C, Page A, Andersen S. ### OP-PM46 Physiology: Respiratory / Hypoxia

#### CAN FOUR NORMOBARIC HYPOXIC EXPOSURES ENHANCE PERFORMANCE IN HYPOXIA?

DEBEVEC, T., MEKJAVIC, I.B.

INSTITUTE JOZEF STEFAN

Introduction While the ability of longer intermittent hypoxic exposures to improve performance at altitude is well established, the results regarding short protocols remain indefinite (Powell et al. 2000). In particular, the minimal dose required to induce beneficial adaptations for altitude performance is unknown (Muza, 2007). This study aimed to investigate whether four intermittent normobaric exposures (SIH) have the ability to improve performance and modulate ventilatory responses during hypoxic exercise. Methods Nineteen healthy male subjects participated in the single blind, placebo controlled, randomised study and were randomly assigned to either experimental (SIH; n=10) or placebo control (SHAM; n=9) group. They underwent four consecutive intermittent exposures (4 h•day<sup>-1</sup>) under hypoxic (FIO<sub>2</sub>: 0.120) or normoxic condition (FIO<sub>2</sub>: 0.209), respectively. Prior to (PRE) and after the exposures (POST) all subjects performed a constant power test to exhaustion (CP) in hypoxic condition at a work load corresponding to 75% of the previously determined normoxic VO<sub>2</sub>max. Oxygen saturation (SpO<sub>2</sub>), heart rate (HR) and minute ventilation (VE) were measured continuously. Results After the SIH neither group significantly improved the CP performance time. Despite the unchanged CP time, only the EXP group showed significant increases in both VE (+ 15%;  $P < 0.05$ ) and SpO<sub>2</sub> (+ 4%;  $P < 0.05$ ) during the POST CP test. No significant differences were observed between groups and testing periods in HR during the CP test. Discussion Compared to the SHAM group, the tested SIH protocol significantly enhanced the hypoxic exercise ventilation and blood oxygen saturation without a concomitant improvement in performance time. Our obtained data are in agreement with the findings of Katayama et al. (2001) and Ricart et al. (2000) who showed that increased hypoxic chemosensitivity following short intermittent hypobaric hypoxia can lead to ventilatory adaptations during hypoxic exercise. In conclusion, this study shows that four intermittent normobaric hypoxic exposures can induce certain ventilatory acclimatization, while the effects on subsequent performance is more unclear. #### THE EFFECTS OF NORMOBARIC HYPOXIA ON MITOCHONDRIAL ADAPTATIONS IN RATS.

BISHOP, D., FERRI, A., RIVOLTA, I., PANARITI, A., ZAZA, A., MISEROCCHI, G.

VICTORIA UNIVERSITY

Introduction In response to stays at high altitude, contrasting mitochondrial changes have been reported. An early study reported increases in cytochrome c oxidase, while more recent research has observed decreases in oxidative capacity [I]. Consistent with this latter study, researchers have also observed decreases in mitochondrial volume, which were accompanied by increases in lipofuscin [I]. However, none of these studies directly measured mitochondrial respiration and little research has investigated changes in the expression of mitochondrial proteins. The purpose of this study was to investigate the effects of 30 days of normobaric hypoxia on mitochondrial respiration, citrate synthase (CS) activity, and the expression of mitochondrial proteins belonging to the electron transport chain complexes. Methods Twenty Wistar rats were randomly assigned to 30 days of either normobaric normoxia (CON; 21% O<sub>2</sub>) or hypoxia (HYP; 10% O<sub>2</sub>). Immediately after being sacrificed, maximal (2 mM ADP) ADP-stimulated mitochondrial respiration was determined on permeabilised muscle fibres from the left (LV) and right ventricle (RV), and the soleus (SOL) and extensor digitorum longus (EDL). The remaining muscle was stored at -80 oC and subsequently analysed for CS activity (spectrophotometer) and the expression of mitochondrial proteins

(Western blot). Result Maximal ADP-stimulated respiration was significantly greater in HYP for SOL and LV, and tended to be higher for RV ( $p=0.06$ ). These differences remained significant when respiration was corrected for citrate synthase activity (an indicator of mitochondrial mass). The changes in the expression of the mitochondrial proteins tended to mirror those of the changes in mitochondrial respiration. Discussion The significantly greater mitochondrial respiration in the LV of HYP (26%;  $P<0.05$ ) was similar to a previous study (16%, ns) [2]. The non-significantly greater mitochondrial respiration in the RV of HYP is also consistent with previous research and the lack of significance can probably be attributed to greater mass of the RV in HYP [2]. We have shown for the first time however, that there is a greater mitochondrial respiration in the soleus of rats exposed to 30 days of hypoxia. Interestingly, there was a 10% decrease in CS activity in SOL, suggesting that there was a decrease in mitochondrial volume (consistent with previous research), but an increase in mitochondrial function (respiration). ## THE EFFECTS OF SHORT-TERM USE OF INHALED SALBUTAMOL ON ANAEROBIC AND AEROBIC EXERCISE PERFORMANCE

SPORER, B.C.1,2, HUTTON, S.1, MCKENZIE, D.C.2

1:CANADIAN SPORT CENTRE - PACIFIC (VICTORIA, CANADA); 2:UNIVERSITY OF BRITISH COLUMBIA (VANCOUVER, CANADA)

**Purpose** The main purposes of this project were to determine the effects of short term (3 weeks) inhaled salbutamol (SAL) use on aerobic and anaerobic performance in non-asthmatic athletes **Methods** This project used a randomized, double-blind, controlled research design. A total of 50 subjects were screened for lung function with three subjects screened out due to abnormal resting values. All remaining subjects underwent a eucapnic voluntary hyperpnea (EVH) test to screen for susceptibility to bronchospasm. A total of six subjects demonstrated a positive EVH response and of the remaining 41 subjects, five subjects were excluded due to a  $VO_{2max}$  score of  $< 55$  ml/kg/min or 5 L/min leaving 36 subjects in the study (18 per group). Treatment was 200µg SAL three times daily over a period of ~3 weeks. Aerobic performance was measured using an incremental exercise test and mean power output in a 20km time trial while anaerobic performance was measured via vertical jump, and 5 second peak and 30 second mean power in a Wingate cycle test. **Results** Mean time trial performance was similar in both groups pre and post treatment (~313 watts). A slight training effect was observed over the course of the study resulting in higher post values for both Wingate 5 second peak power and absolute  $VO_{2max}$  but this did not differ between treatment groups. Furthermore, there was no difference in peak power at  $VO_{2max}$ . Wingate 30 second mean power output also did not differ between groups. Incidence of compromised lung function (drop in FEV1 of  $>10\%$  following EVH test or abnormal resting spirometry) in this study group was 18%. There was no relationship observed between degree of bronchospasm (% change in FEV1) and change in 20km time trial and Wingate performance following SAL treatment. **Discussion** Short term use of inhaled SAL (600µg daily for 3 weeks) does not have an ergogenic effect on either aerobic or anaerobic performance in trained athletes. This is in agreement with the majority of the literature examining inhaled SAL and is the first examination of the effects of its short term use on exercise performance. These results are also in contrast to findings regarding short term use of oral SAL. This difference would suggest that the current WADA stance in allowing SAL treatment by inhalation only remains appropriate. An interesting finding in this study was that the incidence of compromised lung function in cyclists and triathletes, not previously diagnosed with asthma, was 18%. This is in agreement with our previous findings and the percentage of athletes applying for an abbreviated TUE at the Olympic Games for these two sports. **Acknowledgements** This study was funded by a World Anti-Doping Agency research grant.

## THE ERGOGENIC EFFECT OF 800µG AND 1600µG INHALED SALBUTAMOL ON REPEATED SPRINT PERFORMANCE FOLLOWING A FOOTBALL SPECIFIC TREADMILL RUN AT MODERATE AND HIGH AMBIENT TEMPERATURES

DICKINSON, J., HU, J., CHESTER, N., DRUST, B., WHYTE, G.

LIVERPOOL JOHN MOORES UNIVERSITY

**Introduction:** The World Anti-Doping Agency (WADA) stipulates that athletes who declare the use of salbutamol in order to treat asthma should not exceed an accumulated dose of 1600µg over a 24 hour period. There is limited data available investigating the ergogenic effect of inhaled supratherapeutic doses of salbutamol on intermittent sports such as football. The purpose of the present study was to investigate the effect of inhaling supratherapeutic doses of salbutamol on repeated sprint performance following a football specific run at moderate and high ambient temperatures. **Methods:** Five male non-asthmatic football players (mean±SD; age 24.4±4.0 years; weight 71.2±3.6 kg; height 174.6±5.1 cm) volunteered and provided written informed consent prior to taking part in this study. Participants attended the lab on six occasions to inhale either a placebo (PLA), 800µg of salbutamol (800SAL) or 1600µg salbutamol (1600SAL) and complete a football specific run on a motorised treadmill at either 18°C (moderate) or 30°C (hot). Following the football specific run participants completed twelve 17.5m sprints with a 10 second rest interval on a non-motorised treadmill. Performance and physiological variables total time, peak power, average power, peak HR and peak blood lactate were recorded. Repeated measures ANOVA were performed to investigate the differences between sprint performance following inhalation of PLA, 800SAL and 1600SAL. Significance was assumed if  $p<0.05$ . **Results:** At moderate temperatures there was no significant difference between PLA, 800SAL or 1600SAL in the performance and physiological variables: total time (52.8±1.6 s; 52.8±1.8 s; 52.5±0.5 s), peak power (1541.0±296.4 w; 1490±423.8 w; 1409.3±242.7 w), average power (560.8±104.3 w; 561.5±96.1 w; 555.5±72.1 w), peak HR (180.0±8.1 b.min<sup>-1</sup>; 183.5±6.0 b.min<sup>-1</sup>; 184.8±7.1 b.min<sup>-1</sup>) or peak blood lactate (11.4±3.2 mmol.l<sup>-1</sup>; 8.0±6.6 mmol.l<sup>-1</sup>; 13.9±2.8 mmol.l<sup>-1</sup>). At hot temperatures there was no significant difference between PLA, 800SAL or 1600SAL in the performance and physiological variables: total time (52.6±0.5 s; 52.0±0.4 s; 53.0±1.7 s), peak power (1032.0±680.2 w; 1010.8±567.1 w; 1468.3±351.9 w), average power (411.3±271.2 w; 380.5±232.3 w; 556.8±88.6 w), peak HR (185.3±8.0 b.min<sup>-1</sup>; 188±6.0 b.min<sup>-1</sup>; 188.3±2.1 b.min<sup>-1</sup>) or peak blood lactate (7.2±1.5 mmol.l<sup>-1</sup>; 10.4±4.0 mmol.l<sup>-1</sup>; 8.5±2.8 mmol.l<sup>-1</sup>). **Discussion:** Our data suggest the WADA position to allow athletes to inhale up to 1600µg in a 24 hour period does not result in any physiological benefits or improvements in sprint performance in non-asthmatic football players in moderate or hot ambient temperatures.

## THE EFFECT OF DEEP, SLOW BREATHING ON LOCOMOTION DURING MODERATE INTENSITY WALKING AND RUNNING

CLEARY, S., SUSTA, D.

DUBLIN CITY UNIVERSITY

Respiration, primarily under autonomic control is tightly coupled with locomotion, via the 'Locomotor-Respiratory Coupling' (LRC). Locomotion is thought to dictate respiratory patterns via neuro-mechanical and chemical stimuli but evidence of a bi-directional link exists (Rabler and Kohl, 2000). Considerable evidence supports pulmonary limitation to exercise via various mechanisms (Dempsey, 2006), meriting investigations into possible methods of improvement. Respiratory pattern is an easily manipulated extrinsic parameter, as autonomic control may be consciously overridden. The aim of the present study was to compare the effects of two different breathing patterns on locomotion, SB (spontaneous breathing) and DSB (deep and slow breathing) in people exercising at moderate intensities. A heterogeneous group ( $n=23$ ) of healthy male ( $n=14$ ) and female ( $n=9$ ) subjects, aged between 20 and 52 were recruited. Subjects were either trained runners or untrained with  $\text{VO}_{2\text{peak}}$  ranging from 2.102L/min to 5.124L/min. Following baseline assessment of pulmonary function, aerobic capacity ( $\text{VO}_{2\text{peak}}$ ) and lactate threshold (LT), subjects performed two 20 minute exercise trials at constant load, eliciting a blood lactate level (bLa) of 1mmol/l above LT. SB trial preceded DSB so that a learned effect of DSB would not affect SB trial. Statistical analysis using SPSS used paired sample t-tests and repeated measures ANOVA to examine mean differences in all parameters between trials. The level of significance was set at  $P<0.05$  and all significant 't' and 'F-ratios' were reported with significance level. DSB produced significant changes in respiratory pattern, respiratory rate (RR) decreased by  $34.69 \pm 12.68\%$  ( $p<0.001$ ), VT increased by  $43.62 \pm 6.35\%$  ( $p<0.001$ ) and total time (Ttot) increased by  $84.53 \pm 63.87\%$  ( $p<0.001$ ). Altered LRC was evidenced by an increase in stride rate to respiratory rate ratio (SR:RR) of  $1.17 \pm 0.69$  strides/breath ( $p<0.001$ ) due to a relatively smaller decrease in stride rate (SR) of  $1.48 \pm 2.19$  strides/min ( $p<0.01$ ). Interestingly, DSB resulted in a significant mean decrease in ventilation (VE) of  $5.87 \pm 6.49\text{L/min}$  ( $p<0.001$ ),  $10.32 \pm 11.41\%$  lower than SB, and  $\text{VO}_2$  decreased by  $4.96 \pm 8.97\%$  ( $0.138 \pm 0.249\text{L/min}$ ,  $p<0.05$ ), suggesting that the same mechanical output can be afforded with lower oxygen consumption. This study suggests that a deep, slow breathing pattern affects stride frequency and improves locomotory economy at moderate exercise intensities. Rabler, B. and Kohl, J. (2000). 'Coordination-related changes in the rhythms of breathing and walking in humans', *Eur J Appl Physiol*, 82: 280-288. Dempsey, J.A., Romer, L., Rodman, J., Miller, J. and Smith, C. (2006). ## THE ATHLETE BIOLOGICAL PASSPORT FOR THE DETECTION OF AUTOLOGOUS BLOOD DOPING IN A LONGITUDINAL BLINDED STUDY

POTTGIESSER, T., SOTTAS, P.E., ECHTELER, T., ROBINSON, N., UMHAU, M., SCHUMACHER, Y.O.

UNIVERSITY HOSPITAL FREIBURG / UNIVERSITY OF LAUSANNE

**Introduction** - The most promising attempt to screen for otherwise untraceable autologous blood transfusions is the Athlete Biological Passport (ABP) and its adaptive model that enables a longitudinal monitoring of haematological measures to identify patterns of blood manipulations. So far, few studies analysed various blood passport approaches to detect autologous transfusions. Standardised testing protocols were applied with the event of manipulation always known as a reference point. Hence, it remains questionable if these results mirror the true detection sensitivities that can be expected in the field. The purpose therefore was to evaluate the performance of the ABP for the detection of autologous blood transfusions in a blinded setting. **Methods** - Twenty-one subjects were divided into a doped group (multiple transfusions of 1-2 units of erythrocyte concentrates at various time points,  $N=11$ ) and a control group ( $N=10$ ), who were observed over 42 weeks. Up to 10 venous blood samples were ordered per subject by a blinded investigator without knowledge about the group allocation and time point of transfusions. Mimicking an "intelligent testing" approach, the investigator based his testing regime on the haematological data treated by the adaptive model (haemoglobin concentration (Hb) (g/L), reticulocytes (ret%) (%), OFF-hr and respective sequences) and had to identify the doped subjects ("identification" was defined as values beyond the 99% or 99.9% probability thresholds of the ABP). **Results** - Analysis allowed the identification of 4 (probability  $>99\%$ ) or 3 (probability  $>99.9\%$ ) doped subjects using Hb and 8 (probability  $>99\%$ ) or 5 (probability  $>99.9\%$ ) subjects using OFF-hr. One false-positive value for Hb was observed in the control group at both probability levels. Three doped subjects (27%) presented an abnormal Hb sequence and 4 doped subjects (36%) an abnormal OFF-hr sequence, there were no false positive sequence results. The best possible sensitivity was 82% when a combination of all tests was used as 2 of 11 subjects of the doped group remained undetected when applying the above criteria. **Discussion** - This investigation provides evidence that the adaptive model allows detection of autologous blood transfusions with a good sensitivity in a longitudinal blinded setting. An intelligent testing approach and the adherence to WADA's ABP operating guidelines are determinant in the success.

## ASSOCIATION BETWEEN ANTHROPOMETRIC CHARACTERISTICS AND RESISTANCE AGAINST PEAK EXTERNAL WEIGHT DURING EGGBEATER KICK IN WATER-POLO.

BOTONIS, P.G., PLATANOU, T.

UNIVERSITY OF ATHENS

**Introduction** The eggbeater kick is a cyclical movement of the lower limbs, which is performed by the knees with similar and symmetrical actions of the right and left sides, but with alternating leg phases (Platanou 2005). Resistance against opponent's pressure is a very important ability for water-polo players, as it contributes to execute various actions. This ability is dependent on the forces generated upwards to raise the body reacting on the rival's pressure and on the weight of the player acting downwards. In addition, it is known that the force generated is dependent on the pressure differences of the fluid acting on the limbs. However, it is unknown, whether this ability is dependent on players' anthropometric characteristics. The aim of the present study was to exam the association between anthropometric characteristics and the peak external pressure that a player can resist, during an eggbeater kick. **Methods** Twenty-eight water-polo players were tested. In the beginning, 12 anthropometric variables (body mass, stature, arm length, forearm length, hand length, lower limb length, knee length, the length from the ankle to the ground and the perimeter of biceps at rest and after contraction) were measured. Thereafter, each participant performed the eggbeater kick that lasted 20 sec. initially without any external loads and then with a progressive increase of external pressure with hands out of the water. The weights were placed in special sheaths of a zone and were

positioned on the subject's shoulder. The inability of the participant to keep his hands out of the water during the eggbeater with external pressure was considered as the peak external load that a player could resist. Pearson correlation was employed to identify significant correlations between anthropometrics and maximal external weight. Results The analysis revealed that participants' ability to resist peak external weight ( $14.68 \pm 3.43$  kg) was significantly correlated with body mass ( $84.14 \pm 10.03$ ,  $r=0.58$ ,  $P<0.05$ ), stature ( $182.16 \pm 7.54$  cm,  $r=0.61$ ,  $P<0.05$ ), arm length ( $80.46 \pm 5.61$  cm,  $r=0.64$ ,  $P<0.05$ ), lower limb length ( $93.15 \pm 5.40$  cm,  $r=0.39$ ,  $P<0.05$ ) and forearm length ( $47.13 \pm 3.86$  cm,  $r=0.41$ ,  $P<0.05$ ). Moreover, contracted biceps perimeter ( $35.5 \pm 4.44$  cm) and the difference between biceps perimeter at rest and after contraction were significantly correlated with water polo players' ability to resist against the peak external load ( $r=0.46$  and  $r=0.38$ , respectively,  $P<0.05$ ). Discussion In conclusion, the ability to resist peak external loads seems to be dependent on the anthropometric and dynamic characteristics of water polo players. The present data are useful in determining loads during leg training. Platanou T. (2005). J Sports Med Phys fitness. 45(1), 26-31.

## DOES DATE OF BIRTH INFLUENCE PERFORMANCE OF SWISS TRACK AND FIELD ATHLETES?

ROMANN, M., HEYER, L., FUCHSLOCHER, J.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN

Introduction Identifying talented athletes at an early age has become one of the major issues in many competitive sports. The relative age, which refers to the difference in age between children in the same selection year, has a significant influence in the talent identification process (Cobley et al., 2010). The primary purpose of this study was to determine, if the date of birth influences performance of Swiss track and field athletes. Methods 840 female and 840 male athletes who achieved one of the best 30 results (Top 30) in their age category (U10 to elite) in the year 2010 were evaluated. The year was divided into four quarters (Q1: Jan. to Mar.; Q2: Apr. to June; Q3: July to Sept. and Q4 Oct. to Dec.). The percentage of athletes born in the respective quartiles was compared to the distribution of all registered members (RM) in the federation and to all respective births in Switzerland (BP). Sprint, middle-distance, long jump and javelin throw performance were examined for each age group. Statistical comparisons were calculated using chi2-tests. Results Relative age effects (RAEs) were found with a distribution of Q1=38.2%, Q2=26.3%, Q3=20.0%, Q4=15.5% for female and Q1=42.5%, Q2=30.8%, Q3=16.5%, Q4=10.2% for male athletes. The month of birth distribution differed significantly from the BP and the RM for the respective years in both groups ( $p<0.001$ ). RAEs are more pronounced in the U10-U14 age group than in the older athletes, whereas no differences between U10-U14 boys and girls (except for middle-distance) RAEs could be found. No significant differences were found by comparing events. Discussion RAEs exist in many competitive sports worldwide and are clearly evident in athletics in Switzerland. In particular, the chance of achieving a Top 30 male result is 4-fold higher for athletes born in Q1 compared to Q4. Our results suggest, that a significant part of Top 30 results may be explained by RAEs. It seems that Athletes born in Q1 take advantage of their larger experience, enhanced mental and physical skills and hence perform at a higher level (Armstrong & McManus, 2010). Especially for Switzerland, which has a rather shallow talent pool due to the small number of inhabitants, any reduction of RAEs may produce a substantial performance enhancement at elite senior level in future. ## MODELING THE PROGRESSION OF COMPETITIVE PERFORMANCE OF AN ACADEMY'S FOOTBALL TEAMS

MALCATA, R.1, HOPKINS, W.G.1,2, RICHARDSON, S.2

1: SPORT PERFORMANCE RESEARCH INSTITUTE, AUT UNIVERSITY (AUCKLAND, NEW ZEALAND); 2: ASPIRE ACADEMY FOR SPORTS EXCELLENCE (DOHA, QATAR)

Introduction "Have our athletes improved?" is an important question for coaches and support staff, but there appears to have been no published research on this topic with team sports for periods longer than a season. Here we report the progression of three teams of the ASPIRE Academy over five seasons using a novel analytic approach based on generalized mixed modeling. Methods The Aspire teams consisted of players born in 1991, 1992 and 1993; they played totals of 115, 107 and 122 games in Asia and Europe between 2005 and 2010 against teams differing in age by up to 3 years. Game scores predicted by the mixed model were assumed to have an over-dispersed Poisson distribution. The fixed effects in the model estimated annual linear progression of ASPIRE and of the other teams (grouped as a single opponent) adjusted for a home-ground advantage and for a linear effect of age difference between the competing teams. Games played against the same team were accounted for by including a random effect representing each team's mean score. All effects were estimated as factors via log-transformation and presented as percent differences in scores. Inferences were based on the span of 90% confidence intervals in relation to thresholds for small and moderate factor effects of  $\times/\div \pm 1.10$  and  $\times/\div \pm 1.40$  (+10%/-9% and +40%/-29%). Results Most effects were clear only when data for the three teams were combined. Scores of teams playing at home and of teams one year older than their opponents were higher by 27% (90% confidence interval 13 to 42%) and 23% (7 to 42%), both representing small effects. After adjustment for these effects, the Aspire teams scored on average 1.5 goals per match, with little change in the five years of their existence, whereas their opponents' scores fell from 1.4 in their first year to 1.1 in their last. The difference in progression was trivial over 1 year (7%, -4 to 20%), small over 2 years (15%, -8 to 44%), but unclear over >2 years. Conclusion The generalized mixed model has marginal utility for estimating progression of football team scores, owing to the uncertainty in the estimates of single teams. The estimates are likely to be more precise and useful for teams in sports with higher game scores.

## VELOCITY AND ACCELERATION BEFORE THE TACKLE IN REAL MATCH SITUATIONS

HENDRICKS, S., KARPUL, D., LAMBERT, M.I., NOAKES, T.D.

UNIVERSITY OF CAPE TOWN

Background: The tackle event in rugby union, at all levels of play (amateur to professional, juniors to seniors) places both ball-carrier (BC) and tackler (T) at high risk of injury compared to any other facet of play. The velocity at which the BC and T enter the tackle (and the velocity difference between the two) is regarded as a risk factor for injury. For this reason, a better understanding of the dynamics of the tackle is warranted. To date, only velocity and acceleration measurements for the tackle have been conducted in controlled settings. Aim: To determine the velocity and accelerations profiles before the tackle in real match situations at 3 different playing levels. Methods: Ten Front-on and 10 side-on tackle situations in the 2010 Super 14 (S14), Varsity Cup (VC), and Currie Cup Under 19 (U19) matches were analysed. Thereafter, using a novel video analysis system, the BC and T were tracked for 0.5 seconds (s) before contact in each tackle situation. The 0.5s were further divided into 0.1s segments (T1 to T5). The displacement covered by the BC and T were measured for each 0.1

segment. Accordingly, velocity (m/s) and acceleration (m/s<sup>2</sup>) were calculated for the BC and T. Data are reported as mean (over T1-T5)  $\pm$  standard deviation. Results: Velocity profiles for the BC during front-on tackles were; S14;  $4.80 \pm 2.90$ , VC;  $5.20 \pm 1$ , U19;  $4.88 \pm 1.72$  m/s. Velocity for the T during front-on tackles were; S14;  $4.97 \pm 1.78$ , VC;  $6.43 \pm 2.55$ , U19;  $5.73 \pm 1.85$  m/s. Velocity profiles for the BC during side-on tackles were; S14;  $4.85 \pm 2.09$ , VC;  $5.75 \pm 1.78$ , U19;  $4.72 \pm 1.29$  m/s. Velocity for the T during side-on tackles were; S14;  $5.40 \pm 2.20$ , VC;  $5.50 \pm 2.13$ , U19;  $3.86 \pm 1.13$ . Acceleration profiles for the BC during front-on tackles were S14;  $-1.24 \pm 4.88$ , VC;  $1.98 \pm 4.98$ , U19;  $-0.76 \pm 8.56$  m/s<sup>2</sup>. Acceleration profiles for the T during front-on tackles were; S14;  $-1.62 \pm 9.62$ , VC;  $-6.49 \pm 10.64$ , U19;  $-2.65 \pm 8.84$  m/s<sup>2</sup>. Acceleration profiles for the BC during side-on tackles were; S14;  $-1.26 \pm 8.67$ , VC;  $-2.02 \pm 6.24$ , U19;  $-0.95 \pm 9.99$  m/s<sup>2</sup>. Acceleration profiles for the T during side-on tackles were; S14;  $-2.44 \pm 10.12$ , VC;  $-5.28 \pm 6.30$ , U19;  $2.67 \pm 3.59$  m/s<sup>2</sup>. No statistical significant differences were found between the different levels of play and between the BC and T (for each group) Conclusion: Our results are comparable with studies conducted in controlled settings. Surprisingly, no differences for velocity and acceleration were found between the different levels of play. This can be attributed to 1) the variable nature of the tackle, 2) Entering the tackle at a high velocity or positive acceleration is not necessarily a pre-requisite for success in contact, 3) Although the levels of play are different, speed training, ball-carrying and tackle training habits may be the same.

## VISUAL SEARCH STRATEGIES OF VOLLEYBALL PLAYERS IN LIVE ACTION SCENARIOS: A COMPARISON ACROSS DIFFERENT AGE GROUPS

AFONSO, J.I, MESQUITA, I.I, GARGANTA, J.I, MCROBERT, A.2, WILLIAMS, A.M.2,3

1- UNIVERSITY OF PORTO - FACULTY OF SPORT; 2-LIVERPOOL JOHN MOORES UNIVERSITY – SCHOOL OF SPORT AND EXERCISE SCIENCES; 3- THE UNIVERSITY OF SYDNEY – DISCIPLINE OF EXERCISE AND SPORTS SCIENCE

Visual search strategies provide useful insight into decision-making in sport. However, researchers have typically gathered data using laboratory-based protocols rather than collecting data in situ. We examined differences in the visual search strategies employed by female volleyball players varying in age using a field-based test protocol. Twenty-seven participants (twelve under-15 years, nine under-17 years, and six adults), belonging to top-ranked teams within their respective age group were recruited. Participants wore an ASL@3000 eye tracking system during live-action defensive tasks in the backcourt region (six trials each). The opposing team developed various offensive sequences and blockers were employed to enhance the similarity to the competition demands. Separate One-way ANOVAs showed differences across the three groups in the mean number of fixations, total and average fixation duration, and number of fixation locations ( $p \leq 0.05$ ). Post-hoc procedures (Scheffe) showed that the U-15 participants performed fewer fixations and gazed upon fewer locations than both the U-17 and adult players, thus potentially using less sources of information. In contrast, the U-15 group employed longer total and average fixation durations. With respect to the areas fixated upon, chi-square showed differences across the age groups ( $p \leq 0.05$ ). The U-15 participants fixated less often the middle-attacker's action before the setting, while adult players frequently attend to this area. The faster attacks conducted by adult teams may induce a stronger need to attend to such action. In conclusion, younger participants focused on fewer sources of information than older players, but fixated for longer periods of time on each location, suggesting that they needed more time to retrieve meaningful information. Furthermore, the fixation or absence of fixation on the middle-attacker's action may point towards greater attunement to the constraints specific to the level of play at which they perform. ## WORLD RECORD TIMES IN TRACK CYCLING – THE IMPORTANCE OF ALLOWING FOR CHANGES IN ENVIRONMENTAL CONDITIONS

DWYER, D.

VICTORIAN INSTITUTE OF SPORT

Introduction Air temperature, barometric pressure and relative humidity can have a significant effect on track cycling performance, which makes the comparison of world record performances that are achieved under different environmental conditions, unfair. The UCI and some national cycling associations acknowledge that altitude and temperature can affect track cycling performance. However, these acknowledgments ignore the important effects of barometric pressure and humidity, both of which vary daily and seasonally, and also affect air density, aerodynamic drag and performance in pursuit and time trial events. There does not appear to be a comprehensive allowance made for the effect of environmental conditions on track cycling performance that is consistently applied to new performances that are close to world record times. The present study highlights this issue by illustrating the important effect of changes in barometric pressure and humidity on pursuit performance. Methods A case study approach was taken whereby a 3000m pursuit performance, recorded officially at a World Cup event, was modelled to quantify the power output of the athlete throughout the race. Mathematical modelling was performed using published cycling specific equations that relate drag and power to velocity and therefore pursuit time (1,2). Subsequently, by keeping the power output of the athlete constant in the model, the effect of temperature, pressure and humidity on pursuit velocity can be assessed by varying these three environmental factors in a stepwise process. Results Mathematical modelling of the effect of varying ambient conditions indicates that each degree of increase in temperature above 20°C results in a decrease in pursuit time of 0.07 s/1000 m, each 10% increase in humidity above 50% decreases pursuit time by 0.4 s/1000 m and each 6.6 hPa decrease in barometric pressure increases pursuit time by 0.13 s/1000 m. When the actual changes in all three ambient conditions are compared, the relative magnitude of their contribution to the total change in pursuit performance is; temperature 49%, barometric pressure 37% and humidity 14%. Discussion/Conclusion The present calculation of the effect of temperature on pursuit performance is very close to that predicted by Cycling Australia (0.07 vs. 0.08s/1000m). The combined effect of all three factors can account for a difference of up to 6 s between two 4000 m pursuits performed in different conditions, where the difference has nothing to do with the skill, power output or drag coefficient of the athlete. It may be necessary to adjust track times to standard conditions, to allow fair comparison between performances that are close to current world records. References 1. Martin, J. et al. #### TRAINING TIME EFFECTS ON PSYCHO-PHYSIOLOGICAL RESPONSES TO EXERCISE IN MASTER ATHLETES

PIACENTINI, M.F., FERRAGINA, A., AMMENDOLIA, A., CIBELLI, G., CAPRANICA, L.  
UNIVERSITY OF ROME-FORO ITALICO

Training time effects on psycho-physiological responses to exercise in Master athletes Piacentini M.F.,<sup>1</sup> Ferragina A.,<sup>2</sup> Ammendolia A.,<sup>2</sup> Cibelli G.,<sup>3</sup> Capranica L.<sup>1</sup> <sup>1</sup>DISMUS, University of Rome Foro Italico, Italy. <sup>2</sup>School of Medicine, University of Catanzaro, Italy <sup>3</sup>School of Medicine, University of Foggia, Italy Introduction Because most physiological and psychological parameters exhibit circadian rhythms, it is important to understand daily variations of athletic performance components (Cappaert, 1999). This issue is crucial for master endurance athletes who adjust their training schedule according to work and family duties. Therefore, the purpose of the present study was to evaluate psycho-physiological and performance responses to a training performed during morning (M), afternoon (A) and evening (E) sessions. Methods 8 master athletes (45±7yrs) performed three (i.e., M: 6-8h, A: 12-14h, and E: 19-21h pm), running sessions consisting of one 3000m at 80% of the individual maximal aerobic speed, 5-min recovery, and one all-out 1000m. An ANOVA for repeated measures was used to verify differences ( $p < 0.05$ ) between daily sessions in session-ratings of perceived exertion (session-RPE), profiles of mood state (POMS), salivary cortisol (sC), and performance parameters. Moreover, sC concentrations were compared with time-matched values collected during a resting day. Results No difference was found for all-out 1000m performances (M: 17.2±1.3km/h; A: 17.5±0.9km/h; E: 17.5±1.1km/h). Lower ( $p = 0.037$ ) session-RPE emerged only for E (259.3±69 AU) with respect to M (359.7±111AU). Higher post-exercise sC increases were observed for E (169%) with respect to A (80%) and M (89%). However, the AUC was significantly lower ( $p = 0.001$ ) in the E trial (28.8±9.2 AU) compared to M (41±6 AU) and A (41±13 AU) ones. After the 1000m and during 30-min and 60-min of recovery exercise sC was always significantly higher than time-matched resting values. Although no difference was found for post-exercise POMS sub-scales and total mood disturbance, pre-exercise fatigue was higher ( $p = 0.03$ ) in E (11.5±6.8pt) with respect to M (9.1±5pt) and A (10±7pt). Discussion Despite daily variations were expected (Trine and Morgan 1995, Dimitriou et al 2002), in our study performance and total mood did not differ. Conversely, E showed a higher pre-exercise fatigue perceptions and a trend toward higher sC increases due to training, indicating a cumulated fatigue from previous daily activities. However, the lower session-RPE and cortisol AUC observed at the end of E training might indicate a perceived relief effect of exercise, which could be of interest for athletes and coaches. #### DEVELOPMENT OF BURNOUT AMONG ADOLESCENT HIGH LEVEL ATHLETES: CAUSAL RELATIONSHIPS BETWEEN THE THREE DIMENSIONS

ISOARD-GAUTHEUR, S.<sup>1</sup>, GUILLET-DESCAS, E.<sup>1</sup>, CHANAL, J.<sup>2</sup>, GAUDREAU, P.<sup>3</sup>

<sup>1</sup>: UNIVERSITÉ CLAUDE BERNARD LYON 1 (FRANCE), <sup>2</sup>: FACULTÉ DE PSYCHOLOGIE ET DES SCIENCES DE L'ÉDUCATION (SUISSE), <sup>3</sup>: UNIVERSITÉ D'OTTAWA (CANADA)

Introduction Raedeke (1997) have identified three dimensions that define the athlete burnout: reduced sense of accomplishment (RA), sport devaluation (SD), and physical and emotional exhaustion (PEE). In the organizational domain, it has been assumed that it may exist causal relationships between the three dimensions of burnout. Taris, Leblanc, Schaufeli and Schreurs (2005) have shown that emotional exhaustion can lead to depersonalization which may lead to a reduced personal accomplishment. Emotional exhaustion could also have a direct impact on reduced personal accomplishment. To our knowledge, in the sports domain, only two studies tried to share some light on this aspect, they highlighted that sport devaluation is the last step and that physical and emotional exhaustion is the key component of athlete burnout. However, they used retrospective interviews with a small number of athletes (Cresswell & Eklund, 2007; Gustafsson, Hassmén, Kenttä, & Johansson, 2008). Therefore, the objective of this study is to test relationships between the three dimensions of burnout. We postulate that physical and emotional exhaustion is the first symptom of athlete burnout, and that it would have an influence on the sport devaluation, which in turn should have an impact on reduced accomplishment. Methods The study enrolled a total of 919 handball players (438 girls and 481 boys) aged from 13 to 19 years old. The athletes completed a French version of the Athlete Burnout Questionnaire (Questionnaire du Burnout Sportif; QBS; Isoard-Gauthier, Oger, Guillet & Martin-Krumm, 2010) twice a year during three seasons. Results Results of latent growth analyses revealed that RA is higher for players with more PEE and SD, and this difference is constant across time. Among individuals with low SD, PEE rises slowly till 19 years old, and among individuals with high SD, PEE rises till 16 years old then decreases till 19 years old. Among players with higher RA, SD rises more than among individuals with lower RA. Finally, for players with higher PEE, SD rises slower than for players with lower PEE. Discussion The results of the current study highlight the process of athlete burnout among young high level handball players in elite training centers. The development of sport devaluation is influenced by reduced accomplishment and physical and emotional exhaustion and have a reciprocal influence on the development of physical and emotional exhaustion. #### GENDER DIFFERENCES IN STRESS AND COPING DURING EXECUTION OF A COMPLEX MOTOR TASK

POLMAN, R., KAISELER, M.

FACULTY OF PSYCHOLOGY AND EDUCATIONAL SCIENCES-UNIVERSITY OF PORTO; VICTORIA UNIVERSITY (AUSTRALIA)

Introduction Recent reviews have suggested that male and female athletes might utilize different coping strategies when dealing with stressful encounters (e.g., Nicholls & Polman, 2007). However, due to past methodological limitations, and lack of theory driven studies, it is not clear whether gender differences in coping are due to the appraisal process (role constraint theory- Rosario, Schinn, Morch, & Huckabee, 1988) or actual coping behaviour (dispositional hypothesis- Tamres, Janicki, & Helgeson, 2002). Therefore we investigated gender differences in coping using an experimental paradigm. Method 17 Males and 14 females participants aged between 18 and 45 years old (M age = 23.35 years; SD = 7.30), completed a novel golf task under control and stress conditions. Stress responses were assessed in terms of heart rate, task completion time, and state anxiety. Stress appraisal in terms of nature of stressors and coping was

assessed online using a think aloud protocol. Results Similar stress responses were found for males and females, in terms of increased heart rate, task completion time, and cognitive state anxiety. Significant gender differences in relation to the frequency of stressors cited and the coping strategies used were found. Differences in coping strategies observed between the genders were likely to be a consequence of different stress appraisals, in particular the frequency of the stressors reported. Discussion The findings of the present study provide tentative support for the situational hypothesis theory, as males and females have a tendency to use similar coping strategies if they appraise the same stressors within the same situation. It is recommended that future research investigating gender differences in coping in sport considers stress appraisal to a greater extent. References Nicholls, A. R., & Polman, R. C. J. (2007). ## APPROACH-AVOIDANCE GOALS IN TEAM SPORT ATHLETES': THE PREDICTIVE ABILITY OF THE MOTIVATIONAL CLIMATE

STENLING, A., HOLMSTRÖM, S., HASSMÉN, P.  
*UMEÅ UNIVERSITY*

Introduction: The motivational climate is an important determinant of athletes' achievement goals. The relationship between the motivational climate and athletes' achievement goals is also well examined within the dichotomous achievement goal framework. However, the relationship between the motivational climate and athletes' approach-avoidance achievement goals (Elliot, 1999) is still an unexplored area in competitive sports. The only study to date in competitive sports included the higher order dimensions, mastery and performance climate, not the six underlying dimensions (Morris & Kavussanu, 2008). The purpose of this study was to examine whether motivational climate dimensions can predict team sport athletes' approach-avoidance achievement goals. Methods: 319 team-sport athletes' (males=156, females=163, mean age=20 years, SD=3.6) completed measures of the perceived motivational climate (PMCSQ-2) and approach-avoidance achievement goals (AGQ-S). Hierarchical regression analyses for each of the four achievement goals were performed, while controlling for the effect of age and gender. Two sets of analyses were performed: (1) using the higher order dimensions as predictors; and (2) using the six underlying dimensions as predictors. Results: The first set of analyses showed that mastery-approach goals were positively predicted by a mastery climate; mastery-avoidance goals were positively predicted by a performance climate and also influenced by age and gender; performance-approach goals were positively predicted by a mastery climate and a performance climate; and performance-avoidance goals were positively predicted by a performance climate and also influenced by age. The second set of analyses showed that mastery-approach goals were positively predicted by Effort/Improvement; mastery-avoidance goals were positively predicted by Punishment for Mistakes and also influenced by age and gender; performance-approach goals were positively predicted by Intra-Team Member Rivalry; whereas performance-avoidance goals were only influenced by age. Discussion: These findings indicate differential relationships between the motivational climate dimensions and competitive athletes' approach-avoidance goals. The cross-over effects from social-environmental to individual achievement goals (e.g., that a performance climate predicted mastery-avoidance goals) highlight the need for future research to develop measures addressing both approach and avoidance aspects of the motivational climate. References Elliot, A.J. (1999). Approach and avoidance motivation and achievement goals. *Educational Psychologist*, 34, 169-189. Morris, R. L. & Kavussanu, M. (2008). Antecedents of approach-avoidance goals in sport. *Journal of Sports Sciences*, 26, 465-476.

## EFFECTS OF TYPE-D PERSONALITY ON STRESS APPRAISAL, COPING AND COPING EFFECTIVENESS IN ATHLETES

POLMAN, R., KAISELER, M., BORKOLES, E.  
*VICTORIA UNIVERSITY*

The distressed or Type D personality has received significant attention in the health literature. Type D personality is characterized by high levels of negative affectivity and social inhibition (Denollet, 2005). Type D has been shown to be associated with maladaptive coping patterns. We investigated the role of Type D on the appraisal of a self-selected stressor, coping and coping effectiveness in a sample of athletes. We predicted that Type D athletes would perceive a stressful event with higher levels of stress intensity and lower levels of control. Also, such athletes would use more emotion focused and avoidance coping strategies and would rate these as less effective. Method: Participants were 426 athletes (age 20.21 years; SD = 2.07 years) of which 259 were males and 167 females. The athletes completed a questionnaire pack consisting of demographic information, the DS14 and the modified MCOPE in response to a self-selected stressor. Participants also indicated how stressful they perceived this event to be as well as the control they perceived to have over the event. Results: 28.9% (n = 123) could be classified as having the Type D personality whereas 71.1% (n = 303) was classified as not possessing Type D. The MANOVA for stress appraisal was significant ( $P = .03$ ;  $\eta^2 = .02$ ). Follow-up ANOVA indicated that Type D individuals rated the self selected stressors with higher levels of stress intensity ( $P = .008$ ;  $\eta^2 = .02$ ). However, no difference was found in perceived control ( $P = .74$ ). The MANCOVA (controlling for stress intensity) for coping was significant ( $P < .001$ ;  $\eta^2 = .14$ ). Follow-up ANCOVA showed that Type D individuals were more likely to use Active Planning ( $P < .001$ ;  $\eta^2 = .03$ ), Behavioral Disengagement ( $P < .001$ ;  $\eta^2 = .03$ ), Venting Emotions ( $P < .001$ ;  $\eta^2 = .3$ ), and Wishful Thinking ( $P = .01$ ;  $\eta^2 = .02$ ) but less Seeking Informational Social Support ( $P = .02$ ;  $\eta^2 = .02$ ) and Increasing Effort ( $P < .001$ ;  $\eta^2 = .05$ ). The MANCOVA for coping effectiveness was also significant ( $P = .001$ ;  $\eta^2 = .08$ ). The Strategies which were used less by the Type D individuals were also rated as less effective (SISS  $P = .04$ ;  $\eta^2 = .01$ ; Increasing Effort  $P < .001$ ;  $\eta^2 = .04$ ) whereas the strategies which were reported to be used more by Type D individuals were rated to be rated as more effective except Active Planning. Conclusion: The higher levels of stress intensity for Type D individuals indicate that competing in sport is more stressful for them than non Type D individuals. Also, as predicted, Type D athletes were more likely to adopt coping strategies which are considered maladaptive or less effective to deal with acute stressors in sport. In particular, Type D was associated with more use of avoidance and emotion-focused coping strategies but less problem-focused coping strategies. Although not investigated in the present study this could have consequences for performance and satisfaction. Denollet, J. (2005). DS14: Standard assessment of negative affectivity, social inhibition, and Type D personality. *Psychosomatic Medicine*, 67, 89-97.

**BENEFICIAL EFFECTS OF PSYCHOLOGICAL INTERVENTIONS WITH YOUNG FOOTBALL PLAYERS**

VAISBERG, T.M.J.A., VAISBERG, M.W., FERREIRA-TEIXEIRA, M.C.

PONTIFÍCA UNIVERSIDADE CATÓLICA DE CAMPINAS- BRASIL

**INTRODUCTION** Considering that we live in a country marked by deep social inequalities, where young people dream to become football players expecting to achieve personal success and improvement in life's material conditions, it's necessary to investigate special devices of psychological treatment for the beginner athletes. Based on current research about the psychological conditions of female athletes (Brink, Visscher, Coutts & Lemmik, 2010; Patel, Omar & Terry, 2010; Resch, 2010), we create a program of psychological care according to a psychoanalytic approach (Winnicott, 1996). This program is characterized by the proposition of a large range of playful activities and appreciation of the bonds between athlete, group and psychologist. This research aims to evaluate the clinical efficacy of this program focusing on female soccer players, aged between eighteen and twenty-four years old, who were treated over twenty-eight weeks. **METHODS** For verification of clinical effects, we used two of the "Psychopathological Indicators" (Caligor, Kernberg & Clarkin, 2007) – integration of self and forms of defense against anxiety –, qualitatively considered in two moments: before and after participation in the program. **RESULTS** We observed a significant reduction from baseline athletes' levels of anxiety and also their conducts became more mature throughout the process, showing a value contribution to the strengthening of the tendency of personal integration. **DISCUSSION** The girls showed the use of strategies that have become more mature, gaining access to athletic identity as a very important aspect, but not central in terms of personality. These changes are consistent with improved knowledge in the field of psychoanalytic psychopathology of the self, proving that the psychological care given can be considered clinically effective enabling the personal growth of athletes. **REFERENCES** 1-Brink, MS, Visscher C, Coutts AJ, Lemmink KA. **10:15 - 11:45****Oral presentations****OP-PM42 Muscle: Damage and Recovery****EFFECTS OF FATIGUE ON THE FUNCTIONAL HAMSTRINGS-TO-QUADRICEPS RATIO IN AMATEUR FEMALE SOCCER PLAYERS**

DELESTRAT, A., BAKER, J., CLARKE, N.D.

LONDON METROPOLITAN UNIVERSITY

Epidemiological studies have revealed that females are two to ten times more likely than males to have anterior cruciate ligament (ACL) injuries (4). Among the risk factors for ACL sprains, the imbalance between the strength developed by the hamstrings and the quadriceps, usually calculated as the functional hamstrings-to-quadriceps ratio (Hecc:Qcon, ratio of peak eccentric torque of the hamstrings to peak concentric torque of the quadriceps) has been evidenced as a crucial modifiable parameter (5). In soccer, the high incidence of ACL sprains towards the end of games suggests an effect of fatigue on the strength characteristics of the thigh muscles. However, the effect of soccer-specific fatigue on imbalances of the thigh muscles has only been studied in male players (1,2,3). Therefore the aim of this study was to investigate the effects of fatigue induced by a field test representative of soccer-specific movements on the functional hamstrings-to-quadriceps ratio (Hecc:Qcon) in the dominant and non-dominant legs. Fourteen female soccer players (age, 26.1±4.6 years; height, 168±12 cm; body mass, 62.7±5.5 kg; body fat, 23.7±2.2%) volunteered for this study. They took part in the Loughborough Intermittent Shuttle Test (LIST) to induce fatigue. Isokinetic strength assessments of the hamstrings and quadriceps on the dominant and non-dominant legs at 120°•s<sup>-1</sup> were performed before and immediately after the LIST. Peak torque measurements allowed to calculate Hecc:Qcon. A two-way univariate analysis of variance (ANOVA) was used to assess the effect of time and leg dominance on Hecc:Qcon. The main results showed that the modified LIST led to a significant decrease in Hecc:Qcon in both legs ( $P = .02$ ). However, this decrease was not significantly different between dominant and non-dominant legs (-14.1% vs. -8.0%,  $P = .42$ ). Hecc:Qcon decreases with fatigue, by the same extent in both legs. The decrease in the Hecc:Qcon reflected a greater risk of ACL injuries at the end of soccer games, mainly due to the effects of fatigue on eccentric torques of the hamstrings. This suggests the need to implement screening sessions throughout the season to characterise muscle imbalances in female soccer players. The subjects at risk could then be given a specific strengthening programme focused on eccentric strengthening of the hamstrings. **References** 1. Greig M. *Am J Sports Med*. 2008; 36: 1403-1409. 2. **EFFECT OF SET-REPETITION CONFIGURATION IN ECCENTRIC EXERCISE ON MUSCLE DAMAGE AND REPEATED BOUT EFFECT**

CHAN, R.

EDITH COWAN UNIVERSITY

**EFFECT OF SET-REPETITION CONFIGURATION IN ECCENTRIC EXERCISE ON MUSCLE DAMAGE AND REPEATED BOUT EFFECT** Roy Chan, Michael Newton, Kazunori Nosaka Edith Cowan University (Australia) **Introduction** The number of eccentric contractions is a factor determining the magnitude of muscle damage; however, it is not known if a different set-repetition configuration for the same number of eccentric contractions (e.g. 3 sets of 10 repetitions vs 10 sets of 3 repetitions) would result in different magnitudes of muscle damage. Muscles become

more resilient to damage after a single exercise bout (repeated bout effect) with as little as two maximal eccentric contractions [1], but it is unknown how the repeated bout effect can be minimised or reduced. The present study tested the hypothesis that altering the set-repetition configuration would affect the magnitude of muscle damage and the repeated bout. Methods Ten non-resistance trained men ( $26.1 \pm 4.1$  y) performed two bouts of eccentric exercise of the elbow flexors for each arm (4 bouts in total). One arm performed 3 sets of 10 maximal eccentric contractions (3x10) followed 4 weeks by 20 sets of 3 maximal eccentric contractions (20x3). The contralateral arm performed 10 sets of 3 maximal eccentric contractions (10x3) followed 4 week by the 20x3 exercise. The order of the exercise (3x10,10x3) and the use of arm (dominant, non-dominant) were counterbalanced amongst subjects. Changes in maximal voluntary isometric and concentric contraction strength, range of motion, cross-sectional area using extended-field-of-view ultrasonography technique, muscle soreness and plasma creatine kinase activity for 4 days after the first and second exercise bouts were compared between arms by a two-way repeated measures ANOVA. Results The torque produced over 30 eccentric contractions was similar between the 3x10 and 10x3 bouts, and the changes in torque during the 20x3 exercise were similar between arms. All criterion measures changed significantly ( $P<0.05$ ) after the first and second bouts without significant differences between 3x10 and 10x3, and changes following the 20x3 bout were similar between arms. No significant difference was evident for the changes in any measures between the first and second bouts. Discussion The results showed that the set-repetition configuration had little effect on muscle damage. This was likely due to the same peak torque produced during exercise between the 3x10 and 10x3 bouts. The repeated bout effect was similar between arms, suggesting that the set-repetition configuration in the first bout did not influence the effect. The similar changes in criterion measures between the first and second bouts showed that the repeated bout effect was attenuated by increasing the number of contractions. It is concluded that the number of contractions rather than the set-repetition configuration affect the magnitude of muscle damage and repeated bout effect. References 1. Nosaka K et al. (2001) *Eur J Appl Physiol*, 85, 34-40

### **FAM FREQUENCY RESPONSE METHOD AS A TOOL TO ASSESS MUSCULAR AND PHYSIOLOGICAL RECOVERY AFTER ECCENTRIC EXERCISE**

TANSKANEN, M., PIIRAINEN, J.M., SANTALA, J., KURTTI, K., LINNAMO, V.

UNIVERSITY OF JYVÄSKYLÄ

Introduction Definition of optimal recovery between training sessions is difficult because it depends for example on the type of exercise. After eccentric exercise (EE) the recovery may last for several days. Traditionally the assessment of muscular and physiological recovery requires invasive measurements and laboratory settings. Frequency analysis method (FAM) is a non-invasive tool to measure the recovery of tissue balance after exercise. The purpose of the present study was to examine if the recovery after EE measured by FAM method is related to muscular and physiological recovery. Methods Twelve male subjects ( $28 \pm 6$  yrs, BMI  $23.9 \pm 2.3$ ) performed 45 min of EE at 40% of maximal load with cycling ergometer. Before, 2 hours and 2 days after EE FAM measures, plantar flexion and knee extension maximal force (MVC) and rate of force development (RFD) were performed and blood samples were drawn for serum IL-6, creatine kinase (CK), blood lactate, leukocytes, lymphocytes and neutrophils. FAM sensory -, motor - and pain thresholds were recorded from left and right legs with 10, 50, and 100 Hz stimulations which were then averaged for final analyses. Results EE induced an increase in La ( $1.2 \pm 0.5$  vs.  $2.0 \pm 0.7$  mmol/l,  $p<0.001$ ), CK ( $151 \pm 107$  vs.  $182 \pm 130$   $\mu$ l  $p<0.05$ ) and IL-6 ( $0.9 \pm 2.4$  vs.  $2.4 \pm 1.4$  pg/ml,  $p<0.01$ ) 2h after. Similarly, leukocytes and neutrophils increased ( $p<0.001$ - $0.05$ ) 2h after. Furthermore, 2h after decreases ( $p<0.05$ ) were observed in plantar flexion MVC and RFD and knee extension RFD. After 2d leukocytes, lymphocytes and neutrophils were lower ( $p<0.05$ ) than before EE. FAM values from both legs were higher 2 h after (right  $42.3 \pm 9.1$  vs.  $46.9 \pm 9.3$  mA,  $p<0.05$ ; left  $40.3 \pm 7.9$  vs.  $43.9 \pm 7.8$  mA,  $p<0.001$ ) and were still elevated after 2 days (right  $49.1 \pm 11.2$  mA,  $p<0.05$ ; left  $44.8 \pm 9.8$  mA,  $p<0.05$ ). Relative changes in right leg FAM correlated negatively with relative changes in knee extension RFD ( $r=-0.79$ ,  $p<0.01$ ) 2h after and after 2d positively ( $r=0.70$ ,  $p<0.05$ ) with CK. Conclusion EE led to significant changes in muscular strength and physiological variables measured from blood especially when measured two hours after the exercise. Even though muscle strength had recovered already two days after the exercise this was not the case for several physiological parameters. The recovery after EE assessed by frequency analysis method (FAM) followed the behaviour of muscular and physiological variables such knee extension forces, lactate and CK suggesting that FAM method can be used as a noninvasive technique when evaluating individual recovery after eccentric exercise. Due to large individual variation in recovery the final conclusions should, however, be made with caution.

### **TWO MAXIMAL ISOMETRIC CONTRACTIONS ATTENUATE MAGNITUDE OF ECCENTRIC EXERCISE-INDUCE MUSCLE DAMAGE**

NOSAKA, K., CHEN, H.L., CHEN, T.C.

EDITH COWAN UNIVERSITY

Introduction Muscles become resilient to eccentric exercise-induced muscle damage after performing only a few eccentric contractions [1]. Animal studies [2,3] have shown that isometric contractions also confer this type of protective effect. It is not known whether small number of isometric contractions still produces such effect against maximal eccentric exercise. This study tested the hypothesis that 2 or 10 maximal isometric contractions would attenuate the magnitude of muscle damage induced by 30 maximal eccentric contractions of the elbow flexors performed 2 days later. Methods Thirty-nine untrained men ( $22.5 \pm 1.7$  y) were placed into three groups ( $n=13$  per group) by matching the pre-exercise maximal concentric strength among the groups; two experimental groups and one control group. The subjects in the experimental groups performed either 2 or 10 maximal isometric contractions of the elbow flexors at a long muscle length ( $20^\circ$  elbow flexion) 2 days prior to 5 sets of 6 maximal isokinetic ( $90^\circ$ .s-1) eccentric contractions of the elbow flexors from a flexed ( $90^\circ$ ) to a fully extended angle using the non-dominant arm. The subjects in the control group performed the eccentric contractions without isometric contractions. Changes in isokinetic ( $60^\circ$ .s-1) concentric strength of the elbow flexors, optimum angle, range of motion, upper arm circumference, plasma creatine kinase activity and myoglobin concentration, muscle soreness, and echo intensity of B-mode ultrasound images were assessed before and for 10 days following the eccentric contractions, and compared among the groups by a two-way repeated measures ANOVA. Results The isometric contractions did not result in any changes in the dependent variables, and no significant differences in any of the variables were evident amongst the groups before the eccentric exercise. All dependent variables showed significant ( $P<0.05$ ) changes following the eccentric contractions; however, the changes were smaller ( $P<0.05$ ) for the experimental groups compared with the control group. The changes in the dependent variables after eccentric contractions were smaller ( $P<0.05$ ) for the group that performed 10 maximal isometric contractions compared with the group that performed 2 maximal isometric contractions. Discussion These results suggest that only a few maximal isometric contractions attenuate muscle damage induced by maximal eccentric contractions. It appears that the protective adaptation is induced without any indication of muscle damage, and every

muscle contraction counts for the adaptation. References 1) Nosaka K et al. (2001) Eur J Appl Physiol, 85, 34–40 2) Koh TJ, Brooks SV. (2001) Am J Physiol Regul Integr Comp Physiol, 281, R155–61 3) Pizza FX et al. (2002) J Appl Physiol, 92, 1973–78

### POST-MATCH CHANGES IN NEUROMUSCULAR CONTRACTILE PROPERTIES AS RELATED TO PHYSICAL MATCH DEMANDS IN COMPETITIVE RUGBY LEAGUE.

DUFFIELD, R., MURPHY, A., SNAPE, A., SKEIN, M., MINETT, G.

CHARLES STURT UNIVERSITY

**Introduction** Although a range of time-motion data exists for football codes, these data describe physical movement demands without detailing the presence, development or mechanisms of skeletal muscle fatigue. The aim of this study was to investigate the change in neuromuscular contractile properties following competitive rugby matches and determine the relationship between physical match demands and these neuromuscular changes. **Methods** Ten trained, male rugby league players participated in 2-4, in-season, competitive home matches (n=30). Prior to, immediately following (within 15-min) and 2 h post-match, players performed isokinetic tests on the right knee extensors for maximal voluntary (MVC) and evoked force (VA) and twitch contractile properties; including peak twitch force (Pt), rate of torque development (RTD) and relaxation rate (RR). During each match, players wore 1Hz Global Positioning Satellite (GPS) devices to record distance and velocity of movement. GPS data was analyzed based on classification as low-intensity activity (LIA;<14km/h), high-intensity running (HIR;>14km/h) and very-high intensity running (VHIR;>20km/h). Further, each match was filmed and coded for number of tackles and collisions. Changes in neuromuscular properties were assessed with a repeated measures ANOVA; while Pearson's correlation coefficient analyses assessed the association between neuromuscular properties and match physical demands. **Results** Mean±SD total distance, LIA, HIR, VHIR and relative distance covered were 5785±1078m, 5023±935m, 761±265, 216±121m and 75±14m/min, respectively. Mean MVC was significantly reduced immediately and 2 h post-match by 9±15 and 12±16% respectively (P<0.05). Moreover, twitch contractile properties indicated a suppression of Pt, RTD and RR both immediately and 2h post-match (P<0.05). However, VA was not significantly altered from pre-match (90±6%), either immediately (89±10%) or 2h post (88±8%) (P>0.05). Correlation analyses indicated that total playing time (r=-0.50) and relative distance (r=-0.40) were related to the change in post-match MVC. However, total distance, LIA, HIR, VHIR and tackle count were not correlated with change in voluntary force (r<0.10). **Conclusion** The present study highlights that the physical demands of competitive rugby league result in a post-match suppression of voluntary force and skeletal contractile function, without significant alterations to voluntary activation. Further, post-match suppression of voluntary force may be partially associated with the time spent on field and the relative distance covered during the match (m/min), respectively.

### VARIATIONS IN PAIN PERCEPTION AFTER AN EXHAUSTIVE EXERCISE

GRAINER, A.1, ANCHISI, D.2, MEGIGHIAN, A.1, ZANON, M.2, PAOLI, A.1, ANGELI, A.2, AGNOLET, R.2, GREMESE, M.2, REG-  
GIANI, C.1

1: UNIVERSITY OF PADOVA, DEPARTMENT OF HUMAN ANATOMY AND PHYSIOLOGY 2: UNIVERSITY OF UDINE, DEPARTMENT OF MEDICAL AND BIOLOGICAL SCIENCES

**Introduction** Pain perception modulation induced by physical exercise is relevant for exercise physiology, sport medicine, and clinical practice. For example an increase in pain perception may result in a interruption of exercise, while its reduction may contribute to improve mood, motivation and Rate of Perceived Exertion (RPE). The issue has been widely investigated with controversial results. Increase in pain perception threshold has been reported after exercises with both external and internal load. In contrast, the use of animal models has shown a positive relation between hyperalgesia and exhausting exercises. What seems to emerge from these studies is that a number of factors are involved in the exercise related pain modulation, such as different types and intensities of exercise, and age, gender, health and food intake of the subject. Also the mechanism of this kind of pain modulation is still under study. **The study** Subjects (age 22±1, sex M) all in a good state of physical fitness, were invited to pedal to exhaustion with power increasing in steps of 20 W every minute, starting from the power of 80W to activate aerobic metabolism (4 minutes). Pain threshold was measured both before the physical exercise and at exhaustion. Pressure stimuli were delivered to the left hand of the subjects through a plastic or metal point, at intervals of 30 s for 4 minutes. Pressure was measured by means of a load cell and, to identify pain threshold, it was constantly increased during each trial of stimulation until the subject reported pain. **Results** The first results point to a high inter-individual variability in perception of pain threshold. The threshold increased at the end of the exercise suggesting a reduced pain perception and quickly decreases during the first minutes of the recovery phase. **References** Sakamoto A, Maruyama T, Naito H, Sinclair PJ. ### OP-PM25 Nutrition: Supplementation

#### MICRONUTRIENT INTAKE OF YOUNG ELITE GERMAN ATHLETES

BRAUN, H., KOEHLER, K., MESTER, J., THEVIS, M., SCHAEZNER, W.

GERMAN SPORT UNIVERSITY COLOGNE, GERMANY

**Introduction** A balanced, varied nutrition with respect to individual needs (e.g. age, gender, training and season phase) can make a positive difference in an athlete's ability to train and compete and will contribute to good health (IOC Medical Commission). However, limited research on the nutrition requirements of young athletes exists (Meyer et al., 2007). Despite this, studies on nutritional status of young athletes in particular with respect to the intake of micronutrient are rare. Therefore the aim of the present study was to evaluate the nutritional status of young athletes with special focus on micronutrient intake. **Methods & Subjects** Between March 2007 and August 2010, 303 young athletes between 13 and 18 years of age reported their diet using a validated 7-d food and activity record (KoeHLer et al. 2010). Energy Intake (EI) and Micronutrient intake was estimated based on the German food database (Bundeslebensmittelschlüssel II.3) using Ebispro Software. Energy expenditure (EE) was calculated based on the activity record. The present study includes data from 151

male ( $15.6 \pm 1.6$  y,  $69.9 \pm 14.9$  kg,  $179 \pm 11$  cm,  $100 \pm 47$  min/day (training)) and 152 female ( $15.4 \pm 1.3$  y,  $58.3 \pm 9.2$  kg,  $168 \pm 8$  cm,  $104 \pm 59$  min/day (training)) athletes from 28 different sports. Results Based on the German recommended daily allowances (RDA), mean intake of vitamin D (males (m):  $2.0 \pm 1.6$  µg; females (f):  $1.9 \pm 2.7$  µg) and folic acid (m:  $313 \pm 112$  µg; f:  $249 \pm 88$  µg) was systematically below recommendations in both male and female athletes. Additionally at least half of the female group did not reach the RDA for panthotenic acid (80%), vitamin B12 (58%), iron (68%), calcium (56%), potassium (52%). Mean Energy intake (EI) for males was  $2970 \pm 833$  kcal ( $43.5 \pm 12.2$  kcal/kg bw) and for females  $2263 \pm 673$  kcal ( $39.6 \pm 12.6$  kcal/kg bw) and matched EE by  $92 \pm 22\%$  (m) and  $89 \pm 25\%$  (f). Discussion In the present study, a wide range of athletes did not meet the RDA for selected micronutrients. Vitamin D and folic acid are identified as the most critical micronutrients according to intake. Since individual requirements are not known, this does not imply an inadequate status. However, it indicates that the individual dietary intake of some micronutrients in young German athletes may be low for some individuals and more so in female athletes than in male. Therefore more individual nutritional education and consulting are necessary to improve diet quality. References Meyer F., O'Conner H., Shirreffs S. (2007). ## THE EFFECTS OF EXERCISE AND DIET COMPOSITION OF DIET-INDUCED OBESE MICE ON EXPRESSION OF MCP-1 AND OXIDATIVE STRESS-RELATED MRNA OF ADIPOSE TISSUE

KIM, K., KO, J., AHN, N., KIM, J., BYUN, J., HONG, C., JOO, Y., KIM, H., CHANG, I., PARK, J.

KEIMYUNG UNIVERSITY

THE EFFECTS OF EXERCISE AND DIET COMPOSITION OF DIET-INDUCED OBESE MICE ON EXPRESSION OF MCP-1 AND OXIDATIVE STRESS-RELATED mRNA OF ADIPOSE TISSUE Kim, K.I, Ko, J.I, Ahn, N.I, Kim, J.I, Byun, J.I, Hong, C.I, Joo, Y.I, Kim, H.I, Chang, I.I, Park, J.I 1: KMU (Daegu, Korea), 2: KMC (Daegu, Korea), 3: CUD (Daegu, Korea), 4: GJU (Gyeongsangju, Korea) Introduction The subjects with long term and regular exercise showed lower oxidative stress than those without exercise, and this has been proposed to be caused by the increase of endogenous antioxidants, such as Mn-SOD and GPX. Research, particularly on the antioxidant effects of exercise to effectively reduce MCP-1, which induces the inflow of macrophage into adipose tissue, is insufficient. Therefore, the purpose of this study is to analyze how a high-fat diet, diet composition change, and long term exercise on C57BL/6 mice influence the expression of MCP-1, HIF-1α, NOX2, ERK1&2, and Mn-SOD mRNA of white adipose tissue (WAT). Methods Obesity is induced using a high-fat diet (45% fat) for five weeks, and this research analyzed how the change of diet composition for eight weeks and long-term exercise training affected the expression of mRNA in epididymal WAT. For the experiment, 56 four-week-old C57BL/6 mice were used. Their epididymal WAT was extracted and used in real time (RT)-PCR analysis to find the expression level of mRNA. Results A high-fat diet for 13 weeks showed a significant increase in the expression of MCP-1, HIF-1α, NOX2, and ERK1 mRNA in epididymal adipose tissue. Change of diet composition and exercise decreased the expression of MCP-1, HIF-1α, NOX2, and ERK1 mRNA. Particularly, the group combining a high-fat diet and exercise had a significant increase in the expression of Mn-SOD mRNA in epididymal adipose tissue; however, it had a significant decrease in MCP-1, HIF-1α, and NOX2. Discussion This study shows that mice treated by both a high-fat diet and exercise treatment have a significant decrease in MCP-1 mRNA. In the MCP-1 mRNA increased tissue, it can be estimated that the accumulation of macrophage is increased due to the pivotal role of MCP-1 in mobilizing macrophage into obese adipose tissue (Weisberg et al., 2003). Regular exercise and diet composition change can reduce the accumulation of macrophage influencing the expression of inflammatory genes in WAT. Mn-SOD increased in WAT has a high possibility of making MCP-1 expression reduced by ROS reduction rather than weight loss. Antioxidant effects and improvement of hypoxia through exercise can significantly reduce the expression of MCP-1 in WAT (Sakurai, et al., 2009). This result means that the independent antioxidant effect of exercise decreased inflammation and oxidative stress. References Sakurai T, Izawa T, Kizaki T, Ogasawara J, Shirato K, Imaizumi K, et al. ## THE EFFECTS OF CAFFEINE INGESTION ON POWER OUTPUT DURING INTERVAL TRAINING COMMENCED WITH NORMAL OR LOW MUSCLE GLYCOGEN CONTENT

LANE, S.I, COFFEY, V.I, ARETA, J.I, BIRD, S.I, HAWLEY, J.I

RMIT UNIVERSITY

Introduction: Commencing selected training sessions with low muscle glycogen content augments several markers of training adaptation compared to undertaking the same sessions with normal (or high) glycogen availability (Hansen, et al., 2005; Yeo, et al., 2008). However reduced glycogen availability also reduces the capacity to perform high intensity workouts (Yeo, et al., 2008) which are crucial to promoting training adaptation. Hence, the aim of this study was to investigate whether caffeine, a proven ergogenic aid, could 'rescue' part of the deleterious effects on self-selected power output previously observed when individuals commenced high intensity interval training with low compared to normal glycogen availability (Yeo, et al., 2008). Methods: Twelve endurance trained cyclists/triathletes performed four trials according to a double blind randomised Latin square crossover design. Prior to each trial muscle glycogen content was manipulated using standardised exercise-diet manipulations to ensure two trials were commenced with reduced (LOW) or normal (HIGH) muscle glycogen content. Sixty minutes prior to the experimental trials (8 x 5 min at maximal self selected intensity; HIT) subjects ingested an opaque capsule containing anhydrous caffeine (CAFF; 3 mg/kg.bm) or a placebo capsule (PLBO). Mean power output (MPO) was monitored during each performance trial along with blood caffeine, glucose, and lactate concentrations. Results: There was a significant main effect for both pre-exercise glycogen content and caffeine ingestion on MPO ( $P < 0.05$ ). Caffeine increased power output by 2.8% and 3.5% in both HIGH and LOW trials respectively. Commencing HIT with low muscle glycogen availability reduced MPO for both LOW-CAFF and LOWPLBO trials by 8.1% and 8.6% when compared to their respective HIGH trials. Conclusions: Performing high intensity interval training with reduced muscle glycogen significantly reduces self selected MPO. However, caffeine (3 mg/kg) administered 60 min prior to exercise enhances power output independently of muscle glycogen concentration. Hansen, A. K., Fischer, C. P., Plomgaard, P., Andersen, J. ### OP-PM17 Training and Testing: Performance Testing

#### ESTABLISHING REFERENCE RANGES FOR THE YO-YO INTERMITTENT RECOVERY TEST IN JUNIOR RUGBY LEAGUE

PYNE, D.B., HIGHAM, D.G.

AUSTRALIAN INSTITUTE OF SPORT

**Introduction** The Yo-Yo Intermittent Recovery Level 1 (Yo-Yo IRI) test is well established as a field-based measure of endurance fitness (Bangsbo et al. 2008). Endurance capacity is considered an important attribute of fitness in rugby league (Gabbett et al. 2008). However there are no published reference ranges for this test in junior rugby league players for different playing positions or information on magnitudes of variability. The aim of this study was to analyse a large representative set of Yo-Yo IRI test scores in junior rugby league players and establish position-specific reference ranges. **Methods** A total of 759 Yo-Yo IRI tests were conducted at the Australian Institute of Sport on male junior rugby league players (age  $16.8 \pm 0.6$  y) over a seven year period. Player's performances were categorised according to their normal playing position: prop forward (n=121), back row (n=289), halves (including the hooker, n=150), and outside backs (n=189). **Results** The mean, standard deviation and coefficient of variation of Yo-Yo IRI test scores were: all players ( $17.1 \pm 1.2$  levels, 7.0%); prop forward ( $16.2 \pm 1.2$ , 7.4%), back row ( $17.1 \pm 1.1$ , 6.4%), halves ( $17.7 \pm 1.7$ , 6.8%) and outside backs ( $17.1 \pm 1.0$ , 5.8%). Test scores for prop forwards were substantially lower than other positions. Variability was substantially lower for the outside backs compared with the prop forwards (ratio of %CV=1.27). **Discussion** The substantial differences in Yo-Yo IRI test scores between different playing positions in rugby league is similar to other sports (Ben Abdelkrim et al. 2010). The mean and standard deviation can be used directly to establish a reference range (showing levels or metres) for each playing position – assuming a normal distribution the approximate range for each group is estimated as the mean score  $\pm 2$  standard deviations. The larger variability and lower mean Yo-Yo IRI test score for prop forwards reflects their poorer endurance fitness. These data should be useful for rugby league coaches and researchers interested in fitness characteristics, and determining magnitudes of improvement in endurance needed from specific training interventions. **References** Bangsbo J, Iaia FM, Krstrup P. #### RELIABILITY AND VALIDITY OF EXPLOSIVE PUSH-UP POWER TEST

MARKOVIC, S., RADONJIC, V., KOPRIVICA, V., MIRKOV, D.

FACULTY OF SPORT AND PHYSICAL EDUCATION

**Reliability and Validity of Explosive Push-Up Power Test** Markovic, S.I, Radonjic, V., Koprivica, V.I, Mirkov, D.I 1: Faculty of Sport and Physical Education, University of Belgrade (Serbia) **Introduction** Successful performances in sports often require high power output movements of both the upper- and lower-extremities. The assessment of muscular power is essential for understanding the performance capacity of an individual (Newton et al, 1997). Because of limitations of various tests for upper-body power assessment, we developed a simple test based on push-up movements that requires the same equipment as the standard maximum jumping tests (i.e., either a contact mat or a contactless mat with infrared beams). The aim of this study was to establish reliability and validity of the novel test for the assessment of upper-body power. **Methods** Nineteen male junior basketball players (national junior team) performed explosive push-up power test (EPPT) for height, chest pass (CP) and bench press throw (BPT) with loads of 40, 60 and 80% of 1RM. The chest pass and bench-press throw were used as criterion measures. **Results** The maximal height of the explosive push-up test (data averaged across three consecutive trials) were 19.8 cm, 19.0 cm and 19.4 cm, respectively, and no significant differences among them were found. The intraclass correlation coefficient revealed 0.994. Coefficient of variation of 6.2% suggested a low intra-subject variability. Concerning the validity of the evaluated test, significant correlations were obtained between the height in EPPT and distance in CP ( $r=0.51$ ) and the maximal power in BPT with all of the applied loads (0.69, 0.72, 0.70, respectively, for 40%, 60% and 80% of 1 RM). The highest correlation of the evaluated test was obtained with maximal power in BPT ( $r=0.73$ ). **Discussion** In general, when studying sport specific abilities, the development of the assessment tools is of particular concern. The evaluation of upper-body power may be accomplished through a multitude of assessment techniques or tests, like chest pass or bench press throw (Cronin and Owen, 2004). High intraclass correlation, low intra-subject variability and high correlations between trials (Hopkins, 2000) and significant correlations with criterion measures, suggest that the evaluated explosive push-up test could be a valid and reliable test for the upper-body power assessment. Taking also into account its simplicity and cost-effectiveness, the explosive push-up test could provide coaches and strength and conditioning professionals important information concerning both the individual abilities and the choice of training programs. **Acknowledgment:** This study was supported in part by a grant #175037 from the Serbian Research Foundation. **References** Newton RU, Murphy AJ, Humphries BJ, Wilson GJ, Kraemer WJ and Hakkinen K (1997). #### HIGH-INTENSITY INTERMITTENT RUNNING PERFORMANCE IN RELATION TO AGE AND MATURATION IN HIGHLY-TRAINED YOUNG SOCCER PLAYERS

BUCHHEIT, M., SIMPSON, B.M., MENDEZ-VILLANUEVA, A.

ASPIRE

**Introduction** The aim of the present study was to examine high-intensity intermittent running performance in highly-trained young soccer players with regard to age and selected physical performance variables. **Methods** Twenty-seven Under 14 ( $13.0 \pm 0.7$  y;  $-3.1$  to  $0.3$  y to/from age at peak height velocity (PHV),  $154.7 \pm 9.7$  cm;  $41.5 \pm 7.2$  kg), 19 U16 ( $14.9 \pm 0.5$  y;  $-0.1$  to  $2.0$  y from PHV,  $169.2 \pm 7.4$  cm;  $56.8 \pm 9.1$  kg) and 16 U18 ( $16.7 \pm 0.8$  y;  $1.0$  to  $2.9$  y from PHV,  $171.2 \pm 5.9$  cm;  $61.1 \pm 6.8$  kg) highly-trained soccer players performed an incremental running test to estimate maximal aerobic speed (MAS), an incremental intermittent running test (straight-line version of the 30-15 Intermittent Fitness Test, Buchheit, 2008) to estimate maximal intermittent running performance (VIFT) and a 40-m sprint with 10-m splits to estimate maximal sprinting speed (MSS). Anaerobic speed reserve (ASR) was calculated as MSS – MAS. The difference between VIFT and MAS was used as a specific index of intermittent effort ability (IINT, km/h). **Results** There was no correlation between IINT and any of the physical performance, anthropometric or maturation-related variables. There was no age-group difference in IINT ( $19.0 \pm 5.3$ ,  $18.8 \pm 5.1$  and  $19.1 \pm 2.9$  % of MAS for U14, U16 and U18, respectively,  $P = 0.98$ ), even after adjustments on either age from PHV or ASR. MAS and VIFT were largely correlated for each age group:  $r = 0.66$ , 90% CL (0.41-0.89),  $0.73$  (0.48-0.87) and  $0.87$  (0.70-0.95) for U14, U16 and U18,

respectively. Discussion The lack of association between INT and any of the selected variables confirms that INT could be used as a specific index of intermittent effort ability. However, there was no difference in INT between the three groups, which contrasts with the idea that the younger, the better the ability to repeat high-intensity exercise (Ratel et al. 2006). The fact that the expected maturation/age differences in inter-effort recovery capacities (Ratel et al. 2006) did not translate into different INT values could however be related to the particular training background of our players (Mendez-Villanueva et al. 2011). We also observed that the strength of the correlation between MAS and VIFT increased with age. While in the older players, cardiorespiratory function is likely the major determinant of maximal intermittent running performance, the performance of the younger players is more likely explained/confounded by other parameters (e.g., motor coordination and stride patterns during the intervals at higher running speeds). References Buchheit M. (2008). J Strength Cond Res, 22(2):365-74. Ratel, S., Duché, P., Williams, C.A. (2006). Sports Med, 36(12):1031-65. Mendez-Villanueva, A., Buchheit, M. ### **PEAK TORQUES OF THE QUADRICEPS AND HAMSTRING MUSCLES OF PROFESSIONAL SOCCER PLAYERS PARTICIPATING IN DIFFERENT LEVELS.**

PARPA, K., MICHAELIDES, M., HADJICHARALAMBOUS, M.

UNIVERSITY OF NICOSIA-CYPRUS

Parpa, M.I., Koulla, Michaelides, A.I., Marcos, Hadjicharalambous, P.I., Marios. 1: University of Nicosia (Nicosia/Cyprus). Introduction Muscular strength is considered to be an important component of exercise performance in soccer players. The purpose of the present study was to examine the peak torques of the quadriceps (Q) and hamstring muscles (H), and their torque-ratio (H/Q) in professional soccer players competing in different league divisions. Methods Sixty participants of the 1st (n=14), 2nd (n= 20), 3rd (n= 16) and 4th (n=11) divisions were evaluated at slow velocities (60 degrees.sec<sup>-1</sup>) using an isokinetic dynamometer. Results It was found that players of the 1st division produced significantly greater torques in both the right and left Q compared with the players of the other divisions (F (57)=3.16, p<0.05 and F (57)=2.83, p<0.05 for right and left Q respectively). No significant differences were observed in H torques or H/Q ratio among the players of different divisions. Players participating in the 1st division demonstrated that the H/Q ratio for the right leg (M=64.78 ± 5.56) was closer to the "optimal ratio" (63%) compared with players of other divisions (M=68.90±8.37, 69.19±9.40 and 72.18±7.01 for divisions 2nd, 3rd and 4th respectively). Discussion It is concluded that players of the 1st division have stronger quadriceps but not stronger hamstring muscles, in terms of peak isokinetic torque production compared with the players of the 2nd, 3rd and 4th divisions. Isokinetic evaluation of the lower extremities may provide the coaching team with valuable evidence regarding potential asymmetries between Q and H that may progressively contribute in performance deterioration and increase the risk of muscle injuries development but this asymmetry may be eliminated by incorporating the appropriate training into the habitual exercise routines of soccer players.

### **THE EFFECT OF A SOCCER-SPECIFIC NEUROMUSCULAR TRAINING PROGRAM ON STABILITY, AGILITY AND INJURY OCCURRENCE IN ELITE YOUTH SOCCER PLAYERS**

BORGHUIS, A.J.

UNIVERSITY MEDICAL CENTER GRONINGEN

THE EFFECT OF A SOCCER-SPECIFIC NEUROMUSCULAR TRAINING PROGRAM ON STABILITY, AGILITY AND INJURY OCCURRENCE IN ELITE YOUTH SOCCER PLAYERS Borghuis, A.J., Lemmink, KAPM.1,2, Hof, A.L., Visscher, C.I. 1: Center for Human Movement Sciences, University Medical Center Groningen, University of Groningen, Groningen, the Netherlands 2: School of Sports Studies, Hanze University of Applied Sciences, Groningen, the Netherlands Introduction Various studies have investigated the injury-preventive and performance-enhancing effect of neuromuscular training programs (NMTP's), showing varying results. To get insight into the underlying mechanisms, research should focus on the influence of these training programs on improving stability. Therefore, the main aim of this study was to investigate the effect of a soccer-specific NMTP on improving whole-body and core stability in elite youth soccer players. Besides, the effect of such an intervention on agility and injury occurrence was evaluated. Methods In this group-randomized controlled intervention study, 90 elite youth soccer players (ages 10-16) were team-randomized into an intervention (INT) and control (CON) group. The INT group performed a 15 min NMTP on average twice a week for 23 weeks. Prior to, during and after the intervention, all players performed a standing balance task to measure whole-body stability, two sitting balance tasks to measure core stability and a slalom sprint test to measure agility. New non-contact time-loss injuries sustained during the intervention period were recorded. Repeated Measures ANOVA's were conducted to find any differences between INT and CON on the stability and agility test results. Possible differences in injury severity were evaluated using a Mann-Whitney U test. Results Relevant trends were found in the data, indicating a positive effect of the NMTP on standing balance capacity, reactive core stabilizing control and slalom sprint performance in the elite youth soccer players. Results of the Repeated Measures ANOVA's indicated no significant differences in improvement on the stability and agility test results between INT and CON. With respect to injury, no significant difference in incidence or severity was found between both groups. Discussion Based on the positive trends in the data, further research is recommended to further elucidate the effect of the soccer-specific NMTP on improving stability. In the present group of highly trained elite youth soccer players, the small differences found between INT and CON can be very important for a successful career. To amplify the positive effect of the NMTP, the volume and intensity of the exercises should be increased and exercises should be performed on a regular and continuous basis. Furthermore, measurement instruments can be made more sensitive and it would be interesting for future research to study the effect of the NMTP in lower level or female athletes.

### **AGE-RELATED DIFFERENCES IN SPRINTING SPEED AND THE ABILITY TO CHANGE DIRECTION IN HIGHLY-TRAINED YOUNG SOCCER PLAYERS**

MENDEZ-VILLANUEVA, A., SIMPSON, M.B., BUCHHEIT, M.

ASPIRE, ACADEMY FOR SPORTS ACADEMY

Introduction This study investigated age-related differences in the relationships among straight line sprinting speed and the ability to change direction in 71 highly-trained young male soccer players (U14; n=31, U16; n=23 and U18; n= 17). Methods Players were tested for 20-m sprint (straight line sprinting speed) and the ability to change direction (20-m course with 2 10-m sections set out at 90° angle) times. The results of the ability to change direction test were expressed as a percentage of the straight sprinting time over 20-m. A lower percentage (i.e., a smaller relative increase in the ability to change direction test running time) was interpreted as a higher ability to change direction. Results There was age-based differences in 20-m sprint time (3.39 ± 0.16, 3.10 ± 0.11, 2.97 ± 0.07 s for U14, U16 and U18, respectively) and the ability to change direction (33.2 ± 3.7, 38.0 ± 5.6, 42.4 ± 4.6 % of 20-m sprint time, respectively). Straight line

sprinting speed and the ability to change direction were positively correlated for each age group:  $r = 0.81$  90% confident limits (0.63-0.90), 0.45 (0.00-0.71) and 0.25 (-0.29-0.63) for U14, U16 and U18, respectively. Discussion In highly-trained young soccer players, the magnitude of decreases in locomotor speed associated with turning increased with age. This suggests that developing soccer players trade-off the ability to change direction against straight line sprinting speed as growing older. We also observed that the strength of the correlation between straight line sprinting speed and the ability to change direction decreased with age. This loss of linearity in the older groups suggests substantial differences in individual performances with fast individual showing good ability to change direction and vice versa. Future studies should look at the potential factors explaining these individual differences in older players.

### OP-PM19 Cardiovascular: Stem Cells

#### ACTIVITY STATUS OF RESIDENT ADULT CARDIAC STEM CELLS DETERMINES THEIR STEM CELL PROPERTIES AND GROWTH KINETICS

SMITH, A.J.1, ELLISON, G.M.1, WARING, C.D.1, PURUSHOTHAMAN, S.1, NADAL-GINARD, B.1, TORELLA, D.2,1

1LIVERPOOL JOHN MOORES UNIVERSITY, 2MAGNA GRAECIA UNIVERSITY

**Introduction:** The identification of a small population of stem cells resident in the adult mammalian heart, with robust regenerative capacity, indicates the potential to develop new strategies using these cells for cardioprotective and regenerative purposes. Exercise training results in resident cardiac stem cell (eCSC) activation, multiplication and differentiation into the cardiomyocyte and endothelial lineages, which results in new cardiomyocyte and capillary formation, respectively. Here we compared the properties and growth kinetics of quiescent eCSCs with activated eCSCs in vitro. **Methods:** To induce tissue damage and resultant eCSC activation, 5mg kg<sup>-1</sup> Isoproterenol (ISO) was injected (s.c.) into 2-month-old adult Wistar rats (~250g). Saline was injected as control (CTRL; quiescent eCSC group). c-kitpos CD45neg eCSCs were isolated by retrograde coronary enzymatic perfusion, 24 hours post-ISO or saline injection. Quiescent and activated eCSCs were analysed for number, proliferative markers, multipotency genes, growth kinetics, clonogenicity and proliferation index using flow cytometry, immunocytochemistry, qRT-PCR, real time lapse cell culture imaging, and BrdU incorporation assay, respectively. **Results:** ISO-induced injury significantly ( $P < 0.05$ ) increased c-kitpos eCSC number ( $22 \pm 2\%$  of the CD45neg small cardiac cell population, compared to  $8 \pm 2\%$  in controls). Most of these cells were actively proliferating, being 62% Ki67 positive, compared to only 10% Ki67 positive in the quiescent CTRL eCSCs. Activated c-kitpos eCSCs showed increased clonogenicity ( $24 \pm 4\%$  vs.  $2 \pm 4\%$ ), cardiosphere formation and proliferation, measured by BrdU incorporation over 48 hours in culture ( $32 \pm 8\%$  vs.  $5 \pm 2\%$ ). Furthermore, activated and quiescent c-kitpos eCSCs showed differential multipotency gene expression. **Conclusion:** Activated c-kitpos CD45neg eCSCs show enhanced stem cell properties and growth kinetics, compared to quiescent c-kitpos CD45neg eCSCs, in vitro. These data imply that pre-activation of stem cells could improve their cardioprotective and regenerative ability. Identifying factors that influence the activation of eCSCs and the maintenance of this state is of paramount importance for the design and optimisation of cardiac regenerative therapies.

#### EXERCISE-INDUCED UP-REGULATION OF MYOCARDIAL GROWTH FACTORS DIFFERENTIALLY GOVERN RESIDENT CARDIAC STEM CELL BIOLOGY AND FATE

WARING, C.D.1, SMITH, A.J.1, NADAL-GINARD, B.1, TORELLA, D.2,1, ELLISON, G.M.1

1LIVERPOOL JOHN MOORES UNIVERSITY, 2MAGNA GRAECIA UNIVERSITY

**Introduction:** The adult mammalian heart was traditionally viewed as a post-mitotic organ. Increased cardiac mass and contractility following exercise training was thought to occur through physiological hypertrophy of existing myocytes. On the contrary, we have shown that intensity-controlled treadmill exercise training increases myocardial mass through both myocyte hypertrophy and hyperplasia in the rat. The latter is due to activation, proliferation and associated differentiation of the resident (endogenous) c-kitpos cardiac stem cells (eCSCs). Here we elucidated the mechanism of these adaptations and specifically the role of myocardial growth factors, up-regulated with exercise training, in governing myocyte and c-kitpos CSC fate in vitro. **Methods:** To this aim, 9 male Wistar rats (~230g) were exercised at 80-85% of their VO<sub>2</sub> max for 30min/day 4 days/wk for up to 2 weeks. Untrained rats acted as age matched sedentary controls (CTRL). CTRL animals were sacrificed at day 0 while exercised animals were sacrificed at 3, 7 and 14 days ( $n=3$ /time point), and expression of an array of 26 different growth factors and cytokines in isolated myocytes was determined by quantitative RT-PCR analysis. From another 3 CTRL rats, c-kitpos CSCs and myocytes were isolated by coronary retrograde enzymatic perfusion. The effects of the growth factors identified in the qRT-PCR gene array as being significantly elevated above CTRL were determined on myocyte proliferation, c-kitpos CSC proliferation, clonogenicity and differentiation in vitro. **Results:** High intensity treadmill exercise training significantly ( $P < 0.05$ ) up-regulated myocyte expression of IGF-1 ( $+0.4 \pm 0.1$ , fold increase over CTRL), TGF- $\beta$ 1 ( $+0.5 \pm 0.1$ ), Periostin ( $+1.6 \pm 0.2$ ), Neuregulin-1 ( $+1.8 \pm 0.3$ ) and BMP-10 ( $+4.3 \pm 0.7$ ), compared to sedentary CTRL. Supplementation of these growth factors to c-kitpos CSCs revealed differential roles on c-kitpos CSC proliferation, clonogenicity and differentiation. Specifically, IGF-1 enhanced c-kitpos CSC proliferation, while TGF- $\beta$ 1 promoted differentiation of c-kitpos CSCs into the myocyte lineage. Furthermore, none of these growth factors promoted myocyte proliferation in vitro. **Conclusion:** The adaptive response of the adult heart to exercise-induced physiological stress depends on the hypertrophy and hyperplasia of its myocyte population. The latter is specifically dependant on the exercise-induced increase in myocardial growth factor expression which acts upon c-kitpos eCSCs to result in increased myocyte number.

#### C-KIT-POSITIVE CARDIAC STEM CELLS REPLENISH ADULT MAMMALIAN CARDIOMYOCYTES DURING CARDIAC ADAPTATION TO EXERCISE TRAINING

VICINANZA, C., GEORGINA, G.M., LEONE, A., AQUILA, I., IACONETTI, C., BOCHICCHIO, A., GALUPPO, V., INDOLFI, C., NADAL-GINARD, B., TORELLA, D.

MAGNA GRAECIA UNIVERSITY OF CATANZARO, CATANZARO, ITALY

**Introduction** It is widely accepted that regular exercise impacts favorably cardiovascular diseases. Traditionally, it has been considered that exercise improves cardiac function by increasing myocardial mass and contractility through physiological hypertrophy of existing myocytes. Recent data on myocardial cell homeostasis and the identification of cardiac stem-progenitor cells (CSCs) in the adult mam-

malian heart could challenge this concept. Indeed, we have recently demonstrated that c-kit positive cardiac stem cell (c-kitposCSC) activation and new myocyte formation contributes to left ventricular physiologic remodeling induced by exercise training. However, the key issue of a precursor(CSCs)-product(new cardiomyocytes) relationship in vivo cannot be accurately ascertained from these experiments. Thus, in the present study, we sought to assess whether new myocyte formation during exercise training is the direct progeny of the activation of the endogenous resident c-kitpos CSCs. Methods: C57/BL6 mice underwent a program of controlled swimming and were sacrificed at different time points over 28 days. Untrained mice acted as sedentary controls. To track new myocardial generation, BrdU was daily administered i.p. At different time points, the animals were sacrificed and their hearts processed for CSC isolation or immunohistochemistry and confocal microscopy analysis. To ascertain c-kitposCSCs→new myocytes (BrdUpos) relationship, a lentiviral vector carrying Cre-Recombinase under the control of the c-kit promoter (Lenti-c-kit/Cre) or a lentiviral empty vector (control) were myocardially released in male LacZ floxed-stop YFP mice (B6.129X1-Gi(ROSA)26Sortm1(EYFP)Cos/J mice, which carry a floxed 'stop' signal to YFP expression). This strategy permanently labels c-kitpos CSCs and allows to track their cell fate. Seven days following Lenti-c-kit/Cre or lenti-empty injections, mice underwent the 28 day program of swimming exercise. Results: Transcription of GATA-4 and Nkx2.5 progressively increased in the c-kitpos/CD45neg CSCs over the 28 day exercise protocol, showing rapid activation of a myogenic differentiation pathway in CSCs during exercise training. Accordingly, RT-PCR also showed increased transcription over time of contractile protein genes (beta-MHC, c-Actin, cTnI) in c-kitpos/CD45neg CSCs from swimming animals but not in the sedentary controls. The activation and differentiation of CSCs through exercise training was followed by an increased number of small newly-formed myocytes (BrdUpos). Importantly, through the genetic fate-mapping strategy based on cre/lox recombination in vivo, we demonstrated that all new myocyte formation during exercise training was the direct progeny of c-kitpos CSC differentiation. Discussion: Exercise training results in adult myogenesis in the physiologically-conditioned mouse heart. The latter process is directly due to the activation and ensuing differentiation of resident c-kitpos CSCs into newly-formed myocytes.

### THE EFFECTS OF GATA4 GAIN AND LOSS OF FUNCTION ON ENDOGENOUS CARDIAC STEM CELL BIOLOGY AND RE-GENERATIVE POTENTIAL

IMPEY, S., SMITH, A., NADAL-GINARD, B., TORELLA, D., ELLISON, G.

LIVERPOOL JOHN MOORES

The Effects of GATA4 Gain and Loss of Function on Endogenous Cardiac Stem Cell Biology and Regenerative Potential Sam Impey, Andrew Smith, Bernardo Nadal-Ginard, Daniele Torella, Georgina M. Ellison Stem Cell and Molecular Physiology Laboratory, Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, UK. Introduction: Exercise training increases cardiac IGF-1 expression, endogenous c-kitpos cardiac stem cell (eCSC) number, and new cardiomyocyte formation. CSCs with a specific molecular signature, expressing high levels of the cardiac transcription factor GATA4, show enhanced cardiomyocyte differentiation and exert a pro-survival autocrine/paracrine effect on adult cardiomyocytes through induction of the IGF-1R-dependent signalling pathway. These data identify a specific CSC type for potential use in cardiac repair and regenerative therapies. Here we manipulated the expression of GATA4 in c-kitpos CSCs and established two stable cell lines which were either high or low for GATA4 expression. These CSC lines were then used to test for a cause-effect relationship among GATA4 expression, regenerative potential, IGF-1 secretion and the autocrine/paracrine protective effects of c-kitpos CSCs on adult cardiomyocytes. Methods: c-kitpos CSCs were isolated from the adult rat heart through retrograde coronary enzymatic perfusion. A clonal c-kitpos CSC line was generated (named C5 c-kitpos CSCs) and characterised for stemness properties, GATA4 expression and differentiation potential. GATA4 expression in C5 c-kitpos CSCs was manipulated through GATA4 over-expression or specific shRNA transfection to knock down GATA4. These GATA4 manipulated CSC lines were evaluated for their GATA4 expression through Western blot, immunocytochemistry and qRT-PCR. The GATA4 manipulated CSC lines were characterised over culture time for the principle properties of stem cells; clonogenicity, self-renewal and multipotency. Results: The expression of GATA4 was normalised to the level of non transfected parental C5 c-kitpos CSCs, given the value of 1. C5 c-kitpos CSCs that underwent GATA4 knock-down (C5 c-kitpos CSC GATA4KD) showed decreased GATA4 expression at the gene and protein level (0.3 of the parental C5 c-kitpos CSC). On the other hand, C5 c-kitpos CSC that were manipulated to over-express GATA4 (C5 c-kitpos CSC GATA4high) showed increased GATA4 expression, at the gene and protein level (4 fold over of the parental C5 c-kitpos CSC). C5 c-kitpos CSC GATA4KD and GATA4high lines showed significant differences in stem cell properties. In differentiation medium, C5 c-kitpos CSC GATA4high showed enhanced cardiomyocyte differentiation, compared to C5 c-kitpos CSC GATA4KD. Conclusion: Manipulating the expression of GATA4, in c-kitpos CSCs alters their cardiomyocyte differentiation potential and suggests GATA4 as a key factor in defining the optimal cell type for use in cardiomyocyte regenerative therapy.

### THE IMPACT OF NEURONAL NITRIC OXIDE SYNTHASE ON SKELETAL MUSCLE PHYSIOLOGY IN RESPONSE TO ENDURANCE EXERCISE

BAUM, O., ENGELI, A., VIEREGGE, M., RENG, M., MEIER, P., AALDIK, D., KOCH, P., FELICITAS HUBER-ABEL, F., HOPPELER, H. UNIVERSITY OF BERN

Introduction Nitric oxide (NO) is an important signaling molecule effective in many cells and tissues. In skeletal muscle, high concentrations of NO are generated by neuronal NO synthase (nNOS), which is expressed at the sarcolemma of the muscle fibers. Due to this site of localization in close contact to the endomysial microcirculation we hypothesized that the nNOS/NO-system contributes to the adaptation of skeletal muscle to endurance exercise, in particular to the angiogenic response. Methods Human vastus lateralis muscle biopsies (VL) were derived from ten sedentary male subjects before and after moderate training (four 30 minute weekly jogging sessions for six months, with a heart-rate corresponding to 75% VO2max). Murine extensor digitorum muscles (EDL) were collected from cohorts of C57BL/6-mice (10 weeks old) either trained on a treadmill (5 weeks at 18-24 m/min; 5-10° incline; 45 minutes daily) or remaining untrained. These mice as well as additional C57BL/6-mice treated with the specific nNOS inhibitor S-methyl-thiocitrulline (SMTC; approx. 0.0125 mg/day dissolved in tap water) were subjected to a performance test on the treadmill (2 m/min increase of velocity each 90 sec; start at 16 m/min) before and after the training period. The mRNA levels of nNOS in the VL biopsies and the murine EDL were quantified by Realtime-PCR and related to the capillary-to-fiber ratio and the numerical density of capillaries specified by light microscopy. Results The mRNA levels of nNOS were significantly up-regulated (+128%; p≤0.05) in VL biopsies of those five subjects that exhibited significant (p≤0.05) elevations in the capillary-to-fiber ratio (+25%) and the numerical density of capillaries (+21%) and positively correlated (r=0.8; p≤0.01) to the extent of angiogenesis. The treadmill training significantly increased nNOS mRNA expression (+122%; p≤0.05) and capillarity (+19%; p≤0.05) in EDL of C57BL/6-mice (correlation: r=0.6 and 0.8 before and after the training period with p≤0.05 both). The post-exercise performance was significantly higher in the trained than the untrained C57BL/6-mice (+15%; p≤0.05) but lower in the SMTC-

treated mice (-10%;  $p \leq 0.05$ ). Discussion The mRNA expression levels of nNOS were statistically linked to capillarity after exercise in human and murine skeletal muscle. Administration of the chemical nNOS inhibitor led to a reduced performance capacity indicating that the integrity of the nNOS/NO system is important for the capability of C57BL/6-mice to run persistently on a treadmill. Taken together, we that nNOS contributes in the angiogenic response in skeletal muscle to training.

### OP-BN11 EMG

#### REPEATABILITY OF MINIMUM MEAN FREQUENCY OF EMG POWER SPECTRUM DURING CONSECUTIVE SERIES OF DYNAMIC ELBOW EXTENSIONS UNTIL EXHAUSTION

STIRN, I., JARM, T., STROJNIK, V.

UNIVERSITY OF LJUBLJANA, FACULTY OF SPORT

**Introduction** The past research showed that the mean frequency of power spectrum of the EMG signal (MNF) detected during repetitive dynamic contractions until exhaustion, decreases similarly to the MNF obtained during sustained isometric contraction; it decreases more rapidly at the beginning, while at the point of exhaustion the MNF values approached to some plateau asymptotic value (Gerdle et al., 1988; Ament et al., 1993). The aim of our study was to investigate whether the lowest MNF obtained during three consecutive series of repeated dynamic contractions until exhaustions, with one minute rest in-between, was repeatable. **Methods** Twelve volunteers performed dynamic elbow extensions from the 90° elbow flexion to full extension. The load was set to the 80 % of maximal load and the extensions were executed with frequency one extension and flexion per two seconds. When subject couldn't keep the pace, the load was gradually reduced to 60 %, 40%, 30% and finally to 20 % of maximal load without interrupting the working tempo. The EMG of long head (TBLoH), lateral head (TBLaH) and medial head (TBMeH) of m. triceps brachii were collected. Muscle activation within each extension was used for frequency analysis. A 5th order polynomial model was fitted to the MNF time series. Minimum values of polynoms were labelled MNF0LoH, MNF0LaH and MNF0MeH for the long, lateral and medial head of TB, respectively. **Results** Repeated measures ANOVA showed that MNF0 obtained in 1st series of contractions were lower with respect to MNF0 obtained in the 2nd and 3rd series ( $P < 0.05$ ), however ICC(2,1) values were 0.89, 0.95 and 0.72 for the MNF0LoH, MNF0LaH and MNF0MeH respectively. **Discussion** An exponential decrease of MNF was usually observed in the literature, however in our study a MNF decrease showed different pattern which was best fitted by a polynomial curve. Minimum instead of plateau values were obtained. Our results showed that the lowest MNF0, obtained from the repetitive dynamic elbow extensions until exhaustions, was achieved in the first series. However absolute differences in MNF0 obtained in three consecutive series were small and high ICC values were obtained. Results imply that MNF0 obtained of three consecutive fatiguing series presented a stable parameter. This might be interesting when considering MNF0 as a measure for the normalisation of MNF in fatigue studies. **References** Ament W, Bonga GJJ, Hof AL, Verkerke GJ. (1993). #### MEAN AND PEAK FREQUENCY IN THE SEMG POWER-SPECTRUM IS NOT DIFFERENT BETWEEN LAND AND WATER

OLSTAD, B.

NORWEGIAN SCHOOL OF SPORT SCIENCE

**MEAN AND PEAK FREQUENCY IN THE SEMG POWER-SPECTRUM IS NOT DIFFERENT BETWEEN LAND AND WATER** Olstad, BH.1, Cabri, J.1, Zinner, C.2, Nunes, N.3, Kjendlie, PL.1,4 1: NSSS (Oslo, Norway), 2: GSU (Cologne, Germany), 3: UNL (Lisbon, Portugal), 4: VUC (Toensberg, Norway) **Introduction** The use of surface electromyography (sEMG) in water is slightly different from dry land conditions and some challenges are prevalent. Therefore, the aim of this study was to investigate the mean and peak frequency in the power-spectrum between land and water conditions. **Methods** sEMG of isometric maximal voluntary contractions (MVC) on land and in water were collected in six subjects, after a familiarization process, and according to recommendations of the SENIAM project (Hermes et al., 1999). MVC testing consisted of three five seconds maximal contractions separated by approximately 60 seconds of recovery in standardized exercises. The standardized exercises were designed so they could easily be performed in a field setting on the pool deck and in the swimming pool with no stationary machines. Visual feedback of the sEMG signal and verbal encouragement were given to facilitate participants' maximal effort. During the MVC testing in water the water depth for each exercise was set to ensure that the electrodes were fully submerged. Muscles tested were biceps brachii, triceps brachii, trapezius (pars descendens), pectoralis major (pars clavicularis), rectus femoris, biceps femoris, tibialis anterior and gastrocnemius. The waterproof electrodes were covered with insulating tape around the outside perimeter and connected to waterproof emg active sensors for sEMG (Plux Ltd, Lisbon Portugal) with a band pass filter of 25-500Hz (-6dB) and with a gain of 1.000. The sensors were connected to the bioPlux Research (Plux, Lisbon, Portugal) inside a waterproof pouch with 8 analogue channels (12 bit) and sampled at a rate of 1.000Hz. The power spectrum was analyzed using fast Fourier transform. **Results** Mean average frequency on land were 138Hz (SD 28,04) and in water 134Hz (SD 31,11). Peak average frequency on land were 69Hz (SD 24,16) and in water 61Hz (SD 29,21). A paired sampled t-test showed no significant differences either for the mean frequency ( $p=0,31$ ) or the peak frequency ( $p=0,09$ ). **Discussion** The high SD was a result of the different frequencies among the eight different muscles. The results of the present study showed that the sEMG recordings between land and water were not significantly different indicating a good similarity without any additional waterproofing of the electrodes. **References** Hermes, HJ., Freriks, B., Merletti, R., Stegeman, D., Blok, J. #### CONCENTRIC CONTRACTIONS ARE MORE CONDUCTIVE TO EXPLOSIVE TORQUE PRODUCTION THAN ECCENTRIC OR ISOMETRIC CONTRACTIONS

TILLIN, N.A.1,2, PAIN, M.T.G.2, FOLLAND, J.P.2

(1): ROEHAMPTON UNIVERSITY; (2): LOUGHBOROUGH UNIVERSITY

**Introduction** The influence of contraction type (concentric, eccentric and isometric) on maximum strength (maximal voluntary torque, MVT) has been widely documented via the in vivo torque-angular velocity relationship (Rassier et al., 1999). However, due to methodological

limitations, the influence of contraction type on explosive strength (rate of torque development), and the human ability to utilise the available torque capacity of the muscle during explosive efforts has not been documented. This study assessed the influence of contraction type on explosive strength and the utilisation of the available torque capacity of skeletal muscle. Methods Fourteen male participants completed a series of explosive voluntary contractions of the knee extensors in four separate conditions on an isokinetic dynamometer: concentric (CON) and eccentric (ECC); and isometric at two knee angles (101°, ISO101; and 155°, ISO155). CON and ECC were performed at constant accelerations from stationary. In each condition explosive voluntary torque was measured at 25-ms intervals up to 150-ms from torque onset, and then normalised to the MVT specific to that joint angle and angular velocity. Explosive voluntary torque after 50-ms in each condition was also expressed as a percentage of torque generated after 50-ms during an electrically evoked octet (8 pulses at 300 Hz; a measure of the maximum explosive capacity of the muscle) in the same condition. These two procedures of normalising voluntary explosive torque controlled for the influence of joint angle and angular velocity on explosive torque production, and enabled us to quantify human ability to utilise the available torque capacity of the muscle. Agonist EMG normalised to Mmax was also recorded during the four conditions. Results CON explosive contractions were 60% more effective at utilising the available torque generating capacity (explosive torque normalised to MVT) than any other condition (Paired t-tests,  $P < 0.001$ ), after the initial 25-ms. The percentage of evoked torque expressed after 50-ms of the explosive voluntary contractions was also greater for CON (CON,  $76.6 \pm 16.6\%$ ; Paired t-tests,  $P < 0.001$ ), followed by ISO101 ( $46.4 \pm 14.2\%$ ), ISO155 ( $36.4 \pm 12.7\%$ ), and ECC, ( $23.1 \pm 8.7\%$ ). This suggests a higher volitional activation during CON that was confirmed by greater agonist EMG normalised to Mmax in CON (Paired t-tests,  $P = 0.032$ ). Conclusion These results provide novel evidence that human ability to utilise the available torque capacity of the muscle is highly dependent on the type of contraction. Specifically, concentric contractions seem to be considerably more conducive to explosive torque production due to a more effective neural strategy. References Rassier et al. (1999). ## A NEW METHOD FOR MONITORING SKELETAL MUSCLE CONTRACTILE PROPERTIES

MEGLIČ, A.1, DJORDJEVIĆ, S.1,2

INSTITUTE FOR KINESIOLOGY RESEARCH (2), UNIVERSITY OF PRIMORSKA, SLOVENIA, TMG-BMC LTD. (1), SLOVENIA

Skeletal muscles enable efficient movement at varying intensities, duration and different movement patterns. Estimation of contractile properties of skeletal muscles has important influence on all activities regarding human motion, from daily work to physiotherapy and professional sport. The biomechanical and contractile properties of the skeletal muscles have been studied by various methods. The most direct approaches, where the actual muscle fiber type is estimated, require samples obtained by muscle biopsy and are therefore considered invasive (Dahmane & al. 2000). Other approaches include monitoring body movement velocity or movements of specific parts of the body with motion capture systems and force plates, tensiomyography and electromyography (EMG). The first two methods have several limitations, like high cost and lack of portability. The EMG is well established but the results indicate that the surface EMG amplitude cannot be used to predict either the level of muscle activation or the magnitude of muscle force when the muscle exhibits any fatigue (Dideriksen & al. 2010). The contractile properties of skeletal muscles cannot be measured selectively and non-invasively during movement using existing methods. Therefore a new measuring method and device, called the MC sensor (TMG-BMC Ltd.), was developed. The device consists of a sensor with sensor tip, a microprocessor and a supporting part, made of carbon fibre reinforced epoxy polymer, which binds together all of the device parts. Because of the small size and light weight ( $\leq 1g$ ) the MC sensor is suitable for continuous, unobtrusive monitoring of muscle contractile/biomechanical properties. During the measurement the sensor is fixed on the skin above the muscle while the sensor tip is shallowly deepened into the muscle. The measured muscle tension produces force  $F$  in the direction along the muscle surface. This force causes subcutaneous tissue and skin to press on the sensor tip. Vector sum of all forces produce force  $F_s$  in the direction along the sensor tip which is then measured with the force meter. In the simplified 2D model this force would be equal to:  $F_s = 2F \cos(\alpha)$  MC sensor enables muscle load assessment, resulting from muscle contraction or stretching. Preliminary study on m. biceps brachii in isometric conditions showed strong linear relationship between isometric force and MC signal. The aim of the present study was to monitor changes in muscle contractile properties during fatigue. For this we used MC sensor simultaneously with EMG attached to the m. vastus lateralis and medialis on the same leg during a one-leg squat. Dahmane R, Valenčič V, Knez N, Eržen I. (2000). Med. Biol. Eng. Comput., 38, 51-55. Dideriksen JL, Farine D, Enoka RM. (2010). Phil. Trans. R. Soc. A, 368, 2765-2781.

## CHANGES IN SURFACE EMG WITH DISCRETE WAVELET TRANSFORM FOLLOWING A WINGATE TEST

PEÑAILLO, L., NOSAKA, K., SILVESTRE, R.

EDITH COWAN UNIVERSITY

Introduction Surface electromyography (sEMG) amplitude increases but the frequency of the signal decreases with fatigue. Fourier transform (FT) has been used to analyse sEMG frequency, but its mean frequency does not necessarily provide actual frequency changes. Discrete wavelet transform (DWT) is a novel method for time-frequency analysis of sEMG and is expected to provide greater sensitivity to changes in frequency than FT (1). A previous study (2) reported that the intensity of the 12-27 Hz wavelet domain increased after 50 maximal knee extensor concentric contractions. However, no previous studies have used DWT to investigate sEMG frequency spectrum changes following a Wingate test. Thus, this study examined the changes in frequency during maximal voluntary isometric contractions (MVC) of the knee extensors performed after supramaximal cycling using DWT. Methods Seventeen men ( $24.4 \pm 2.6$  y) performed 30-s maximal pedalling on a cycle ergometer with a load of 7.5% body mass, during which power output was recorded, and changes in peak power were calculated later. Before, and 1, 3, 6, 9, 12 and 15 min after the cycling, 3-s MVC of the non-dominant knee extensors was measured at 90°, and sEMG of the vastus lateralis was recorded. sEMG root mean square (RMS) was used for amplitude analysis and DWT decomposed the sEMG signal into 10 frequency domains between 0 and 500 Hz using a Daubechies mother. Blood lactate concentration was measured at the same time points as the MVC measures. Changes in the variables over time were analysed by a one-way repeated measures ANOVA, and significance was set at  $P < 0.05$ . Results Peak power output during the Wingate test was  $7.8 \pm 0.6$  W/kg and decreased  $33.2 \pm 8.8\%$  at the end. Blood lactate increased to  $11.5 \pm 1.1$  mmol/L at 1 min post-cycling and remained elevated for 15 min. MVC decreased from baseline between 3 and 15 min post-cycling. RMS increased  $34.4 \pm 8.3\%$  at 1 min post-cycling and remained elevated for 15 min. Intensity of all DWT frequency domains increased from baseline at all time points after cycling. The greatest increase was found for the 16-32 Hz domain than others with the greatest increase at 1 min post-exercise and gradual decreases thereafter. Discussion The increases in DWT intensity and RMS suggest greater muscle activity in the fatigued muscle. The greatest increases in DWT intensity in the 16-32 Hz domain in the present study are in line with the finding of the previous study (2). It is speculated that decreases in conduction velocity and increases in slow twitch fibre recruitment were associated with the frequency changes. References 1) Karlsson S et al. ### OP-BN12 Balance and Stability 2

#### ATTENTION AND BALANCE CONTROL IN SPORT: A STUDY BY ACCELEROMETRY

OLIVEIRA, A.R., GALLAGHER, J.D., OYEN, A.S.

STATE UNIVERSITY OF LONDRINA - PARANA, SPONSORED BY ARAUCARIA FOUNDATION

**ATTENTION AND BALANCE CONTROL IN SPORT: A STUDY BY ACCELEROMETRY** Oliveira, AR.1, Gallagher, JD.2, Oyen, AS.3 1: UEL/CNPq (Londrina, Brazil), 2: UP (Pittsburgh, USA), 3: PSU (State College, USA) **Introduction** This study proposed to determine the relationship between a motor skill postural and focal components (Frank & Earl, 1990) and moving balance. Increased motion and reduced smoothness of head and trunk in the medial-lateral plane might be related to decreased balance skills for children, especially after 7 years of age, a period where it is expected that they demonstrate an adult pattern of balance control strategies (Yack et al., 1992). The study investigated the influence of selective attention on the development of balance control. **Methods** The sample involved sixty female subjects (6-, 12-, and 19-years old). In each age group there were 10 gymnasts and 10 non gymnasts. The instruments were a scale with stadiometer, three tri-axial accelerometers (ADXL150/EM-3, 5g, Analog Devices, Norwood, MA) placed on head, hip and ankle, a footswitch, a line on the floor, a balance beam, and an AD computer. The tasks were: walk on a line on the floor (3.68 m long, 10.0 cm wide), over a white obstacle, walk across a balance beam, and over an obstacle. The dependent variables were Root Mean Square and Index of Smoothness of the head and trunk in three planes of movement: vertical, anterior-posterior, and medial-lateral,  $p < 0.05$ . Children were cued to look at the end of the line and beam in the experiment. **Results** Selective attention improved vertical head and trunk smoothness in the ML plane. The younger children group stabilized the trunk and head regardless of strategy use. The 12-year olds displayed smooth trunk motion without the use of a strategy and decreased smoothness with strategy. The adults demonstrated trunk stability regardless of strategy and deteriorated performance with strategy. When the selective attention strategy was used subjects differed in terms of head stabilization in space to improve their balance and the non gymnasts decreased their head motion but did not alter the trunk. **Discussion** The youngest group demonstrated a smoother trunk ML pattern when not using the strategy, independent of task conditions (obstacle absent and present). Otherwise, in the older groups (12- and 19-years old) the use of strategy made the difference and a smoother trunk in the ML plane was demonstrated in the experiment. The greatest difference was observed in the 12-years old group. Experience and selective attention strategy influenced the balance control across age and task complexity levels. **References** Frank JS, Earl M. (1990). #### NEUROMUSCULAR EFFICIENCY DURING SIT TO STAND MOVEMENT IN WOMEN WITH KNEE OSTEOARTHRITIS

PATSIKA, G., KELLIS, E., AMIRIDIS, G.I.

NEUROMECHANICS LAB, ARISTOTLE UNIVERSITY OF THESSALONIKI

**Introduction** Knee osteoarthritis (OA) is associated with pain, quadriceps dysfunction, joint stiffness, instability and difficulties in performing daily activities. The purpose of this study was to investigate the neuromuscular efficiency of women with knee osteoarthritis when performing a sit to stand (STS) movement and during maximum strength efforts. **Method** Twelve women with unilateral knee OA (age  $60.33 \pm 6.66$  yrs, height  $1.61 \pm 0.05$  m, mass  $77.08 \pm 9.2$  kg) and eleven controls (age  $56.54 \pm 5.46$  yrs, height  $1.64 \pm 0.05$  m, mass  $77.36 \pm 13.34$  kg) participated in this study. Subjects performed a STS movement from a normal height chair while position of center of pressure and knee angular velocity were recorded. Furthermore, maximal isokinetic knee extension and flexion strength at  $60^\circ/\text{s}$ ,  $120^\circ/\text{s}$  and  $150^\circ/\text{s}$  was measured. Surface, electromyography (EMG) from the biceps femoris (BF), vastus lateralis (VL) and vastus medialis (VM) was recorded during all tests. Analysis of variance was used for the statistical analysis. **Results** During the STS test that women with knee OA demonstrated significantly lower knee angular velocity ( $44.49 \pm 9.61^\circ/\text{s}$  vs  $71.68 \pm 19.86^\circ/\text{s}$ ), a more posterior position of the center of pressure ( $39.20 \pm 7.02\%$  vs  $41.95 \pm 2.49\%$ ) and a higher antagonist BF activation ( $57.13 \pm 20.55\%$  vs  $32.01 \pm 19.5\%$ ) compared with typical women ( $p < 0.05$ ). Further, women with knee OA demonstrated a lower moment : EMG ratio than controls in extension, but not in flexion. **Discussion** The lower ability of women with OA to rise from a chair is mainly due to a lower knee extension capacity, which, coupled with a higher BF co-activation is indicative of a reduced neuromuscular efficiency than typical individuals.

#### MEASURING LOCAL DYNAMIC STABILITY OF ATHLETE IN AGILITY DRILL USING LYAPONOV EXPONENT

ARSHI, A., MEHDIZADEH, S., KOMASI, P., SHIRZAD, E., NABAVI, H.

AMIRKABIR UNIVERSITY OF TECHNOLOGY

**MEASURING LOCAL DYNAMIC STABILITY OF ATHLETE IN AGILITY DRILL USING LYAPONOV EXPONENT** Arshi AR.1, Mehdizadeh S.1, Komasi P.2, Shirzad E.2, Nabavi H.1 1: AUT (Tehran, Iran), 2: NOAI (Tehran, Iran) **Introduction** Local dynamic stability is defined as the ability of the system to recover its original state in movement after small perturbations (Gates et al., 2010). During the recent years, nonlinear dynamics has been implemented increasingly in studying facets of movement science such as fatigue and local dynamic stability (Sanjari et al., 2010; Gates et al., 2010). Agility is defined as the ability to change the body direction effectively while maintaining dynamic stability, coordination, speed (Vescovi, 2004). In the present study the local dynamic stability of the movement of the athlete performing an agility workout is measured using Largest Lyapunov Exponent (LLE). **Methods** An agility test designed during which participants completed two 180-degree and two 90-degree turns. Five semi-professional soccer players who had no previous injury experience participated in the experiment. 2D coordinates of the body center of mass (COM) were recorded at the sampling frequency of 300 Hz. Three two-dimensional and one three-dimensional state spaces are constructed. Two-dimensional state spaces are  $v_x$  vs.  $x$ ,  $v_y$  vs.  $y$  and  $v_r$  vs.  $r$  where  $v_x$ ,  $v_y$  and  $v_r$  are velocity in  $x$ ,  $y$  and tangential velocity, respectively. The three-dimensional state space is constructed by COM position ( $r$ ),  $v_r$  and  $a_r$  where  $a_r$  is COM acceleration. Local dynamic stability of the COM is measured in each state space using Largest Lyapunov Exponent (LLE) is used. LLE is defined as the exponential rate of divergence or convergence of the neighboring points of the system state space (Rosenstein et al, 1993). Greater amount of LLE indicates greater instability. **Results** Average LLEs of the five athletes in each state space are as follows: 1.5 for  $v_x$  vs.  $x$  state space, 2.25 for  $v_y$  vs.  $y$  state space, 0.12 for  $v_r$  vs.  $r$  state space and 0.0625 for  $a_r$  vs.  $r$ . **Discussion** The results show that definition and dimension of state space are important in quantifying local dynamic stability. It also can be seen from the results that although athlete COM in  $x$  and  $y$  directions has instability, the athlete in the direction of movement

is stable. Due to complex nature of body COM in agility drill and also due to the importance of stability in agility performance, LlyE as nonlinear measure of system stability is a useful tool to quantify athlete agility performance. ## DYNAMIC BALANCE CONTROL AND H-REFLEX SENSITIVITY DURING SLOW PERTURBATION IN YOUNG AND ELDERLY MALES

PIIRAINEN, J.M., AVELA, J., SIPPOLA, N., LINNAMO, V.

UNIVERSITY OF JYVÄSKYLÄ

**INTRODUCTION** High muscle force and especially rapid force production are related to balance control during balance perturbations (Piirainen et al. 2010). Age related decreases in force production have been shown to be caused by decreased muscle mass and lower activation efficiency from the central pathways. In addition, activation of the alpha-motoneuron pool, as revealed by H-reflex, may be modulated during dynamic tasks (Chalmers & Knutzen 2000). The purpose of the study was to evaluate if H-reflex sensitivity is affected by ageing and if it is related to dynamic balance control during balance perturbation. **METHODS** Totally 19 young (n=9, 27±3 years) and elderly (n=10, 68±3 years) males participated in this study. Dynamic balance control was measured using custom build balance measurement device with 7,5cm perturbation amplitude and with 0.3m/s<sup>2</sup>, 15cm/s in posterior directions in horizontal plane. COP displacement peak amplitudes and slopes were analysed from acceleration and deceleration phases of the perturbation. H/M20% was measured during 10ms, 30ms and 90ms after posterior direction perturbations. RMS EMG activity was measured from the soleus and medial gastrocnemius muscles and related to the maximal isometric RMS value. **RESULTS** In balance displacement, only significant difference between the age groups were observed in deceleration phase slope and peak amplitudes, which were 27.9% (p<.05) and 36.4% (p<.05) lower in young group, respectively. During balance perturbation, young group showed higher H/M20% ratio in all three time points, although only significant difference was observed 10ms after the perturbation (p<.05). All three H/M20% ratios correlated negatively (lowest r=-.775, p<.05-.01) with the deceleration phase slope in young, but not in elderly. Young had higher EMG activity in both acceleration (Sol 120.8% p<.001, MG 210.2% p<.01) and deceleration phases (Sol 178.9% p<.001, MG 323.4% p<.01). **DISCUSSION** Age related differences in dynamic balance control were seen during deceleration phase of the slow type balance perturbation. Deeper slope of the balance displacement curve in the deceleration phase and lower H-reflex sensitivity in the elderly might be connected to lower spinal level coordination. On the other hand, higher EMG activity and higher H-reflex responses in the young subjects may indicate more efficient Ia-afferent feedback and voluntary response. In addition, higher EMG activity in the acceleration phase in young could be an indication of higher stretch reflex response after the perturbation. **REFERENCES** 1.Piirainen JM, Avela J, Sippola N, Linnamo V. 2010. ## INFLUENCE OF AGE ON BALANCE TASKS

ROEMER, K.

MICHIGAN TECHNOLOGICAL UNIVERSITY

**Influence of Age on Balance Tasks** Karen Roemer, Louisa D Raisbeck, Michigan Technological University **Introduction** 1.8 million falls occur within the elderly population that is directly related to instability. Postural instability has been linked to poor proprioception, vision, imbalance within the vestibular system, slow reaction time and decreased lower limb strength (Manfield & Maki, 2009). This study is focusing on the relationship between sway and lower limb strength in elderly. It is hypothesized that increased lower limb strength will enhance postural stability for dynamic balance tasks. **Methods** Ten subjects, aged 20 – 40 years (Y) (24.13±/- 4.24) and ten subjects, aged 60 -80 years (O) (66.5 ±/- 5.02) with no fall related injuries participated. To measure dynamic balance, subjects were asked to perform maximal number of lunges with each leg. An AMTI force plate was used to quantify the full body center of pressure (COP). Local sway area (LSA) of the front foot was measured using a TekScan pressure distribution mat. Dynamic strength (ANL) was determined using amplitude and number of the lunges (noL). ANL was normalized to step length and body height for each subject. Relative base of support (RBS) was calculated determining the LSA relative to the normalized base of support. Kinematics were quantified using a Vicon Motion Analysis System. **Results** Two sample t-tests were used to identify significant differences between Y and O. Y showed smaller ANL values(Y: 2.33±2.07cm/noL; O: 5.02±3.83cm/noL), decreased LSA (Y: 24.79±7.64cm<sup>2</sup>, O: 31.22±15.01 cm<sup>2</sup>), and increased normalized step length (SL) (Y: 0.4±0.03cm, O: 0.36±0.04cm) (p<0.05) for both the left and right lunges. O showed increased values for distance of COP to the front foot (FF) (Y: 0.65±0.1cm/SL, O: 0.73±0.08cm/SL) and RBS (Y: 61.43±19.25cm<sup>2</sup>, O: 102.47±65.48cm<sup>2</sup>) (p<0.05) for the right lunges only. **Discussion** Similar to previous studies, our results show that balance and strength decrease with age (Karamanidis et al 2008). Specific changes in the COP distance to the FF and RBS suggest that the older age group adjusts the COP to reduce the load on their left leg. Arampatzis et al 2011 found that dynamic stability and base of support is related to leg strength. Six out of ten elderly performed more right lunges suggesting a relationship between the location of COP and leg strength. Increasing the relative load on the right leg increases LSA and RBS and seems to increase the danger of falls while the right leg is in front. **Acknowledgement:** This investigation was funded by: Michigan Technological University Research Excellence Fund. ## MODULATION OF SPINAL IA AFFERENT INPUT DURING UPRIGHT STANDING IN VARIOUS BALANCE CONDITIONS FOR YOUNG AND ELDERLY ADULTS

BAUDRY, S., LECOEUVE, G., DUCHATEAU, J.

UNIVERSITE LIBRE DE BRUXELLES

**Modulation of spinal Ia afferent input during upright standing in various balance conditions for young and elderly adults** Baudry S, Lecoivre G, Duchateau J. Laboratory of Applied Biology, Université Libre de Bruxelles - Belgium **INTRODUCTION** Alterations in balance capacity with ageing have been associated with differences in the modulation of Ia afferent pathway from soleus muscle, as tested by the Hoffmann reflex (H-reflex)(Koejca et al. 1995). The H-reflex can be modulated presynaptically and such inhibitory mechanism seems to differ in young and old adults during upright standing (Earles et al. 2001). The purpose of this study is to determine if changing visual and proprioceptive information involved specific modulation of Ia presynaptic inhibition in young and old adults during upright standing. **METHODS** Seven young (21-35 yrs; 4 women) and eight older adults (67-88 yrs; 5 women) participated in this study. Surface electromyogram (EMG) was recorded from the soleus, gastrocnemii medialis and lateralis, and tibialis anterior during the four following balance

conditions: rigid surface/eyes open (REO); rigid surface/eyes closed (REC); foam surface/eyes open (FEO); foam surface/eyes closed (FEC). These tests were performed on a force platform that allows computing the center of pressure (COP). Maximal H-reflex (Hmax) and M-wave (Mmax) were obtained by stimulating the posterior tibial nerve at rest and during the four balance conditions. Submaximal H-reflexes were then conditioned by a single pulse delivered to the common peroneal nerve (conditioned H reflex). Modulation in presynaptic inhibition was inferred from the ratio of the conditioned H reflex and test H reflex (no conditioning stimulation). RESULTS The COP data indicate that postural stability decreases with age and balance complexity (age x balance condition,  $P < 0.05$ ). The Hmax/Mmax is reduced in old compared with young adults ( $P < 0.05$ ) and tends to differ across age and balance conditions ( $P = 0.06$ ). The conditioned H-reflex/test H-reflex decreased from rest to upright standing ( $P < 0.001$ ), and was greater in old compared with young adults ( $P < 0.05$ ). DISCUSSION These preliminary data confirm differences in the modulation of Ia afferents during balance conditions of various complexity (Koceja et al. 1995). Moreover, these results suggest that altering vision and proprioception induces greater increase in Ia presynaptic inhibition for old than young adults during upright standing. This may indicate that old adults manage balance complexity by limiting to a greater extent Ia afferent inputs onto motoneurons. #### ANALYSIS OF THE PERFORMANCE IN THE FIRST TENNIS SERVE UNDER THE EFFECT OF AN INDUCED AERODYNAMIC FLOW (WIND)

MENDES, P.1, MENDES, R.2, MARTINS, F.3, FACAS VICENTE, M.A.4, COELHO-E-SILVA, M.J.1, FUENTES, J.P.5, DIAS, G.1, MENAYO, R.6

ESCOLA SUPERIOR DE EDUCAÇÃO DE COIMBRA

1: CIDAF (Coimbra – Portugal), 2: CIPER (Lisboa – Portugal), 3: IT (Covilhã – Portugal), 4: Department of Mathematics, Faculty of Sciences and Technology of the University of Coimbra and INESC-C, 5: FCD – UEX (Cáceres – Spain), 6: FCSAFD (Murcia – Spain). Introduction The present study provides an analysis of the tennis serve performed by 12 expert players when constrained with an induced streamlined flow (ISF) or “side wind” produced by an industrial ventilator. Methods The sample comprised 12 tennis players who were asked to perform 100 serves at the maximum speed and accuracy towards an intersection point between the central and the service lines (“T” point). In the practical procedure, an electronic variator of 11 positions, SEW Eurodrive, and a telescopic elevator, GUIL ELC – 506, were coupled to the industrial ventilator, METEC - HCT - 45 - 4T. Five practical conditions were previewed: without ISF; ISF1 (2,4m/s); ISF2 (4,3m/s); ISF3 (5,8m/s) and; Random ISF (random series of the 3 speed values used in this study). Human movement was recorded using two digital cameras to allow a 2D analysis and manual tracking based on Kwon software (version 3.16) to determine serve’s accuracy. The speed of the ball was assessed by radar, Stalker Pro Sport Results No significant differences in accuracy and precision between the different speeds of ISF were found. In addition, it was possible to identify meaningful statistical changes in speed for six of the 12 players. Concerning to the relation between the speed of the serve and the accuracy (measured by the radial and absolute errors), the results estimated negative correlations for the speed ISF1 (2,4m/s), ISF3 (5,8m/s) and for random ISF. Discussion Tennis experts’ serve accuracy and precision showed a substantial stability under the effect of ‘side wind’. Through the ellipses of error (in the least squares sense), we observe that tennis serve’s accuracy and precision is smaller in depth (anterior-posterior location) than in direction (lateral location). The results also supported the “Fitts Law”, that established an inverse relationship between increments in service velocity and decrements in the accuracy. Additional research is needed to provide the best learning design to combine a powerful serve with accuracy.

#### THE DEVELOPMENTAL ACTIVITIES OF ELITE INTERNATIONAL SOCCER PLAYERS AGED 16 YEARS

FORD, P.R., CARLING, C., GARCES, M., MARQUES, M., LE-GALL, F., SALMELA, J.H., WILLIAMS, A.M.

LIVERPOOL JOHN MOORES UNIVERSITY

Introduction The activities that expert athletes engage in during their development may follow either an early specialization or early diversification pathway (for a review, see Ford et al., in press). Early specialization involves high amounts of practice and competition in the primary sport from childhood onwards, whereas early diversification involves engagement in several sports in childhood with delayed specialization. We examined the developmental activities of elite soccer players from around the world to test whether their engagement followed one of these pathways. Methods Participants were elite 16 years of age soccer players at top league professional clubs or national academies in Brazil, England, France, and Mexico ( $n = 200$ ). They completed the Participation History Questionnaire (PHQ; Ford et al., 2010) under supervision. The PHQ recorded their developmental milestones (e.g., start age in soccer), hours in soccer-specific deliberate practice, deliberate play and competition, and number of other sports. Results Participants started playing soccer at 5 years of age. Between 6 and 12 years of age, they engaged in 171 hrs/yr of deliberate practice in soccer, 186 hrs/yr of deliberate play in soccer and 34 hrs/yr of soccer competition. Players participated in an average of 2 other sports, which indicates the extent of early diversification. Participants started playing at an elite soccer academy at 12 years of age. Between 13 and 15 years, they engaged in 411 hrs/yr of deliberate practice in soccer, 91 hrs/yr of deliberate play in soccer and 59 hrs/yr of soccer competition. Some between-country differences were found. For example, during childhood, Brazilian players engaged in futsal for 181 hrs/yr over four years alongside a high amount of deliberate play in soccer (224 hrs/yr) and a low amount of deliberate practice (124 hrs/yr) compared to players in the other countries. Discussion The developmental activities of elite soccer players aged 16 years generally did not follow the early diversification pathway. The number of other sports during childhood was very low. Elite soccer players aged 16 years tended to follow the early specialization pathway. However, some between-country exceptions to this rule were found. Implications for talent identification and development are discussed, including the hypothesis that it takes “10,000 hours of practice” to become an expert. ## EFFECTS OF EXTERNAL AND INTERNAL FOCUS TRAINING ON FOOT-STRIKE PATTERNS IN RUNNING

WOO, M.T.1, CHOW, J.Y.2, KOH, T.H.1, DAVIDS, K.3

1: REPUBLIC POLYTECHNIC(SINGAPORE), 2: NATIONAL INSTITUTE OF EDUCATION(SINGAPORE), 3: QUEENSLAND UNIVERSITY OF TECHNOLOGY (AUSTRALIA)

**Introduction** The provision of instructions is critical in the acquisition of skills; and, in the exploration of functional movement solutions. In the case of running, studies have shown that heel strike running pattern generates greater impact on the foot, which leads to injuries. Numerous studies have been undertaken to examine how injury can be prevented or alleviated. We postulate that alteration of foot-strike patterns, from rear foot to fore foot strike, could be a viable strategy to minimise injuries through the provision of different attentional instructions, namely, instruction with either external or internal focus. The objective of this study was to investigate the effectiveness of external or internal focus instructions on encouraging a change from a heel strike to a forefoot strike pattern. **Methods** Nine participants, aged 21-40 years old, were randomly assigned to either an internal focus group (n=4) or an external focus group (n=5). Participants underwent six training sessions with their respective instructional conditions over three weeks with 10 one-minute running trials per session during the intervention phase. 3D motion analysis system (MAC, USA), with 8 cameras was used to capture 21 reflective markers, which were placed at the lower extremities, during pre and post-test sessions. Kinematic calculations were performed through Visual 3D. **Results** Both groups showed a significant change in calcaneus displacement ( $p=0.001$ ) at initial contact (IC), which indicates the change from heel strike to fore-foot strike. However, external group displayed greater plantar flexion at IC compared to internal group. Cycle time ( $p=0.036$ ) and cycle length ( $p=0.024$ ) were significantly decreased for the external group. **Discussion** Internal and external focus of attention on the impact of skill acquisition have been investigated in different skill performances such as vertical jump (Wulf & Dufek, 2009) & standing broad jump (Chow et al, 2009), with beneficial effects observed for external focus of attention instructions. Similarly, external focused group in this study showed greater and functional changes in limb kinematics as compared to internal focused group. However, the effectiveness of both focus instructions could be task and individual dependent. Further empirical investigations should be undertaken across a variety of tasks as well as a function of learners' skill levels. **References** Chow, J. Y., Koh, M., & Davids, K. (2009). (2009). Increased Jump Height with an External Focus Due to Enhanced Lower Extremity Joint Kinetics. *Journal of Motor Behavior*, 41(5), 401-409.

## THE INFLUENCE OF MOTOR SKILL ON DECISION MAKING ACROSS THE DEVELOPMENTAL SPECTRUM

BRUCE, L., FARROW, D., RAYNOR, A.

RMIT UNIVERSITY

A considerable body of knowledge has developed addressing the perceptual-cognitive and perceptual-motor skills which differentiate expert and novice sport performers, yet relatively little work has directly examined how these skills interact during the development of domain specific expertise (Starkes, Cullen, & MacMahon, 2004). Expert (19 international), developmental (20 Australian underage), and novice (19 social) netballers completed tests designed to evaluate three different components of domain-specific expertise: (i) motor skill-execution; (ii) perceptual-cognitive decision making; and (iii) perceptual-motor decision making. The perceptual-cognitive and perceptual-motor tests were designed such that the participant had two available passing options, however, tactically one option was considered to be a better choice due to the distance of the required pass and/or the position of the defensive players. Visual search measures were also recorded on the perceptual-cognitive task. A series of ANOVA's revealed that irrespective of skill level, when players were able to combine their decision with movement as in the perceptual-motor task, the decision they made (i.e., direction of the path) was more accurate than when they were required to provide only a simple verbal response as in the perceptual-cognitive task. However, when an execution component (i.e., team mate successfully catching the ball) was included in the response accuracy of the perceptual-motor task, the performance of the novice participants diminished relative to their performance on the perceptual-cognitive condition. Although an individual's motor skill was found to be related to the successful execution of their decision in a game situation, it was not found to limit the nature of the decision made by participants. Visual search mean values indicated that the novice participants spent more time viewing the short options and less time viewing the long option when compared to the expert and developmental athletes, however these differences fell short of the required level of statistical significance. As such, no evidence was found to support the supposition that lesser skilled participants bias their perceptual-cognitive decisions towards ones that are more aligned with their own personal motor ability. Results fail to comprehensively support the contemporary models (Starkes, et al., 2004) for the development of perceptual-cognitive and perceptual-motor skill in sport. Starkes, J. L., Cullen, J., & MacMahon, C. (2004). A life-span model of the acquisition and retention of expert perceptual-motor performance. In A. M. Williams & N. J. Hodges (Eds.), *Skill acquisition in sport: Research, theory and practice* (pp. 259-281). London: Routledge.

## EFFECT OF ACHILLES TENDON VIBRATION DURING SUBMAXIMAL ISOMETRIC PLANTARFLEXION AND POSTURE

AMIRIDIS, I.G., SPILIOPOULOU, S., HATZITAKI, V., BALTZIS, P., KELLIS, E.

LAB OF NEUROMECHANICS

**Introduction** Tendon Vibration (TV) is known to modify proprioceptive input by eliciting a selective discharge of spindle group Ia afferents, which evokes an increase of the plantarflexors' tension, due to the tonic vibration reflex (Burke et al., 1976). Nevertheless, the vibration induced muscle tension regulation at the ankle joint cannot fully account for the posterior shift of the Centre of Pressure (CoP), favoring the hypothesis of task dependent processing of vibration based on the active state of the muscle and the degree of instability of a particular task. To further explore this hypothesis, we compared vibration induced responses of the ankle plantarflexors across different levels of submaximal force production and static postural tasks of increasing difficulty. **Methods** Twenty seven young women performed 3 isometric plantarflexions at 10, 20, 30 and 50% of MVC and 3 postural tasks of increasing difficulty (Normal Quiet Stance, Sharpened Tandem and the One Leg Stance) with a vibrator applied to the Achilles tendon (80Hz). Both isometric plantarflexion and postural tasks were performed under 5 successively presented experimental conditions, each lasting 10": i. vision, ii. no vision, iii. no vision – TV, iv. vision – TV and v. vision. Isometric plantarflexion moment, CoP displacement and EMG activity from Medial Gastrocnemius (MGAS), Tibialis Anterior (TA) and Soleus (SOL) were recorded. During posture, the fascicle's length and pennation angle of the MGAS was also determined by use of ultrasonography. **Results** An increase ( $P<0.01$ ) in isometric plantarflexion moment was observed during the TV application at all percentages, accompanied by a greater ( $P<0.01$ ) MGAS and SOL activation. No differences were observed in TA activity. During all postural tasks, the application of the TV resulted in a backward displacement of the CoP that was accompanied by an increase in EMG activity of MGAS, SOL and TA muscles. Moreover, an increase ( $P<0.05$ ) of the pennation angle of MGAS and decrease ( $P<0.05$ ) of the fascicle length

was observed during posture, confirming the contraction of the plantarflexors, during the TV application. Discussion A vibration induced excitatory Ia afferent input, resulting in an increase in EMG, was confirmed during both submaximal force production and postural performance. The tonic vibration reflex is clearly manifested during force and static balance tasks. It does not seem unreasonable to hypothesize that the amount of central drive to the ankle muscles, controlling both submaximal force production and postural sway, modulates the spindle's sensitivity to the vibration stimulus, possibly through the  $\gamma$  system. ### QUIET EYE TRAINING IN A VISUO-MOTOR CONTROL TASK

CAUSER, J., HOLMES, P.S., WILLIAMS, A.M.

THE UNIVERSITY OF SYDNEY

QUIET EYE TRAINING IN A VISUO-MOTOR CONTROL TASK Causer, J. 1, Holmes, PS. 2, Williams, AM. 1,3 1: USYD (Sydney, Australia), 2: MMU (Cheshire, UK), 3: LJMU (Liverpool, UK) Introduction: Several researchers have reported the importance of maintaining a longer final fixation on the target (quiet eye period, QE) prior to performing an aiming task (Causer et al., 2010; Vickers, 1996). We present an innovative, perceptual training intervention intended to improve the efficiency of gaze behavior (i.e., QE) in shotgun shooting. Methods: A sample of 20 international-level, skeet shooters were assigned equally to one of two, matched-ability groups based on their pre-test shooting scores. A perceptual training group participated in a 4-step, pre-shot routine, alongside three video feedback sessions involving their own gaze behaviors and those of an expert model in an effort to influence positively QE behaviors. A control group received video feedback of performance, but without the addition of feedback on QE behaviours. Participants completed pre- and post-tests along with an 8-week training intervention. Eye movement and gun barrel kinematic data were collected during the pre- and post-tests. An ASL Mobile Eye system allowed point of gaze to be calculated in relation to the scene, while motion of the gun was evaluated using markers placed on the barrel which were captured by two stationary cameras. Results: The perceptual training group significantly increased its mean QE duration (397 v 423ms), employed an earlier onset of QE (257 v 244ms), and recorded higher shooting accuracy scores (62 v 70%) from pre- to post-test. Participants in the perceptual training group significantly reduced gun barrel displacement and absolute peak velocity on the post- compared to the pre-test, even though neither variable was overtly trained. A transfer test, based on performance during competition, indicated that perceptual training significantly improved shooting accuracy pre- to post-intervention. No pre- to post-test differences were observed for the control group on the measures reported. Conclusion: Significant improvements in visuo-motor control were reported after an 8-week intervention programme, as indexed by an earlier onset of QE, a prolonged QE duration and more economical gun barrel displacement and absolute peak velocity. These modifications led to increases in shooting accuracy pre- to post-test and in a measure of transfer involving a comparison of shooting scores in competitions pre- to post-intervention. Findings have implications for those examining the role of attention and gaze orientation in the organization of motor performance. In a more applied setting, the results identify a number of potential avenues for improving coaching strategies, including early gaze behavior training and video feedback to enhance performance. ### IS-SH07 Novel Modalities for Increasing Adherence to PA in Children: Exergaming

#### NOVEL MODALITIES FOR INCREASING PHYSICAL ACTIVITY AND REDUCING SEDENTARY BEHAVIOUR IN CHILDREN: EXERGAMING

STRATTON, G.

LIVERPOOL JOHN MOORES UNIVERSITY

The genre of exergaming began in the 1980s. Dance Dance Revolution sold over three million copies and was probably the pioneer of exergaming. Over the past decade, a number of devices and games have used exergaming to much success: the Sony EyeToy camera has sold over ten million units while Nintendo's Wii Fit has sold in excess of 21 million copies. Recently the X-Box Kinect having shipped 10 million sensors and forecasts suggest that this game will possibly break all previous records. In the UK more than 80 per cent of nine to 19-year-olds own a games console and 70 per cent play computer games online. The research literature in the area is growing rapidly although there are few prospective interventions on the effect of exergaming on increasing physical activity and decreasing sedentary behaviour. This presentation will review current research on exergaming in children and young people Increasing physical activity (PA) and reducing the time spent sedentary can favourably impact health in youth. Active video games discourage sedentary behaviour by incorporating PA into video gaming, and have the potential for increasing opportunities for, and the promotion of, PA. The aims of this workshop will be a) review current research on exergaming b) compare adolescents' energy expenditure (EE) whilst playing sedentary and active video games; c) to examine methodological approaches to assessing physical activity and sedentary behaviour related to active video games; d) to compare the physiological cost and enjoyment of active video gaming, e) to evaluate the effects of active video gaming interventions on children's habitual PA and sedentary time, behaviour preferences, and, body composition. At present more complex interventions that consider the wide range of PA and sedentary behaviour opportunities available to young people in the home environment appear necessary to benefit PA and health. Further, the novelty effect observed for active video game use supports the call for the production of new active video games that can sustain their interest.

#### WII KINETC WITH PHYSICAL ACTIVITY – ACTIVE VIDEO GAME PLAY IN OBESE CHILDREN

MCMANUS, A.

UNIVERSITY OF HONG KONG

Introduction Exercise is routinely recommended to obese children and adolescents as a means of attenuating risk of later cardiovascular disease, improving glycaemic control and limiting excessive weight gain. The traditional exercise paradigm, that at least 20 minutes of moderate-to-vigorous activity at least 3 days a week, will counteract specific risk factors related to cardio-metabolic diseases has dominated child and adolescent exercise prescription. Yet interventions utilizing this exercise prescription have generally failed those who are overweight or obese (Lobstein et al., 2004) Recently interest has been re-focused toward the role low-intensity exercise plays in metabolic

health and although evidence in children is limited it would appear that low-intensity exercise results in greater levels of lipid oxidation in comparison to the more commonly prescribed moderate-to-vigorous exercise (Lazzer et al., 2007). Furthermore, a number of low-intensity home-based exercise options in the form of activity-enhanced video game play or exergames (e.g., Wii, XBOX Kinect) are now available and being promoted as alternative exercise modalities for young people, particularly the overweight and obese. While it is likely that these activity-enhanced video game options are more feasible and sustainable compared to traditional moderate-to-vigorous intensity exercise, it is important to establish the level of play necessary to attain metabolic and clinical benefit. It is also important to establish whether compensation occurs during exergame interventions i.e., a parallel reduction in energy expenditure elsewhere in the day to compensate for the increase in energy expenditure from the exergame. Methods Data from our work on the use of exergames with overweight and obese children will be shared. Attention will be given to energy expenditure levels, as well as lipid oxidation rates during exergame play. We will also discuss the problem of compensation and whether this occurs during low-intensity activity-enhanced video game play. Discussion A greater understanding of the metabolic benefits which low-intensity exergames may confer in obese children and adolescents is of major importance if these games are going to be used for the treatment of obesity. ## THE USE OF NEW TECHNOLOGIES TO IMPROVE HEALTH: EXERGAMING AND EXCESSIVE USE

HUSSAIN, Z.

UNIVERSITY OF DERBY

Physical inactivity among young and old people is a serious health problem and could lead to lifestyle related illnesses such as diabetes and cardiovascular disease. It has been suggested that video game playing, television viewing and computer use are contributory factors that encourage sedentary lifestyles in young people. Although video game playing has often received a lot of criticism, more recent forms of video gaming technology, called Exergaming, may help to increase physical activity. Exergaming has experienced an increase in popularity especially with the advent of the Nintendo Wii, Microsoft Kinect and the Sony PlayStation Move. Research investigating the effectiveness of Exergaming and the negative consequences of excessive video game playing will be reviewed.

## Invited symposia

### IS-BN06 Intrinsic high and low running capacity: Models for health and disease

#### TRANSCRIPTOME – PHENOTYPE ASSOCIATIONS IN HIGH AND LOW CAPACITY RUNNER RATS

KAINULAINEN, H.

UNIVERSITY OF JYVÄSKYLÄ

A strong statistical association exists between low aerobic exercise capacity and complex metabolic diseases. The difference in aerobic endurance capacity between individuals is the sum of inborn capacity and that acquired via lifestyle activity. Despite much study, however, the explicit genetic programs for neither the intrinsic nor acquired components of aerobic capacity have been defined. To probe the linkage between low aerobic capacity and diminished health status, we utilized rat models of low and high intrinsic aerobic endurance running capacity that differ also in the risk for metabolic syndrome. We investigated in skeletal muscle gene network-phenotype relationships that might connect aerobic endurance capacity with metabolic disease risk factors. The comparison was performed between 12 high capacity runners (HCRs) and 12 low capacity runners (LCRs) from generation 18 of selection that differed by 615% for maximal treadmill endurance running capacity. Gene set enrichment analysis (GSEA), a statistical technique that relies on the principle that genes act as groups in a coordinated manner and not in isolation, was used to identify the subsets of genes that are congruently regulated within a given gene set. Centroids (centroid is the mean expression of the coregulated genes within a subset) are known to correlate with various systemic metabolic and physiological factors and may therefore be used to probe for gene expression patterns that are causative of complex metabolic diseases. On average, LCRs were heavier and had increased blood glucose, insulin, and triglycerides compared with HCRs. HCRs were higher for resting metabolic rate, voluntary activity, serum high density lipoproteins, muscle capillarity, and mitochondrial area. Bioinformatic analysis of the skeletal muscle gene expression data revealed significant differential expression for 239 genes in gastrocnemius muscle that can underlie at least part of the phenotypic differences for low and high intrinsic aerobic endurance capacity. Seven mean mRNA expression centroids, including tricarboxylic acid cycle, oxidative phosphorylation, fatty acid metabolism, PPAR signaling, and STAT3 pathways correlated significantly with several exercise capacity and disease risk phenotypes such as voluntary activity, insulin sensitivity, blood triglycerides, and fatty acids. These expression-phenotype correlations, together with diminished skeletal muscle capillarity and mitochondrial area in LCR rats, support the general hypothesis that an inherited intrinsic aerobic capacity can mediate a difference between health and disease.

#### EXPERIMENTAL MODELS OF COMPLEX DISEASE: A THERMODYNAMIC STRATEGY

BRITTON, S.L., KOCH, L.G.

UNIVERSITY OF MICHIGAN

Symposium Title: Intrinsic high and low running capacity: Models for health and disease. Steven Britton: Experimental Models of Complex Disease: A Thermodynamic Strategy Heikki Kainulainen: Transcriptome – phenotype associations in high and low capacity runner rats Jatin Burniston: Muscle proteome changes associated with differences in whole-animal aerobic capacity Experimental Models of Complex Disease: A Thermodynamic Strategy Britton, Steven L. and Koch, Lauren Gerard Background The statistical linkage between low aerobic capacity and low health initiated the idea that artificial selection for low and high treadmill running capacity might yield models that differ for disease risks (ca. 1988). Yet, we knew of no direct fundamental mechanisms that explained the strong link between aerobic function with morbidity and mortality: this made initiating a large-scale selection paradigm based solely upon clinical association an insufficient path. Our search for a predictable hypothesis led us to these two tenets: a) the transfer of energy to mediate the motion of atoms and molecules into function was the central obligatory feature of evolution, and b) disease process must be tightly associated with the mechanism underlying evolution. Temporal evaluation of earth's geochemical and fossil records supports the notion that development of atmospheric oxygen was mechanistically essential for evolution from single to multicellular complexity (1). The coupling of Ilya

Prigogine's (2) ideas about "energy dissipative structures" as they operate through Peter Mitchell's (3) chemi-osmotic theory of ATP formation provide explanation for evolution of complex organisms that are far from thermodynamic equilibrium. Outcome of Artificial Selection These ideas formed a qualitative logic that much of complex disease arises from spatial and/or temporal dysregulation of oxygen and ATP metabolism. Upon this theoretical base we started two-way selective breeding to develop strains of rats that contrast for intrinsic (i.e., untrained) aerobic treadmill running capacity in 1996 (4). The founding population was 168 genetically heterogeneous rats of the N: NIH outcrossed stock. Now at 28 generations of selection, the low capacity runners (LCR) and high capacity runners (HCR) differ by over 500% for endurance running capacity. The LCR display cardiovascular risks, features of the metabolic syndrome, accelerated aging, and reduced longevity. The HCR are higher for VO<sub>2</sub>max, heart function, blood high density lipoproteins (5), and state 3 mitochondrial function in skeletal muscle. These rats represent a potentially useful model for understanding the networks connecting exercise endurance capacity and complex disease risks at all levels of biologic organization. 1. ## MUSCLE PROTEOME CHANGES ASSOCIATED WITH DIFFERENCES IN WHOLE-ANIMAL AEROBIC CAPACITY.

BURNISTON, J.

LIVERPOOL JOHN MOORES UNIVERSITY

The proteome is the cell-specific protein complement of the genome and is what defines a cell and dictates its functional characteristics. High-capacity runner (HCR) and low-capacity runner (LCR) rats exhibit marked differences in functional capacity and susceptibility to disease that are likely to be underpinned by differences in their heart and skeletal muscle proteomes. Further to providing confirmation of mRNA findings, proteomic analysis offers the opportunity to discover site-specific post-translational modifications using an unbiased systems biology approach. Difference in-gel electrophoresis (DIGE) and sophisticated protein identification by tandem mass spectrometry (MS/MS) are important techniques in this endeavor. We have used these tools to construct detailed gel maps describing the abundance and different post-translational states of soluble muscle proteins. Image analysis of such maps can provide novel information regarding key features in cardiac and skeletal muscle that correlate with either enhanced whole-body aerobic capacity or susceptibility to cardiometabolic disease. The muscles analysed were from animals of generations 23 and 25 of selection. On average, the intrinsic running capacity of HCR was 5-fold greater than LCR. DIGE resolved almost 1000 gel spots in each striated muscle and the proteins within the majority of these spots were unambiguously identified by MS/MS analysis. Protein expression profiling detected 68 statistically significant ( $P < 0.05$ ; false discovery rate  $< 10\%$ , calculated using q-values) differences between HCR and LCR hearts. In skeletal muscle, 45 statistically significant differences were detected. The majority of differentially expressed proteins were associated with the Biological Processes category: generation of precursor metabolites and energy. In particular, each enzyme of the beta-oxidation pathway was modulated in the heart and differential expression of enzymes involved in branch-chain amino acid metabolism was a consistent feature in cardiac and skeletal muscle. These findings complement transcriptome data, but the majority of gene products were resolved as multiple isoelectric species. Thus, some of the differences in spot expression represent differences in post-translational modification not evident in microarray investigations. In particular we found novel modifications of metabolic enzymes and greater phosphorylation of molecular chaperones, including alpha B-crystallin and glucose-regulated protein 58 in LCR heart and skeletal muscle respectively. Our findings suggest selection on running capacity is associated with robust changes in energy metabolism and that the muscle proteome of LCR is exposed to greater oxidative stress.

## Invited symposia

### IS-PM09 Exercise and Energy Balance in Cancer Risk and Treatment

#### FIT OR FAT? EXERCISE AND ENERGY BALANCE IN CANCER RISK AND PROGNOSIS

ULRICH, C., STEINDORF, K.

GERMAN CANCER RESEARCH CENTER AND NATIONAL CENTER FOR TUMOR DISEASES (NCT) HEIDELBERG

Energy balance and its contributing factors (physical activity and body weight) are known to play a role in the primary prevention of cancer, but may also impact tertiary prevention, affecting the quality of life and prognosis of cancer patients. Low physical activity levels and overweight or obesity have been associated with increased risk of several types of cancer, particularly of the colorectum and postmenopausal breast (for physical activity) or the colorectum, postmenopausal breast, liver and esophagus (for obesity). Possible biologic mechanisms include influences on systemic inflammation, immune parameters, insulin-like growth factors, insulin resistance, steroid hormones, vitamin D status, and lipid metabolism. A novel possible mechanism linking energy balance to cancer risk includes effects on DNA repair capacity. Defects in DNA repair function foster carcinogenesis and intriguing preliminary evidence suggests that regular exercise results in an adaptive response of enhanced antioxidant defenses and perhaps DNA repair. Among cancer patients, initial clinical studies illustrate benefits of exercise training on quality of life or fatigue as well as fitness levels, strength and cachexia. Epidemiologic studies also suggest a positive influence of physical activity on prognosis, particularly for colorectal cancer patients. However, many questions remain regarding causality of the associations, interrelationships between exercise and body weight, and the most appropriate type and timing of exercise training for cancer patients to achieve the maximum benefit with minimal risks.

#### CANCER PREVENTION: THE EFFECT OF EXERCISE ON SEX HORMONES

CAMPBELL, K.L.

UNIVERSITY OF BRITISH COLUMBIA

Lower levels of physical activity and higher body weight and body fat are associated with an increased risk of postmenopausal breast cancer. One proposed mechanism for this association is through greater exposure to steroid hormones, particular estrogen. In postmenopausal women, the primary source of estrogen is conversion of steroid precursors into estrogen by adipose tissue. This presentation will: 1) provide an overview of cancer prevention intervention trials on sex hormones and 2) present findings from a recent diet and exercise intervention in postmenopausal women that collected subcutaneous adipose tissues samples and examined changes in adipose tissue gene expression.

**EXERCISE IN HEMATOPOIETIC STEM CELL TRANSPLANT PATIENTS – NEW STRATEGIES AND OUTCOMES**

WISKEMANN, J.1, JÄGER, D.2, BOHUS, M.3, NIES, R.1, HUBER, G.4, DREGER, P.5, ULRICH, C.M.1

1: NCT/DKFZ (HEIDELBERG, GERMANY), 2: NCT/UNIVERSITY CLINIC (HEIDELBERG, GERMANY), 3: CIMH (MANNHEIM, GERMANY), 4: ISSS (HEIDELBERG, GERMANY), 5: UNIVERSITY CLINIC (HEIDELBERG, GERMANY)

EXERCISE IN HEMATOPOIETIC STEM CELL TRANSPLANT PATIENTS – NEW STRATEGIES AND OUTCOMES Wiskemann, J.1, Jäger, D.2, Bohus, M.3, Nies, R.1, Huber, G.4, Dreger, P.5, Ulrich, C.M.1 1: NCT/DKFZ (Heidelberg, Germany), 2: NCT/University Clinic (Heidelberg, Germany), 3: CIMH (Mannheim, Germany), 4: ISSS (Heidelberg, Germany), 5: University Clinic (Heidelberg, Germany) Introduction Before, during and after allogeneic hematopoietic stem cell transplantation (allo-HSCT) patients experience considerable physical, psychological and psychosocial distress. Besides GvHD and infections, particularly reduced physical performance and functioning as well as high levels of fatigue affect patient's quality of life negatively (Kovalszki et al., 2008). In light of the increasing numbers of successfully treated patients the need is growing for evidence-based adjuvant therapy options, which reduce treatment-related side effects and consequently enhance the rehabilitation process. Physical exercise therapy constitutes a potentially promising intervention to support the stem cell transplantation process (Wiskemann et al., 2008). Methods In a multicenter RCT, founded by the German José Carreras Leukaemia Foundation, 112 patients were equally randomised to an exercise (EX) and a social contact group (Control). Exercisers trained in a home-based setting prior to hospital admission, during inpatient treatment and a 6-8 weeks period after discharge (partly self-administered with an intervention manual and DVD). Physical performance was assessed via 6-minute walk test and handheld dynamometry, fatigue via Multidimensional Fatigue Inventory (MFI) and QoL via EORTC-QLQ-C30. Overall distress was ascertained by the NCCN distress thermometer. Results EX showed significantly improvement in fatigue scores (up to 15% improvement in EX vs. up to 28% deterioration in Control; p-values <0.01-0.03), physical fitness/functioning (p-values 0.02-0.03) and global distress (p=0.03). All effects were at least detectable at one assessment time point after hospitalization or repeatedly. Physical fitness correlated significantly with all reported symptoms/variables. Discussion Our study demonstrates that a partly-supervised exercise intervention that is initiated prior to HSCT and continues post discharge significantly reduced cancer-related fatigue and improves the secondary outcome parameters physical capacity, functioning, anger/hostility, pain and global distress, which are the most common and impairing adverse effects of allo-HSCT beside GvHD. Because of its low personnel effort (only partly supervised training during and telephone calling before and after hospitalization) the here tested exercise intervention can be easily integrated into standard supportive medical care. **12:00 - 13:15****Plenary sessions****PS-PL03 NEW HORIZONS: For (Para)Olympism in 2012 and Beyond****THE FUTURE OF OLYMPISM**

PARRY, J.

CHARLES UNIVERSITY IN PRAGUE

I have previously tried to outline a philosophy of Olympism, including a theory of sport and physical education, that represents our common humanity at both the interpersonal and the political levels, and that seems to me to be the essence of the optimism and hope of this and other forms of humanism and internationalism. (Parry, 2006) This paper enquires into possible future directions for the Olympic Movement and its Games. Firstly, it will examine some of the external challenges to current conceptions and arrangements, such as the challenge of eastern thinkers to the cultural hegemony of the west and its pretensions to universality. Secondly, it will outline and examine some of the internal developments and emphases (i.e. within the IOC and the Olympic Movement), such as the focus culture and multi-culture, and on environmentalism. Thirdly, it will describe and discuss some recent developments and exemplars, including the introduction at the Youth Olympic Games of novel sport forms and events, and its emphasis on culture, education and festival. The paper will conclude with some thoughts as to likely future developments. Parry J, 2006, Sport and Olympism: Universals and Multiculturalism (Journal of the Philosophy of Sport, 33, pp. 188-204).

**PARA-OLYMPISM: SPORT AS PLAY VERSUS SPORT AS WORK**

NOAKES, T.

SPORTS SCIENCE INSTITUTE OF SOUTH AFRICA

I was 4 years old when Roger Bannister ran the mile in less than 4 minutes. Bannister trained for less than an hour a day and said that athletics could not be a real profession since it was not possible to train for more than 2-3 hours a day. So what did you do with the other 21 hours? Or with your life? I find modern international sport much less compelling than in the pre-professional era which perhaps ended with the 1968 Olympics. There athletes from East Germany competed for the first time as a country separate from (West) Germany. The success of East German (and Russian) athletes in Olympic competition added a new political edge to global sporting competition. No longer was sport purely about inter-individual competition. Instead sport became saddled with novel responsibilities that would change the focus of its top participants increasingly from players to workers. With the potential for a significant downside that becomes ever more apparent with each passing year as yet another global sporting icon falls prey to one or other misbehaviour. Most Para-Olympians at least in my country exist in the pre-professional era; they are overwhelming sports players not sports workers. The incentives to perform come wholly from within; the financial incentives to be successful are almost non-existent. Instead other forces must inspire their continuous search for sporting excellence. The existence of the Para-Olympic movement invites the interesting question: What is the cost of sports work? What happens to those who devote their childhood to the pursuit of sports work but who ultimately fail to join the ranks of those few icons who succeed. This question is especially relevant in the developing world from which I come. Professional sport in my country is simply unable to provide job security for anything more than a few hundred professional sportsmen and women at any time. Yet tens of thousand, perhaps more, live out their childhoods in dreams of becoming professional athletes only to discover too late the

extent of their and often their parent's and their nation's deception. As sports coaches, sports doctors and exercise scientists we play an important part in that deception. Our contribution is not neutral; we are part of the problem. In contrast many Para-Olympians are introduced to sport only after they experience a life-changing physical challenge for which the search for sporting perfection seems the ideal antidote. Para-Olympians have re-defined our understanding of what it is to be differently abled. Perhaps they can also help us better to understand which elements of competitive international sport need to be nurtured and conversely what we can be discarded if international sporting competition is to avoid the fate that befell the original Greek Olympic Games.

##### EFFECTS OF PACING STRATEGY ON PERFORMANCE AND ANAEROBIC ENERGY CONTRIBUTION DURING MAXIMAL PEDALING

KITADA, T., SASAKI, H., NAITO, H.

JUNTENDO UNIVERSITY, OSAKA INTERNATIONAL UNIVERSITY

**Introduction** During maximal exercise lasting for approximately 1 min, anaerobic energy supply accounts for 50-60% of the total energy supplies (Gastin, 2001). For a high intensity short exercise, the performance outcome largely depends on the pacing strategy, especially in the first half of the race (Saraslanidis et al., 2010), with several race paces being selected by different individuals. It is however not clear how varying paces in the first half of the race affects the contribution of anaerobic energy supply throughout the entire race. This study therefore aimed to investigate the influence of different pacing strategies on performance (total work per body mass) and anaerobic energy contribution during maximal 1-min pedaling. **Methods** Five 400-m runners (best 400-m record:  $60.2 \pm 1.0$  -s, age: 20-22 y-o, mass:  $52.1 \pm 3.3$  kg) volunteered for this study. Subjects were familiarized with the testing procedures of the bicycle exercise before the testing. During the test, subjects performed maximal bicycle pedaling on a cycle ergometer (load equivalent to 6% body mass, kp) for 1 min with similar racing strategies to their own 400-m race. In the following days on two occasions, the self-paced cadence in the first 30-s was increased (fast) or decreased (slow) by 5 % and the subjects pedaled again for 1-min for the best performance. The total work was calculated from the cadences and exercise load. Oxygen uptake and oxygen debt were obtained by collecting expired gas in Douglas bags at rest, during exercise and the recovery for each condition. Anaerobic energy contribution was determined by dividing the oxygen debt by the oxygen demand. **Results** Both the total work per body mass (self-paced:  $37.7 \pm 1.3$ , fast:  $35.6 \pm 0.6$ , slow:  $34.6 \pm 1.4$  kpm  $\cdot$  kg $^{-1}$ ,  $p = 0.001$ ) and anaerobic energy contribution (self-paced:  $73.5 \pm 3.7$ , fast:  $67.0 \pm 8.0$ , slow:  $66.8 \pm 5.4$  %,  $p = 0.029$ ) were greatest for the self-selected pace. The correlation between the total work and the 400-m record was relatively high ( $r = 0.813$ ), but was not statistically significant. **Conclusion** Changing the pace strategies in the first half of exercise affected the total work and anaerobic energy contribution, with the self-selected pace resulting in the greatest values. 400-m runners appear to have selected the optimum pace strategy already through their racing experience. **References** Gastin PB. Energy system interaction and relative contribution during maximal exercise. *Sports Med.* 2001, 31(10):725-41. Saraslanidis PJ, Panoutsakopoulos V, Tsalis GA, Kyprianou E. The effect of different first 200-m pacing strategies on blood lactate and biomechanical parameters of the 400-m sprint. *Eur J Appl Physiol.* 2010, DOI 10.1007/s00421-010-1772-4.

##### EFFECT OF LOW-INTENSITY CYCLING EXERCISE WITH SKIN COOLING ON INTRAMUSCULAR OXYGEN SATURATION AND GAS EXCHANGE RESPONSES

NAITO, Y.1, YONA, M.2, SHIMOSE, R.3, SUGAWARA, H.3, TADANO, C.3, MURO, M.3

1:KOKUSHIKAN UNIVERSITY(TOKYO,JAPAN),2: TUPLS(TOKYO, JAPAN), 3: TUMS(TOKYO, JAPAN)

**(Introduction)** Stimulation of the skin's cold receptors in working muscle changes the pattern of motor unit recruitment during sub maximal voluntary contraction. Our recent study has shown that low-intensity aerobic training with skin cooling increased muscle strength. The purpose of this study was to investigate the effect of skin cooling on muscle deoxygenation and cardio respiratory function during low intensity cycling exercise. **(Methods)** Seven healthy male (age:  $26.2 \pm 8.7$ yr,  $\text{VO}_{2\text{max}}$ :  $54.6 \pm 10.2$  ml/kg/min) participated in this study. All participants performed two cycling exercise trials corresponding to 80% anaerobic threshold (AT) intensity for 15 minutes with skin cooling and without skin cooling as a control. Pedal frequency was 60rpm. Maximum  $\text{VO}_2$  was measured on separate days and AT was determined by V-slope. Skin surface cooling was applied to the quadriceps femoris muscle by circulating water at 5 degrees through cooling pads (Japan Sigma Co.). The mean skin temperature was maintained at 25-26 degrees during exercise. Pulmonary gas exchange and ventilation were measured continuously using a gas analysis system, and beat to beat heart rate (HR) was recorded continuously by a three-lead electrocardiogram. Additionally, EMG activity and intramuscular oxygen saturation of the right vastus lateralis were measured. This muscle oxygenation status was monitored by near infrared spectroscopy (Omegawave, Tokyo Japan). **(Results & Discussion)** The EMG activity during exercise was significantly higher with skin cooling than the control. Additionally, the intramuscular oxygen saturation level during exercise with skin cooling was significantly lower than control. There were no significant differences in oxygen uptake and HR during exercise between skin cooling and the control. On the other hand, skin cooling increased  $\text{VCO}_2$  values and respiratory exchange ratio during exercise compared with control. Thus, skin cooling had a significant effect on the physiological responses, except for HR during low intensity endurance exercise. Moreover, this study demonstrated that skin cooling during aerobic exercise influences muscle activity and the intramuscular oxygen environment, both of which play an important role in exercise induced muscular hypertrophy.

## THE FOUR WEEKS AQUA CYCLING TRAINING FOR TRI-ATHLETES VS DETRAINING EFFECTS: STUDY OF THE CARDIO METABOLIC PARAMETERS.

COLLU, G.1, MILIA, R.1, FARA, A.2

1 LABS (LABORATORY OF SPORTS AND PHYSIOLOGY, UNIVERSITY OF CAGLIARI) – 2 REGIONAL SCHOOL OF SPORT OF SARDINIA, REGIONAL OLYMPIC COMMITTEE, ITALY

**Introduction** The effects of the Detraining on the cardio metabolic parameters are well known and, above all on athletes that practice sport characterized by a great volume of training, they result to be more determinants to the goals of the performance. Triathlon is a plural-sports characterized by manifold stimuli (run - bicycling - swimming), for which the preparation and the different distances of competition are united for the load of prevailing training in running and biking; nevertheless the tri-athletes has also a discreet aquatic motor abilities. This study was set to analyze if during a phase of rest the practice of a period of Aqua Cycling training following a short and intense protocol, could be an effective training of maintenance to make to practice to the Tri-athletes. **Methods** 9 male athletes at Italian national level, homogeneous for category according to the rule of the Italian Federation Triathlon (age  $39.2 \pm 13.2$  years, weight  $73.5 \pm 4.5$  kg, height  $178 \pm 9$  cm) agreed to participate in this investigation. In a first phase they were submitted to an incremental test to exhaustion with the use of the Hydro Bikes (Hydrosider Professional -Italy) with incremental RPM (frequencies of pedaled) every 2 min. During the test they wore a portable metabolic device (VO2000, MedicGraphics, USA) and data of maximal oxygen uptake ( $\text{Vo}_{2\text{max}}$ ), maximal heart rate ( $\text{HR}_{\text{max}}$ ) and anaerobic threshold (AT) were gathered. Subsequently they have participated in 10 sessions of Aqua Cycling (training: 30 min, freq.: 3 times week, duration: 4 weeks) following a protocol of training type Interval Training 4' : 3' x 4 (references 1 - 2). After such period and with the same materials and methods they have been repeated the incremental test to exhaustion. **Results** Statistic analysis revealed that the values of  $\text{Vo}_{2\text{max}}$ , HR and AT have not statistically had any meaningful increases but that the same are also maintained unchanged after the period of training effected with the Aqua Cycling. **Discussion** Results of the present study reveal that a protocol of training with Aqua Cycling of brief duration and high intensity can also oppose the detraining effects in athletes that usually practise great volumes of training. **References** Di Prampero, (1985) The human locomotion on earth, in water, in air. *edi-ermes*. 1- Impellizzeri F. ## POWER PROFILES OF CIRCUIT RACES IN FEMALE COMPETITIVE CYCLISTS

SCHMIDT, A., KILIAN, Y., ROTH, R.

DEUTSCHE SPORHOCHSCHULE KÖLN

**Introduction** This study aims to characterise the demands and exercise intensity of women's criterium races, to reveal how the lengths of a circuit race track influence the power profile and to compare these results with demands of men's criterium races and women's road races. Previous studies investigated the exercise intensity via heart rate recordings. However, it is the mechanical power output, which reveals the most accurate information about exercise intensity. **Methods** SRM power output profiles (SRM, Jülich, D) were collected from 22 criterium races (mean  $\pm$  SD; distance:  $42.31 \pm 7.82$  km; duration:  $67:28 \pm 13:40$  min; number of laps:  $26 \pm 15$ ; distance of laps:  $3.08 \pm 3.10$  km; number of curves:  $100 \pm 62$ ) run by five female cyclists (mean  $\pm$  SD; age:  $29.0 \pm 5.1$  years; body mass:  $56.6 \pm 5.0$  kg; height:  $165.4 \pm 5.5$  cm; BMI:  $20.7 \pm 1.1$  kg/m<sup>2</sup>; race experience:  $5.2 \pm 6.1$  years). Power controls recorded power (W), cadence (rpm), distance (km), speed (km/h) and heart rate (bpm) with a recording interval of one second. **Results** The competitive female cyclists in this study performed an average power of  $194.50 \pm 18.52$  W ( $3.45 \pm 0.32$  W/kg). In 28.89 per cent of the race time the power ranges from 0 – 99 W ( $0 - 2$  W/kg; 31.11 %). In contrast to the relatively constant heart rate, the power, measured during the race, varied to a large extent. Mean values for the heart rate and cadence were  $182.11 \pm 7.00$  bpm and  $90.42 \pm 5.69$  rpm. A total and remarkably high number of 175.42 kicks and 175.15 breaks between pedalling was counted averagely during one race. Concomitantly, a significant correlation between the length of a circuit and the number of power peaks above 8 W/kg and 10 W/kg could be found. The data used in this study reveals that there are more peaks on a shorter circuit than on longer ones. During the race a significant decrease of the power can be observed. This means that power, which is performed at the beginning of a race, cannot be kept on the initial level during the whole race due to local muscle fatigue. **Discussion** In contrast to road races, which show rather constant exercise intensity for the cyclist, circuits can be characterised through the intermittent peaks of power. In comparison to the power profiles of men's criterium races, the relative power output is similar to the women's data ( $3.45 \pm 0.32$  for women and  $3.51 \pm 0.36$  for men). However, the longer distance and duration of the men's races might distort this comparison. In conclusion, the intermittent exercise intensity during the race implies that training focused on the anaerobic capacities, strength and the abilities to sprint can be beneficial for a successful performance in criterium races. **References** Ebert, T.; Martin, D.; Stephens, B.; Withers, R. ## TIME TO EXHAUSTION AT MAXIMAL LACTATE STEADY STATE DURING CYCLING INTERMITTENT EXERCISE

GUGLIELMO, L.G.A.1, GROSSL, T.1, DE LUCAS, R.D.1, DE SOUZA, K.M.1, COSTA, V.P.1

FEDERAL UNIVERSITY OF SANTA CATARINA

**Introduction** The maximal lactate steady state intensity ( $w\text{MLSS}$ ) is usually determined by continuous protocols of 30 min. However, the prescription of aerobic training in sports like cycling and swimming is also conducted intermittently. Thus, the aim of this study was to analyse the time to exhaustion (TTE) and physiological response at  $w\text{MLSS}$  determined by cycling intermittent exercise ( $w\text{MLSS}_{\text{int}}$ ). **Methods** Fourteen trained cyclists performed a maximal incremental test followed by 3-5 visits to measure the  $w\text{MLSS}_{\text{int}}$ . Later, the subjects performed a TTE test in intermittent protocol until exhaustion. The intermittent tests were performed with exercise/rest ratio of 5:1. Blood samples were collected at 110, 230 and 350 min to determine the  $w\text{MLSS}_{\text{int}}$ . The  $w\text{MLSS}$  was defined as the highest [La] that increased by no more than 1.0 mM during the end 20 min of net working time. Oxygen uptake ( $\text{VO}_2$ ) and pulmonary ventilation (VE) were measured breath-by-breath. Heart rate (HR) was recorded continuously.  $\text{VO}_2$ , VE and HR were analysed as percentage of TTE ( $\text{t}20\%$ ,  $\text{t}40\%$ ,  $\text{t}60\%$ ,  $\text{t}80\%$  and  $\text{t}100\%$ ). Blood lactate samples were analysed at min 110, 230, 350 ( $\text{t}_1$ ,  $\text{t}_2$ ,  $\text{t}_3$ , respectively) and at exhaustion ( $\text{t}_{\text{end}}$ ). One-way ANOVA with repeated measures was used ( $p < 0.05$ ). **Results** TTE at  $w\text{MLSS}_{\text{int}}$  was  $67.8 \pm 14.3$  min. Blood lactate at  $\text{t}_{\text{end}}$  ( $5.5 \pm 1.8$  mM) was significantly higher than  $\text{t}_1$ ,  $\text{t}_2$  and  $\text{t}_3$  ( $4.3 \pm 1.0$ ;  $4.8 \pm 1.1$ ; and  $4.9 \pm 1.2$  mM, respectively). VE increased over a time ( $89.6 \pm 12.6$  vs.  $113.3 \pm 23.4$  L•min;  $p < 0.05$ ). Also, HR increased over a time ( $166 \pm 8$  vs.  $179 \pm 7$  bpm;  $p < 0.05$ ). On the other hand,  $\text{VO}_2$  did not rise

significantly between  $\dot{V}O_2$  and  $\dot{V}O_{2\max}$  ( $50.1 \pm 7.3$  vs.  $50.6 \pm 7.7$  mL•kg<sup>-1</sup>•min<sup>-1</sup>). Discussion The TTE found at wMLSSint was supposedly higher than TTE found by Baron et al. (2008) and Fontana et al. (2009) during continuous protocol. The increase in HR and VE values between  $\dot{V}O_2$  and  $\dot{V}O_{2\max}$  are in agreement with Baron et al. (2008) and Lajoie et al. (2000). Furthermore, Baron et al. (2008) also found that  $\dot{V}O_2$  on TTE did not rise between  $\dot{V}O_2$  and  $\dot{V}O_{2\max}$ . In contrast, Lajoie et al. (2000) found that  $\dot{V}O_2$  increased over a time. We found a tendency of [La] accumulation after the 30th min of exercise. A supposed mechanism that could be highlighted to elucidate our finding is the greater recruitment of type II fibres after 30 min of exercise. ## 6-5 MAXIMAL CYCLING SPRINT TEST: THE PREDICTION OF OPTIMUM LOADING FOR MAXIMIZING MUSCLE POWER OUTPUT

NEDELJKOVIC, A.

UNIVERSITY OF BELGRADE, FACULTY OF SPORT AND PHYSICAL EDUCATION

6-s MAXIMAL CYCLING SPRINT TEST: THE PREDICTION OF OPTIMUM LOADING FOR MAXIMIZING MUSCLE POWER OUTPUT Nedeljkovic, A.1, Pazin, N.1, Bozic, P.2, Berjan, B.2, Jaric, S.3 1: Faculty of Sport and Physical Education (Belgrade, Serbia), 2: Serbian Institute of Sport (Belgrade, Serbia), 3: University of Delaware (Newark, USA) Introduction 6-s maximal cycling sprint test has been widely used for the assessment of muscle power output (MPO). It has been generally presumed that there is an optimum external loading (Lopt) that allows for the muscular system to maximize MPO (Hill, 1938). In cycling task, Lopt has been shown to be within 5-10% of body weight (BW) for Wingate test (Dotan and Bar-Or, 1983) or 5-12% of BW for 6-s maximal cycling sprint test (Pazin et al., 2011). The aim of this study was to investigate the regression model that could predict Lopt. Since the higher relative loads could be more sensitive for the differences among MPO recorded in individuals with different training history (Pazin et al., 2011), we hypothesized that the relation between Lopt and MPO would be higher for higher relative loads. Methods Forty-one healthy male subjects with different training history were tested through the standard 6-s maximal cycling sprint test protocol on a mechanically braked cycle ergometer (834 E, Monark). Eight different loads relative to the subjects' body weight (i.e., 5-12% of BW) were applied. In order to determine Lopt, the obtained data were plotted for each individual subject and a second order polynomial regression was employed to assess the changes in MPO associated with changes in loading conditions (Pazin et al., 2011). Thereafter, the obtained Lopt were plotted against the recorded MPO normalized for BW (i.e., W/kg0.67). The calculated linear regression model and corresponding correlation coefficients were taken for further analysis. Results The applied second order polynomial regression revealed the average value of Lopt 8.9% of BW (range: 5.6-11.4%). The calculated linear regression models appear to be relatively stable across different loading conditions. The corresponding correlation coefficients (R<sup>2</sup>) were: 0.21, 0.20, 0.31, 0.34, 0.44, 0.58, 0.61 and 0.72, calculated for 5-12% of BW, respectively. Discussion The relatively stable outcomes of the conducted analysis suggest that the applied regression model could be considered as a valid method for the prediction of Lopt. The hypothesized higher correlation coefficients indicate increased significance of the prediction model when the higher relative loads are used (i.e., 12% of BW). The valid prediction of Lopt that maximize MPO could be of utmost importance for improvement of routine testing of neuromuscular system and its adaptations to training and rehabilitation procedures. ## EFFECT OF VIRTUAL REALITY DURING INDOOR CYCLING ON TIME TRIAL PERFORMANCE

BORGHOUTS, L.B., OOMEN, J.M.

FONTYS UNIVERSITY OF APPLIED SCIENCES

Introduction Indoor cycle trainers have been developed that simulate 'real life' conditions by providing means for video feedback with synchronized power fluctuations. While they view digital video from the course, cycling speed of the video is controlled by power output, and realistic power fluctuations are simulated on ascents and descents. Studies have suggested enhanced training motivation through virtual reality cycling (1-2). It is unclear whether this leads to an increase in actual cycling performance. We hypothesized that virtual reality-enhanced indoor cycling would lead to a better performance on a 48 km time trial. Methods Seventeen male well-trained cyclists age 34(11); maximal power 350(58); maximal heart rate 190(9) were recruited for the study. Subjects cycled an incremental maximal exercise test, and thereafter the virtual reality cycling time trial (VRC), and the same time trial test without video (CON) (random order) on a Tacx Fortius Multiplayer cycletrainer (Tacx b.v., the Netherlands). Subjects cycled 48 km of the Pro Tour cycling classic 'Amstel Gold Race'. Measurements: power output, speed, cadence, time to completion, heart rate and Borg-score. After the study participants were asked whether they favored VRC, CON or neither condition. Participants had no feedback of any of these parameters during the investigation. Paired samples T-tests were used to assess significant differences between groups. Results Data are mean (SD). Time to completion was 90m24s (10m10s) vs. 89m54s (9m12s) in VRC vs. CON (NS). Heart rate was 156(8) vs. 156(9). There were no significant differences in any of the other performance parameters between the two conditions. Ratings of perceived exertion were identical with an average Borg-score of 14 (1) in both VRC and CON. All but one participant (94%) subjectively favored the VRC to CON time trial test. Discussion The current study demonstrated that virtual reality cycling does not elicit a performance increase during a time trial compared to a control time trial without video. Perceived exertion was also unaltered by video feedback. Participants may have been well able to maximize their motivation and performance level at a given distance and course irrespective of video feedback being present. Although we found no direct effect on cycling performance, VRC might promote training adherence and thus enhance performance in the long term, since participants favored the VRC to CON time trial test. ## DIURNAL EVOLUTION OF CYCLING BIOMECHANICAL PARAMETERS DURING A 60-SECOND WINGATE TEST

GAUTHIER, A., LERICOLLAIS, R., BESSOT, N., DAVENNE, D.

INSERM ERI 27

DIURNAL EVOLUTION OF CYCLING BIOMECHANICAL PARAMETERS DURING A 60-SECOND WINGATE TEST Gauthier, A., Lericollais, R., Bessot, N., Davenne, D., INSERM, ERI27, Caen, F-14000 France; Univ Caen, Caen, F-14000 France Introduction The power recorded during the Wingate test presents a circadian rhythm which can be partly explained by (i) the higher level of motivation (Racinais et al., 2005), (ii) the

higher rate of strength developed by the lower limb (Nicolas et al., 2005), (iii) the higher aerobic contribution to energy release (Souissi et al., 2007) and (iv) the higher body temperature (Souissi et al., 2007) in the evening than in the morning. However, the movement involved during a Wingate test is complex and requiring several muscular chains based on a free pedal rate. Consequently, we have hypothesized that the freedom and complexity of pedalling allow for adaptations in movement patterns at different time of day, in order to help to maintain higher performance in the evening. The aim of this study was to examine the evolution of biomechanical cycling parameters during a fatigue exercise at two times of day. Methods 20 active male subjects were asked to perform a 60-second Wingate test at 06:00 and 18:00 h. Two classical parameters of the Wingate test were analyzed: the Peak Power (PP) and the Mean Power over 60 s (MP60s). The evolution in 30 averaged power output values throughout the Wingate test was used to evaluate and describe the fatigue phenomenon. Kinematic variables were measured during 2 intervals Wingate test: I1 from the 5 to the 20th s and I2 from the 45 to the 60th s. The mobilization of ankle, knee and hip was characterized by studying 2 parameters: the mean angle and the range of motion (ROM). Results PP and MP60s were significantly higher at 18:00 than at 06:00 h. Power output value decrease revealed 2 distinct phases. From the 4 to 20th s, all power output values recorded at 18:00 h were higher than those values recorded at 06:00 h, while from the 22nd to the end these values were not significantly different. The ROM of the ankle angle recorded during I1 was significant lower at 18:00 h than at 06:00 h. The diurnal changes in ankle ROM showed correlation ( $r = -0.68$ ) with the diurnal fluctuation in power outputs. Discussion These results indicate a greater progression of fatigue in the evening than in the morning. In addition, the diurnal changes in power outputs can be mainly associated with modifications in cycling kinematic parameters. This phenomenon has a direct influence on performance and fatigue. These data lead us to believe that there could be diurnal adaptations in pedalling movement allowing an optimization in movement in the evening. ### PHYSIOLOGICAL CHANGES CAUSED BY SMALL VARIATIONS IN SADDLE HEIGHT IN ELITE UNDER-23 PORTUGUESE CYCLISTS.

SANTOS, A.M.C., MENDES, G.R., FONTES RIBEIRO, C.A.  
UNIVERSIDADE DE COIMBRA

**Introduction** The optimization of the relationship between the cyclist and the bike is important for performance maximization. There are only a few studies with elite cyclists, and the published studies used large changes of the saddle height. Thus, this study aimed to observe physiological variations with a sub-maximal laboratory test when vertical changes of the saddle position (DVS) occurs. **Methods** Ten cyclists, aged  $22.2 \pm 2.3$  years old, presented a body mass, stature, sitting height and skinfolds sum (triceps, subscapular, suprailiac, abdominal, anterior mid-thigh and medial calf) of  $67.1 \pm 5.8$  kg,  $172.3 \pm 7.5$  cm,  $90.8 \pm 3.2$  cm and  $47.3 \pm 2.08$  mm, respectively. Geometrical variables of the cyclists' bikes were also measured, and questionnaires about their athletic past and saddle positioning were given. A sub-maximal test with VO<sub>2</sub> and heart rate determination was performed in three saddle positions (reference position (REF), REF plus 2.5% of the DVS and REF minus 2.5% of the DVS). The drawing back of the saddle (RS) and the height between the handle-bar and the base of the saddle were held constant in all of the tests. The load and frequency on the pedal thrust used in the sub-maximal tests were individualized, corresponding to the anaerobic lactate threshold (LAL) values obtained from each cyclist in a previous direct maximum test. The sub-maximal tests of each saddle position were randomly done on the same day. The athletes pedalled for 11 min (8 with a load equal to their LAL), followed by an active and passive recovery of 5 and 15 min between each position. Capillary lactate analyses were performed before and after the tests. **Results** The symphysis pubis height (SP) correlated with the DVS ( $r=0.959$ ;  $p<0.01$ ) and with the height of the saddle (AS) ( $r=0.958$ ;  $p<0.01$ ). In spite of being able to observe an elevated correlation between the SP with the DVS and the AS, the adjustment of the saddle position for the cyclist by the mean of the SP or trochanteric height might lead to considerable differences in the adjustments (of the saddle position) when compared with the individual adjustment. **Discussion** Among the physiological variables measured in this study, VO<sub>2</sub> was the most sensitive to the variation of vertical saddle position, establishing a valid criterion for optimization. VO<sub>2</sub> was influenced by the variation of the saddle position, but the rising and lowering of its position had not just led to a single tendency concerning VO<sub>2</sub> variation. Our results concerning saddle position and VO<sub>2</sub> do not agree with other studies. Our work suggests that the best saddle position for competing cyclists is an individualized task and should be done with the direct measuring of physiological and biomechanical variables.

### EFFECT OF CADENCE ON BOTH CRITICAL POWER AND THE END POWER OF A 3-MIN ALL-OUT ISOKINETIC TEST

DEKERLE, J.  
UNIVERSITY OF BRIGHTON

**Introduction** The end power of a 3-min non-isokinetic all-out test (EP) has been suggested to represent the boundary between the severe and heavy intensity domains (Burnley et al., 2006). One piece of evidence was the non significant difference found between EP and the asymptote of the power – time relationship (Critical Power, CP; Vanhalato et al., 2007). If EP truly represents CP, a cadence-induced change in CP (Barker et al., 2006) should be mirrored by a change in EP. The present study aimed at testing the relationship between EP and CP at two different cadences (60 vs 100 rpm) with the 3-min all-out test performed in an isokinetic mode. **Methods** Nine habitually active subjects completed an exhaustive ramp test, two 3-min all-out isokinetic tests to establish EP (EP-60 and EP-100) and eight predicting exhaustive trials to establish CP (CP-60 and CP-100). CP was represented by the intercept of the P-1/time relationship ( $P = CP + W'/t$ ). All tests were performed on an electrically-braked cycle (Schoberer Rad Messtechnik with 8 strain gauges, SRM, Germany). **Results** The Maximal Minute Power at the end of the ramp test was  $315 \pm 55$  W. EP-60 ( $247 \pm 46$  W;  $P<0.01$ ) was systematically and significantly lower than CP-60 ( $228 \pm 47$  W). The two sets of data were significantly correlated ( $r=0.95$ ;  $P<0.01$ ). The bias  $\pm$  95% level of confidence were  $-18 \pm 26$  W with intra-individual differences ranging from  $-29$  to  $+2$  W. EP-100 ( $236 \pm 53$  W) was significantly lower than CP-100 ( $207 \pm 41$  W) with a significant correlation being the two sets of data ( $r=0.74$ ;  $P<0.05$ ). The bias  $\pm$  95% level of confidence were  $-30 \pm 69$  W with intra-individual differences ranging from  $-79$  to  $+13$  W. Mean CP-60 and CP-100 were not significantly different ( $P=0.06$ ) and were significantly correlated ( $r=0.76$ ;  $P<0.05$ ). Mean EP-60 and EP-100 were not significantly different ( $P=0.34$ ) and were significantly correlated ( $r=0.83$ ;  $P<0.05$ ). **Discussion** EP has previously been reported to be sensitive to training-induced changes in CP (Vanhalato et al., 2008). The physiological responses during constant-load exercise performed just above and below EP have been shown to characterise the severe and heavy intensity domains respectively (Burnley et al., 2006) leading the authors to conclude a 3-min all-out test provides a good estimation of CP (Vanhalato et al., 2007). In the present study, strong correlations were indeed found between the two sets of EP and CP values but with EP underestimating CP at both cadences ( $-9\%$  at 60 rpm and  $-15\%$  at 100 rpm). Interestingly, when a 3-min all-out test is performed in an isokinetic mode, EP does not correspond to CP. Therefore, an all-out test lasting 3 minutes should not be seen as an

alternative test to measure CP. References Barker T, Poole DC, Noble LM, Barstow TJ. (2006). *Exp Physiol*, 91(3), 621-632. Burnley M, Doust J, Vanhatalo A. ### EFFECT OF POLAR TRAINING LOAD-GUIDED VERSUS NON-GUIDED TRAINING IN CYCLISTS

BRUCH, A.3, KINNUNEN, H.2, STAPELFELDT, B.1,3

1 INSTITUT FÜR SPORTWISSENSCHAFT, UNIVERSITÄT FREIBURG, GERMANY 2 POLAR ELECTRO OY, KEMPELE, FINLAND 3 RADLABOR GMBH, FREIBURG, GERMANY

**Introduction** One possibility for finding the right balance between intensity and recovery is to calculate the impacts of different training sessions (1). In this study a new system based on the Training Load (TL) concept by Polar Electro Oy, Finland, was studied. TL aims to make different exercise sessions comparable in terms of adaptive or exhausting characteristics. Input information for TL are gender, weight, VO<sub>2</sub>max, HRmax, HRrest, lactate threshold (LT), and anaerobic threshold (IAT). This novel feature can be utilized by using PolarPersonal-Trainer.com service (PPT.com) and RS800CXBike Computer. The training software guides cyclists' training based on their individual Cumulative Training Load value (CTL) with a colour based system. **Methods** 22 competitive cyclists (11 males, 11 females) were randomised in a study group (PPT.com) and a control group (PPT) with 5 or 6 males and females in each group. The average VO<sub>2</sub>peak of PPT.com group was 58,3 ml/min/kg and VO<sub>2</sub>peak of PPT group was 60,3 ml/min/kg with an average training time of 15h/week. All subjects trained for 8 weeks, PPT.com group guided by the Polar RS800CXBike and PPT.com, PPT group without guiding. At the beginning and end of the study a standardized incremental exercise test (IET) was performed on a SRM-ergometer (Schoberer Rad Messtechnik, Jülich, Germany). Two subjects dropped out of the study due to illness. **Results** PPT.com group completed on average 49 training sessions with an average HR of 133 bpm and an average duration of 133 min. PPT group completed on average 55 training sessions with an average HR of 138 bpm and an average duration of 116 min. CTL was significantly lower in PPT.com group regarding the following parameters: CTL before ( $p=0,013$ ) and CTL after training ( $p=0,049$ ), CTL impact of all training sessions ( $p=0,048$ ). PPT.com group had significantly less too intense training sessions, according to CTL limits ( $p=0,038$ ). In PPT.com group power output increased on average 0,33 W/kg at IAT ( $p=0,0086$ ) and 0,15 W/kg at Pmax ( $p=0,039$ ). In PPT group power output increased on average 0,22 W/kg at IAT ( $p=0,011$ ) and 0,05 W/kg at Pmax ( $p=0,63$ ). **Discussion** PPT.com and PPT group had similar training time while PPT.com group had fewer but longer training sessions with lower training intensity. Training analysis in terms of CTL clearly documented the difference in training intensity. Nearly all calculated CTL markers showed significant differences between PPT.com and PPT groups. Pre and post IET predominantly showed significant improvements at both thresholds and Pmax in both groups, PPT.com group tending to get higher increases. PPT.com group achieved slightly higher increase of performance with similar training time at significantly lower average intensity. **References** 1 BANISTER E.W., MORTON R.H., FITZ-CLARKE J. (1992): Dose/Response Effects of Exercise Modeled from Training: Physical and Biochemical Measures. *Ann. Physiol. Anthropol.*, 11(3): 345-356.

### REST HRV FOR PROFESSIONAL CYCLISTS DURING 2010 TOUR OF SPAIN.

NAVARRO, D., PARDO, A., ZAHONERO, J., ALIS, R., ROMAGNOLI, M.

CATHOLIC UNIVERSITY OF VALENCIA

**Introduction** Knowing the effect of effort during training or competition is one of the concerns of coaches and trainers. This information is important in all sports, but especially in cycling where the results depend directly on the physiological parameters (Faria, Parker et al. 2005). Thus in the Grand Tours of cycling, knowing the effort in each stage, through non-invasive means such as registration of heart rate variability (HRV) is a key element for the control of the athlete. Heart rate variability is related to the modulation of autonomic nervous system (sympathetic and parasympathetic) (Task Force 1996). In this study we try to find a relationship between effort on previous stage and HRV at rest day on early morning, for professional cyclists on Tour of Spain 2010. **Methods** 4 professional cyclists participated in the study (age:  $28 \pm 2.6$ ) during the Tour of Spain 2010. HRV records were taken at rest immediately after waking. Also monitored the heart rate of cyclists during the stages to establish the effort by trumps (Earnest, Jurca et al. 2004). It took a single case methodology for the study of data, for each rider. MANOVA was also carried out analysis and effect size to find intra-subject variables. **Results** We didn't find similar patterns on HRV variables evolution for any of our cyclists. Also we didn't find significant differences for any HRV variables (average RR, average HR, RMSSD, HF y LF) between mountain and plain stages for any subject, although we find significant differences on response to mountain stages for one subject (subject 1  $\eta^2=0,121$ ), possibly caused by cyclist specialization. The calculated effort by trumps was greater for all subjects in mountain stages ( $\eta^2 = 0.822$ ) as well as perceived exertion according to Borg scale ( $\eta^2 = 0.628$ ). **Discussion** HRV at rest may be a valid tool to detect fatigue states associated with different stages types. Due to our results we can't determine a causal relationship between the intensity of the stages and HRV response. We consider important a better quantify of cyclists efforts during the stages to more effectively discriminate different stages types. **References** Earnest, C. P., R. Jurca, et al. (2004). ### PP-SH14 Physical Education 2

#### SCHOOL PERCEPTION RELATED TO EXTRA-SCHOLAR PHYSICAL ACTIVITIES: A CASE STUDY AT ESCOLA PIA BALMES SCHOOL.

FRANCO-SOLA, M., SEBASTIANI, E., FIGUERAS, S., GUERRA, M.

UNIVERSITAT RAMON LLULL

School perception related to extra-scholar physical activities: a case study at Escola Pia Balmes School Marc Franco-Sola, MS1, 2; Enric Mª Sebastiani PhD1; Sara Figueras PhD1; Myriam Guerra PhD1 1 Universitat Ramon Llull (Barcelona, Spain); 2 Escola Pia Balmes (Barcelona, Spain) **INTRODUCTION** Extra-scholar sport activities, after SPM, are very popular in Spain, very motivating and can be used as an educa-

tional tool. As students get older, many of them hang off these activities. The purpose of this study was to identify the perceptions on extra-scholar sport of students 8 to 12 years old in a school of Barcelona (Spain) METHODS This is a case study focused at the Escola Pia Balmaes school in Barcelona. After an inform consent, 205 boys and girls, 8-12 years of ages, volunteered answering a questionnaire. The questionnaire included four main questions: quantity of sports practice, reasons of choosing the place where to train, motivations of the participants and the evaluations of the activities. SPSS (v.15.0.1) was used obtaining descriptives the statistic frequency to obtain their perception information. RESULTS Results showed that students have a positive perception on the sport they train. They enjoy playing and learning new aspects of the sport, and they feel happy when playing. They prefer to practice sport where they feel next to their friends, so there is an important social component of this practice. The practice diminishes as they become older (86% of sports practice at 8 years and 76% of practice at 12 years old). DISCUSSION and CONCLUSIONS Students enjoy with extra-scholar sport, but the practice diminishes when they get older. As there is a positive perception and a social component, it is important to consider, when organizing these educational programs, the social aspect just to motivate and hang them on to continue training. During these age stages, from the schools where the activities are organized, it is important to consider not only the technical learning and the competition results, but also the educative and social point of view. ## THE STATE AND STATUS OF PHYSICAL EDUCATION IN SELECTED SCHOOLS IN FOUR SOUTH AFRICAN PROVINCES: A SURVEY

VAN DEVENTER, K.

STELLENBOSCH UNIVERSITY

The state and status of Physical Education in selected schools in four South African provinces: a survey Karel J. van Deventer (Department of Sport Science, Stellenbosch University, Stellenbosch, Republic of South Africa) Introduction Democracy in South Africa (SA) brought about a new education system that implied a radical paradigm shift for Physical Education (PE). Curriculum 2005 reduced PE from an alone-standing subject to a learning outcome of Life Orientation (LO). The main aim of the study was to determine the perspectives of LO teachers regarding the implementation thereof with specific reference to the Learning Outcome, PE in selected primary and secondary schools in the Eastern Cape (EC), Free State (FS) and North West (NW) Provinces. Methods Quantitative data was captured by a self-designed questionnaire that was tested in a pilot study and adapted according to the problems identified. The questionnaire was also used in a study conducted in Western Cape (WC) Province in 2007. The survey schools (N=300) (primary n=150 and secondary n=150) were randomly selected in the EC, FS and the NW Province. Results The 2007 study in the WC had the same intention as the current study, which was to determine the progress of the implementation of LO. It was found among other things that 60% of the LO teachers were not qualified in PE (Van Deventer & Van Niekerk, 2008). Compared to the WC study, the current study found that 50% of the LO teachers were not qualified in PE. In Grades R-3, 54% of the LO teachers were not qualified in PE and in Grades 10 to 12, 42% were not qualified to teach PE. Discussion Although most of the time set aside for LO should be allocated to PE, it is not sufficient according to international standards, which stipulate daily PE lessons. According to the European Parliament, schools should provide for at least three PE lessons per week (Seghers et al., 2009). This situation is further complicated by LO teachers not qualified in PE, who either ignore the learning outcome or learners perform a once off activity to have marks available. Learners' right to participate in a fully-fledged PE programme will realise when schools have qualified PE teachers and when PE has the status of an alone-standing subject (Seghers et al., 2009). However, not much has changed regarding the unfairness of equal education opportunities in unequal settings in SA (Jansen, 1999); Botha, 2002; Fiske & Ladd, 2004; Prinsloo, 2007). References Botha RJ. (2002). International J for Leadership in Education, 5(4), 361-371. Fiske EB, Ladd H. (2004). Equity. Education reform in post-apartheid South Africa. ## SCHOOL SPORT FOR BOYS: THE CRADLE OF SPORTSMANSHIP?

CUSI, M.1, BOFARULL, I.2, AGUILO, J.3

\*ORTHOSPORTS. +UNIVERSITAT INTERNACIONAL DE CATALUNYA. # ESCUELA DEPORTIVA BRAFA

Introduction In its Olympic charter, the IOC defines its role as 'To encourage and support the promotion of ethics in sport as well as education of youth through sport and to dedicate its efforts to ensuring that, in sport, the spirit of fair play prevails and violence is banned (Olympic charter 1 September 2004, p.10). The education of youth through sport is a worthwhile ideal, but it is difficult to identify content, values, means and methodology to carry it out. The spirit of fair play is closely related to the idea of sportsmanship or sportpersonship. The Multidimensional Sportpersonship Orientations Scale (MSOS) (Vallerand et al, 1997) has been validated as an objective measurement of sportpersonship. From an educational point of view it incorporates notions of patience, respect for others, courage, cooperation, commitment and sacrifice. Strategies to develop sportpersonship can be assessed and compared, as a first step to validate the role of sport in the education of youth and development of character (Nucci & Narváez (2008). Handbook of Moral and Character Education. NY, Rutledge). Brafa is an extracurricular sports school in a migrant district in Barcelona, Spain. For the last 30 years it has developed SportsMagister, a values education programme through sport for boys between the ages of 4 and 13. Children play either football or basketball. Every week they train twice (outside school hours) and play competition games on weekends. The SportsMagister programme is implemented by the coaches within training sessions. It is supportive and intends to assist parents in the education of their children. The outline of the Sports Magister Programme, its background and methodology will be outlined. Methods A random cohort of 100 boys (ages 14-17) from Brafa undertook the MSOS assessment questionnaire, and compared to an equivalent cohort (n=100) of boys from other clubs in the same competitions and to a control group (n=100) of boys who did not practice organised sports or competitions. Results The primary outcome is the assessment and comparison of the levels of sportpersonship achieved in each of the three groups, the null hypothesis being that the students from BRAFA achieve higher levels of sportsmanship. The secondary outcome is the relationship of these results with family structure and relationships, family income and education levels of the parents, assessed by regression analysis of the data obtained. Discussion The results suggest that the Sports Magister Programme can be a good model to teach educational and personal values through sport and achieve good levels of sportsmanship and contribution to society, thus validating the IOC charter. sonship Orientations Scale. Journal of Sport and Exercise Psychology, 19. 197-206 Nuci LP, Narvaez D (2008) Handbook on Moral and Character Education. NY, Rutledge .

### CHILDREN AND ADOLESCENTS PERCEPTION ABOUT PE CLASSES IN ELEMENTARY AND HIGH-SCHOOLS OF TIRANA

SHYTI, A., PANO, G., GUGALLI, G.

*TIRANA SPORTS UNIVERSITY*

Abstract CHILDREN AND ADOLESCENTS PERCEPTION ABOUT PE CLASSES IN ELEMENTARY AND HIGH-SCHOOLS OF TIRANA. Shyti, A. Asc. Pr. PhD; Pano, G. Msc; Gugalli, G. Msc (2010) Tirana Sports University, Introduction Understanding attitudes towards sport and PE, especially in children and adolescents, is becoming increasingly important. Early learning experiences are recognized as being crucial to continuing involvement in physical activity (Kirk, 2005). Bailey (2005) has argued that 'much more empirical research is necessary if the benefits of sporting participation for young people and society are to become much more than a theoretical aspiration'. The aim of this study was to examine the perception that children and adolescents of elementary and high-schools of Tirana have about PE classes, in the context of the general program of the school. Methods 12.338 children, 10-14 years old and 7512 adolescents, 15-18 years old, were asked through a questionnaire: • Write the 3 most important classes for you. • Write the 3 most amusing classes for you. • If the school will be open in your leisure time, which are the 3 most interesting activities that you will prefer to do? Results Question 1 results show that PE is part of the 3 most important classes for 6.2% of the elementary and 2.1% for high-school. Question 2 results show that 38% of the children and 21.2% of the adolescents considered PE classes as amusing. Question 3 results show that 54.9 % of the children and 40. 2% of the adolescents preferred sport among their leisure time activities. Discussion There is a very low percentage for PE as "important" among the classes in the school programs, reflecting the traditional tendency of considering education in school based only on theoretical classes. Surprisingly, PE in school is considered "amusing" only from a relatively low percentage of participants, for both 10-14 and 15-18 years old. And in adolescents the evaluation of PE in school as "amusing" is less evident than in children. The positive perception of the PE in school tends to decrease from elementary to high school despite the general interest, showed by the participants, for PA in general and sport in particular as an activity to follow in free time. ### SPORT ACTIVITIES OF LATVIA BASIC AND SECONDARY SCHOOL STUDENTS

POROZOV, J., POROZOVA, D.

*RIGA TEACHER TRAINING AND EDUCATIONAL MANAGEMENT ACADEMY*

Introduction In order to stay healthy regular physical activities and healthy lifestyle are of great significance. Young people who participate in regular sport activities are less corpulent and they have rare problems with excess weight. Their muscular strength develops and sustains, metabolism improves, as well as their behaviour changes and less often they suffer from depression (Malina, 2005). The aim of the work was to compare sport activities of different age Latvian basic and secondary school students. Methods The questionnaire of Riga basic school 6th and 8th grade students and secondary school 10th and 12th grade students about their sport activities and interest about sports was carried out. 310 students were questionnaire. Results The results of investigation showed that sport activities of basic school students are higher than secondary school students. The highest level of sport activities have 6th grade students but the lowest level of sport activities have 12th grade students. The majority of students have positive attitude to sports. 6th grade students miss less sport lessons than 8th grade students and secondary school students. 26% of 6th grade students, 22% of 8th grades students, 19% of 10th grade students and 12% of 12th grade students go into separate branches of sports. Most of all students (among boys as well as girls) train into basketball. The most popular branches of sports among boys are sport games (basketball, football and hockey). Rather many boys go into various branches of wrestling. Among girls popular are basketball, volleyball, swimming and sport dances. For many basic school students sport is the main hobby. The main reason that doesn't allow students to go in for sports more than they do it is a lack of time. At the same time there are students who have other interests which are not connected with sports. The main motivation for majority of basic school students to go in for sports is to improve their physical condition or they enjoy physical activities. The main motivation for majority of secondary school students to go in for sports is to improve their health level. Discussion It is necessary to increase the level of sport activities (especially for secondary school students). Physical condition program should be emphasized more on the aerobic activities such as cross-country running, swimming, skiing but not only teaching the skills used in team sports such as basketball etc. To promote student's motivation of healthy lifestyle the qualitative physical education process, taking into account student's current needs, is necessary. Health, Fitness and Behavioral Outcomes Associated with Physical Activity in Youth // In: 9th International Scientific Conference "Sport Kinetics 2005", Book of Abstracts – Rimini, Italy, 2005 - p. 27.

### THE IMPACT OF A HYBRID SPORT EDUCATION-INVASION GAMES COMPETENCE MODEL SOCCER UNIT ON DEFENSIVE DECISION MAKING AND SKILL EXECUTION ACCORDING TO STUDENTS' SKILL LEVEL

SANTOS, D., FARIAS, C., ARAUJO, R., MESQUITA, I.

*FADEUP*

THE IMPACT OF A HYBRID SPORT EDUCATION-INVASION GAMES COMPETENCE MODEL SOCCER UNIT ON DEFENSIVE DECISION MAKING AND SKILL EXECUTION ACCORDING TO STUDENTS' SKILL LEVEL Santos, D., Farias, C., Araújo, R., Mesquita, I. Centre of Research, Education, Innovation and Intervention in Sport, CIFI2D, FADEUP, Porto, Portugal Introduction The coalition of SE and TGFU has been efficient in promoting students' performance improvements (2). Given that the Invasion Games Competence Model (IGCM) takes also into account the strategic specificity of invasion games, the purpose of this study was to examine the impact of the application of a hybrid SE-IGCM unit on students' improvements in defensive decision making (DM) and skill execution (SE) during a soccer season. Method A class of fifth-grade (17 girls and 9 boys) from a Portuguese elementary school participated in a 22-lesson season of soccer following a hybrid SE-IGCM unit. One Pre-test (PTT) and two post-tests (PTT1, PTT2) measured the defensive decision making and skill execution using the instrument developed by Blomqvist et al. (1). Results From PTT to PTT1 all students improved in guard/mark (DM); students of high skill improved in movements as required by the flow of the game (DM); medium skill students improved in duel (SE). From PTT to PTT2 all students improved in

movements as required by the flow of the game (DM); students of medium and high skill improved in guard/mark (DM); students of low skill improved in duel (SE). From PTT1 to PTT 2, students of medium skill improved in movements as required by the flow of the game (DM). No differences were found between groups at PTT, PTT1, or PTT2. Discussion The program had a positive impact on the defensive performance of all students. The specific structure of the unit may account for most of these improvements (4) as it encouraged largely the systemization of defensive positioning and the defensive skill execution. The lower entry scores of low skill students may have given them more scope for improvements; the higher skill students (medium and high level) showed less improvement as probably they already were in transition to a more competitive and strategically more complex form of defensive behavior (3). ### EFFECT OF PHYSICAL EDUCATION CLASS ON BEHAVIORAL CHANGE OF NON-ACTIVE UNIVERSITY STUDENTS.

SUGIURA, K.1, SAKAI, K.2

1) RIKIKYO UNIVERSITY, 2) JOSAI INTERNATIONAL UNIVERSITY

The purpose of this study was to evaluate the influence of certain physical education class on behavioral change of exercise and nutrition of non-active university students. Seven male and sixteen female students (age;  $19 \pm 1$  ys, height;  $164 \pm 9$  cm, weight;  $53.4 \pm 9.3$  kg, BMI  $19.9 \pm 2.7$ ) who attended the class were recruited as participants. The class was conducted once a week for thirteen weeks including 30-min lectures and 60-min exercises; stretch, stabilizer ball, dumbbell, walking and Ba Duan Jin. Three evaluation scales were used in both first and last week of the class: mean energy expenditure using 3-axes activity monitor (Tanita AM-120, Japan), mean nutrition intakes using 3-day food records (Meiji Seika Kaisha, Japan) and behavior of exercise and nutrition by the questionnaires. There was no significant change in body size and nutrition intakes compared among two periods. The mean energy expenditure of last week was significantly higher than that of first week. ( $p=0.007$ ). The behavioral skills was also significantly higher in last week. The results of this study suggested the possibility that this type of physical education class enhanced the readiness for exercise behavior and activity level of non-active university students.

### PRACTICAL KNOWLEDGE AND PHYSICAL EDUCATION: A CONCEPTUAL ANALYSIS AND A REVIEW OF THE LITERATURE

MOE, V.F.1, STANDAL, Ø.2

1: SOGN OG FJORDANE UNIVERSITY COLLEGE & 2: NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction It is an old debate about knowledge which says that we need a differentiated understanding of it (Ryle 1949). All knowledge cannot be reduced to theoretical or propositional knowledge, that is, to justified true beliefs. There is also practical knowledge which enables one to move around in the world and to act in complex situations. Whereas theoretical knowledge is associated with the intellect, has high status and interested philosophers the most, practical knowledge is usually associated with the body, has lower status and is of interest to anyone engaged in the performance of skill. The purpose of this paper was to study the concept of practical knowledge in the context of physical education by reviewing literature on the subject. Method A combination of conceptual analysis and a review of literature were conducted. The databases ERIC, ISI Web of Science and SportDiscus were searched for the combination of key words 'physical education' and 'practical knowledge'. Inclusion criteria were: a) Journal article or book chapter; b) Physical education or education of physical education teachers as contexts; c) Available in English. Results The study showed that the use of "practical knowledge" in the context of physical education is many-sided and not clearly delineated. Authors often contrasted the concept to theoretical knowledge with the risk of creating a strong dichotomy and thus not illuminating properly how deeply intertwined theory and practice are to teaching and learning situations in physical education. Practical knowledge was mainly related (i) to the performance of motor skills. But the concept was also used (ii) to account for the skill of teaching others, and (iii) to the skill of learning others to teach. Discussion Even though it is interesting to discuss how skilled or competent one needs to be in performing a motor skill in order to teach well, the discussion circulates around the second and third point above. These two points are discussed in relation to work in sport pedagogy (Tinning 2010), that is, the practical work of teaching on the one hand and the learning experiences and meanings emerging on the side of the participant on the other hand. Hence, by using the concept of practical knowledge as an entrance to work in sport pedagogy, one can illuminate the intentions and learning experiences of both teachers and participants in sport pedagogical settings. ### LEARNING FROM THE EXPERTS: EXPLORING PLAYGROUND EXPERIENCE AND ACTIVITIES USING A WRITE AND DRAW TECHNIQUE

KNOWLES, Z., PARNELL, D., RIDGERS, N.D.

LIVERPOOL JMU

Introduction Research exploring the role of playtime (or recess) during the school day has offered findings with regard to children's social, cognitive, emotional and creative development together with impact on physical activity levels. Understanding and exploring the playtime experience is important yet qualitative studies have generally involved small samples of older primary school children. Research amongst those in the early years of compulsory education is deemed problematic requiring a more developmentally appropriate and creative methodology such as 'write and draw'. The aim of this study was to use a write and draw technique to examine both younger and older primary school children's views, experiences and perceptions of playtime. Methodology 299 children aged 7-11 years from 4 primary schools participated with their respective schools enlisted into the Liverpool Sporting Playgrounds Project (Ridgers et al., 2010). Children were grouped into Years 3 & 4 and 5 & 6. The write and draw instructions asked children to think about 'what I like about playtime' and 'what I dislike about playtime'. A large box titled 'what playtime means to me' offered the child an opportunity to draw, write or present a combination of these in order to answer the question. Pen profiles were used to analyse the data to provide a composite of key themes deduced via an efficient process which offers examples of verbatim data as opposed to more comprehensive (in number) and truncated (due to space) offerings within content analysis (Ridgers et al, 2012). Results Results indicated 'likes' were focused on play,

positive social interaction and games across both age groups but an increasing dominance of games in older age group together an appreciation for being outdoors was also found. Dislikes focused on dysfunctional interactions linked with bullying (physical & verbal), membership, equipment for games/activities and conflict for playground space. Discussion Football was a dominant feature across both cohorts and 'likes/dislikes' in respect of causing conflict and dominating the physically active games undertaken. Data support the importance of playtime for the development of skills such as conflict management, social skills and contributing to physical activity engagement thus contradicting suggestions within the literature to remove/reduce playtime in the face of behavioural issues. Ridgers, N.D., Fairclough, S.J. & Stratton, G. (2010). 12-month effects of a playground intervention on children's morning and lunchtime recess physical activity levels. *Journal of Physical Activity and Health*, 7, 167-175. ## RESEARCH INTO THE PROCESS OF PRACTICAL KNOWLEDGE ACQUIREMENT IN PE TEACHERS

YASUYUKI, N., TAKASHI, I.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

**Introduction** The aim of this research is to discern the practical knowledge behind "the energetic lesson," from among all practical knowledge held by physical education teachers used in their decision-making and actions. Physical education does not involve learning theory from any particular textbook, or learning using workbooks, so it relies heavily on the practical knowledge of the teacher (Elbaz: 2000). The educational effectiveness of physical education is also enhanced by "energetic lessons" in which students learn independently. In this research, we investigated the practical knowledge of three physical education teachers who guarantee "energetic lessons," by studying their past lives. **Methods** Subjects: A proficient physical education teacher (35 years teaching experience), average teacher (15 years teaching experience), new teacher (1 year of teaching experience). Lesson Studied: A high school soccer lesson. **Methods:** 1) Videotaping of the lessons given by the three teachers. 2) Retrospective interviews of the three teachers while showing videotapes of their own lessons. 3) Interviewing students on their impressions of the three teachers and what they learned. **Results** 1) The systems of practical knowledge and knowledge acquirement of the proficient and average teachers were simple, like those of the new teacher, when they too were not very experienced. Their philosophical knowledge was that of an understanding of "the response relationship between the teacher and students." Methodical knowledge included those of "student management" and "unilateral guidance provided by the teacher." 2) As teachers grew from being average teachers to proficient teachers, they underwent changes to acquire complex systems of practical knowledge. Their philosophical knowledge was that of ways to "promote student independence," and understanding that "as students grow they will engage more independently in the lessons." Methodical knowledge included ways to "ask questions and provide guidance within the context of the students' overall understanding," "provide assistance in guiding them to promote their growth," "promote their growth through asking questions," "evaluate their growth" and "evaluate their efforts during lessons other than those leading to growth." **Conclusion** The research clarified the system of practical knowledge behind "the energetic lesson" used by proficient teachers, which until now had been vague. As teachers become increasingly proficient, their philosophical knowledge and methodical knowledge grow in variety and complexity. They also change to a system of supporting the independent learning of students. **References** Elbaz, F.(2000)The teacher's "practical knowledge": Report of a case study, *Curriculum Inquiry*, 11(1), pp.43-71. ## THE WEEKLY HOURS OF PHYSICAL EDUCATION LESSONS IN HUNGARIAN PUBLIC EDUCATION: A STUDY FROM EUROPEAN PERSPECTIVES

HAMAR, P.1, SOOS, I.2, HUSZAR, A.3

1 SEMMELWEIS UNIVERSITY, BUDAPEST; 2 UNIVERSITY OF SUNDERLAND, UK; 3 EÖTVÖS LORÁND UNIVERSITY, BUDAPEST

According to some specialty writers (Báthory, 2003) teaching time assigned to subjects is not, or only in a very small degree influences students performance. The number of the physical education lesson problem in public education is a constant issue in Hungary among the curriculum theory professionals and the physical education teachers in more specific terms: the question of the "physical education lesson every day". It is a question whether the time frame that is what the current physical education curriculum documents provide meets the requirements of more diverse goals and tasks of the physical education or not. „The PE is a unique domain that has a direct influence on students' physical development and which provides the opportunity for learning motor activities of place and position accompanied by development of gross muscle groups. In addition to improving motor skills and abilities, physical education undertakes the role of: creating a balance between a healthy body and mind, promoting a healthy lifestyle, combating harmful addictions and against substance abuse, forming proper hygienic and sexual habits, fostering recreation and/or rehabilitation" (Hamar et al., 2006). The alteration of the Public Education Act in 2003 declares unambiguously that it stands up for the "physical education lesson every day". However in our view, the everyday (compulsory) physical education class, and daily physical activity and exercise are not the same. To confirm the mentioned statement through the analysis of Hungarian and European curricula answers were looking for that what number of hours of physical education can be found in the curricula of some European countries. The current time frame for physical education in Hungary is more or less compared to other European curricula? As a result of our analysis it is concluded that the minimum and maximum curricular time frame of the physical education classes -expressed in minutes per week- shows significant differences among the 27 EU member states (Hardman, 2007). In Hungary this data is 90 minimum/minute and 225 maximum/minute. In the Hungarian public education the percentage of the physical education classes in the 12-14 year age group falls behind the countries in Europe. To confirm these, there are some data: Austria 11%, Portugal 10%, Netherlands 9%, Finland 8%, while Hungary is 6% (source: Education at a Glance, 2000). These data speak for themselves, but it is also known that the available number of hours doesn't guarantee the effective teaching and learning. The number of physical education classes can be raised as high as enough if these are not matched by a generous teacher, a certified professional work and love of children.

## ORGANIZATION OF THE SCHOLAR SCHOOL IN THE EDUCATION CENTERS ACCORDING TO THE ENTITIES

GONZÁLEZ, M.D.1, CAMPOS, A.2, PABLOS, C.3, PABLOS, A.4

1: UNIVERSITY OF ALCALÁ (ALCALÁ DE HENARES, SPAIN), 2: TECHNICAL UNIVERSITY OF MADRID (MADRID, SPAIN), 3: UNIVERSITY OF VALENCIA (VALENCIA, SPAIN), 4: UNIVERSITY CATHOLIC OF VALENCIA (VALENCIA, SPAIN)

**Introduction** The scholar school in Spain is developed in a diversify way and with heterogeneous structure within the regions and the towns. The consequence of this reality produces that each scholar center organize the scholar school in a different way according to the

importance that they give to the sport. In that way, we analyze the organization taking into account the entities involved in the scholar school centers in Madrid. The main target is to define the improvement lines. Methods We have used a quantitative methodology of descriptive cut. For this target the sectional survey through personal interview have been applied to people who is working teaching scholar school in Primary Centers of Madrid (300 teachers). To catch the relevant information for the study we have used a structured interview (González y Campos, 2010). Results The main activity for teachers is to work for private sector companies (33,6%), then in sports association and sports clubs (24%) and finally in educational centers (20,6%). Furthermore, there are a lot of entities that arrange the out of school sport activities. In the first place we find the AMPAS (38,3%) and the educational centers (38,3%) and then the town council (19%). Discussion We agree with Augustin (2003) when he suggests that the scholar school teachers work for different entities. This is because the educational centers prefer to contract private companies for this item. Furthermore, we have found several companies that organize and promote out of school sport activities. The percentages of use of this external companies are different from other studies (Campos, 2010). Due to this big diversity of management it is necessary to create a clear organization structure (De la Iglesia (2004). References Augustin, J.P. ## REGULATION DOCUMENT STUDY ON ITALIAN PRESCHOOL

RAIOLA, G.

UNIVERSITY OF SALERNO

Introduction In recent years Italian pre-school, called commonly pre-primary, infant, kindergarten or childhood and the pupils go between 2 years old to 5, has been updated the ministerial documents relating to the educational contents and activities. At the same time, last discoveries about the neurophysiology of the brain changed the scientific bases on which are based psychological and pedagogic paradigms on educational theories. These theories are the basis on body learning according to motor control theory such as closed loop system (Adams 1975), open loop system (Schmidt 1985) and motor imagery (Rizzolatti 2006, Iacoboni 2008). The aim is to identify, into the regulation documents regarding the educational activity, aspects of psychology and pedagogy in the field of body and movement Method Research is integrated by two approaches: Theoretical and argumentative one on scientific paradigms regarding the motor control system theory and the related body learning in the early years of life and, the second one, historical and documentary approach on regulation documents relating to the contents and the teaching activities Result It does not carry out any aspects of education and didactics that can be connected to psychological and pedagogic aspects according to the new scientific and neurological theories. All regulation documents do not provide any reference to recent discoveries related to motor theory relating the body learning Conclusion It may be useful to update the regulation documents. It needs to deep properly the study and then to deliver the results to the governmental experts for the necessary updates to fill up the vacuum of the contents, didactics and teaching method for the particular field of body learning. Furthermore, the body and its movement field must help the educational science in an holistic vision of development References Latash M., (2008) *Neurophysiological Basis of Movement*, Human Kinetics, Champaign IL USA Schmidt, R., A., Wrisberg, G., A., (2008) *Motor Learning and Performance*, Human Kinetics, Champaign IL, USA Iacoboni M., (2008) *Mirroring People*. ### PP-SH15 Sport Statistics: Performance Analysis

#### T-PATTERN DETECTION ANALYSIS: DEFENSIVE PROCESS IN FOOTBALL

MARTINS, N., SARMENTO, H., BARBOSA, A., CAMPANIÇO, J., LEITÃO, J.

DEPARTMENT OF SPORT SCIENCES, EXERCISE & HEALTH, UNIVERSITY OF TRÁS-OS-MONTES AND ALTO DOURO, VILA REAL. CENTRO DE INVESTIGAÇÃO EM DESPORTO, SAÚDE E DESENVOLVIMENTO HUMANO, CIDESD, VILA REAL

It is acknowledged that the defensive process has an important role in a football team success; however, there is a discrepancy in the scientific literature on defensive process when compared with the offensive process. The observation of sports performances has focused on the frequency of occurrence as its performance index, still is debatable whether the frequency data alone allow to successfully distinguish effective performances and less effective performances, therefore observational studies should expand their indices of performance further than the frequency (Borrie et al, 2002). The detection of play patterns is one tendency to be followed, being emphasized the potential of THEME software in detecting temporal patterns of behaviour (James, 2006). To analyse and characterise the defensive process of successful teams were the main purposes of this study. The study observational design was multidimensional, nomothetic and sequential. The behaviour was coded through an “ad hoc” observational instrument combining field formats and categorical systems. Values above 0.9 for all criteria were achieved in this instrument reliability analysis, calculated through inter and intraobserver agreement. Three games of the Italian national team winner of the World Cup 2006 and 3 of the Spanish national team winner of the EURO 2008 were registered using Thème Coder software. For t- patterns detection we used THEME 5.0, ( $p < .005$ ). The results show that top-level teams have made a total of 459 defensive processes during the six observed games, making an average of 76.5 in each game. 11080 t-patterns were detected, corresponding to 3419 different t-patterns, ranging from a minimum of one level to a maximum of nine levels and two to 16 events. We conclude that the scoreline and the game time influenced the characteristics of the detected t-patterns, while the numerical relationship between teams did not influence the characteristics of the detected t-patterns. ## VELOCITY AND ACCELERATION DIFFERENCES BETWEEN BALL-CARRIER AND TACKLER, AND ITS RELATIONSHIP TO POSITION AND TACKLE OUTCOME

HENDRICKS, S., KARPUL, D., LAMBERT, M.I., NOAKES, T.D.

UNIVERSITY OF CAPE TOWN

Background: The tackle event in rugby union, at all levels of play (amateur to professional, juniors to seniors) places both ball-carrier (BC) and tackler (T) at high risk of injury compared to any other facet of play. The velocity at which the BC and T enter tackle (and the velocity difference between the two) is regarded as a risk factor for injury. For this reason, a better understanding of the dynamics of the tackle is warranted. Aim: The aim of this study was to determine the velocity and acceleration differences between BC and T, and relate these differences to i) position of BC and T and ii) tackle outcome. Methods: Ten Front-on and 10 side-on tackle situations in the 2010 Super 14 (S14), Varsity Cup (VC), and Currie Cup Under 19 (U19) matches were coded for. Thereafter, using a novel video analysis system, the BC and T were tracked for 0.5 seconds (s) before contact in each tackle situation. The displacement covered over this period, by the BC and T, were subsequently measured. Accordingly, velocity (m/s) and acceleration (m/s<sup>2</sup>) were calculated for the BC and T. For each tackle, position of BC and T (back or forward), and tackle outcome (ball-carrier or tackler and; territory change – much/very much, fair amount, little/no change) was recorded. Results: During the front on tackle, backs, whether as a BC or T had a higher velocity difference than forwards at all levels of play. During the side-on tackle however, forwards had a higher velocity difference as a BC. During the front-on tackle, a velocity deficit does not necessarily mean an unsuccessful outcome, whether as BC or T. Interestingly, during the side-on tackle the ball-carrier in all probability had a successful outcome at all levels of play. Acceleration differences between BC and T for backs and forwards were seemingly similar for both front-on and side-on tackles. In front-on tackles, BCs with a higher acceleration than Ts were more likely to succeed in the tackle than Ts with a higher acceleration. For side-on tackles, the outcome of the tackle favoured the BC regardless of acceleration differences. Conclusion: BCs seemingly have an advantage during the tackle situation, especially during side-on tackle situations. During front-on tackles, BCs usually make their intentions clear in terms of running line or passing the ball; therefore tacklers have more time to properly prepare for the imminent contact. In contrast, during side-on tackles, BCs are typically running at angles or executing a set-play making it hard for the T to commit. This delay results in Ts executing the tackle at a late stage, often when the BC is already beside him.

## ANALYSIS OF MIDDLE-BLOCKER ANTICIPATORY BEHAVIOUR RESPECT SETTING ACTIONS IN HIGH-LEVEL VOLLEYBALL. A PRELIMINARY STUDY IN A SPANISH TOURNAMENT.

BUSCÀ SAFONT-TRIA, B., FEBRER MIQUEL, J.

PSYCHOLOGY, EDUCATION AND SPORT SCIENCES FACULTY OF BLANQUERNA; INSTITUT NACIONAL D'EDUCACIÓ FÍSICA DE CATALUNYA

Introduction The anticipation of middle-blockers to assist the right and left blockers in the net game is an important and hidden skill in high-level volleyball (Liviotti et al, 2007). The setter try to fool the middle-blocker to avoid double and triple blocks while the blockers try to guess the direction of the setter passing. The aim of the present study was to analyze the temporal behaviour of the volleyball high-level middle-blockers and the opponent setters to get advantage in blocking. Anticipated responses were established when blocker movements start before 0.15 sec. after the setter ball contact (Broker & Crawley, 2001). Methods 300 actions were analyzed from a randomized sample of the 2009 Spanish Cup male tournament, held in Almería (Spain). A high-speed video camera (300 Hz) was used to record the rallies of 7 matches between the 8 best teams of the season. Frame by frame analysis was carried out to determine temporal intervals between middle-blocker and setter actions. We analysed the association between temporal behaviours and blocking efficacy (chi-square) considering other independent variables. Results The middle-blocker play 27% of attacks in first tempo (M= 0.403 sec, SD=0.083) and 66% second tempo (M= 1.052 sec, SD=0.178). Middle-blockers develop anticipated responses over 60,94% of the actions analyzed. When blocker's response overpass the temporal threshold (0.15 sec), the percentage of negative blocks increased ( $\chi^2=4.87$ ;  $p<.05$ ). When the middle-blocker time response was categorized into 6 intervals of 0.1 sec. before and after setting, we observed averages close to 50% of positive blocks in the category just prior and after the setter ball contact. Discussion The middle-blocker needs to anticipate his response around 60% of situations because the players in this level of performance play 27% of attacks in first tempo and 66% in second tempo. Considering timing of the conscious intention to move (Matsuhashi & Hallett, 2008) and the spatial conditions in volleyball blocking, middle-blockers develop anticipatory strategies to respond in front of these temporal demands. We also detected a marked trend to increase time response of blockers in first tempo situations (M= 0.158 sec, SD=0.021) respect the second and third tempo (M= 0.056 sec, SD=0.008). These data confirm the necessity to improve perceptual and specific motor skills to perform in blocking (Ker, 1990). References Broker J.P., Crawley J.D. (2001). ## DEVELOPMENT AND VALIDATION OF A NOTATIONAL SYSTEM TO STUDY THE DEFENSIVE PROCESS IN FOOTBALL

MARTINS, N., SARMENTO, H., BARBOSA, A., CAMPANIÇO, J., LEITÃO, J.

DEPARTMENT OF SPORT SCIENCES, EXERCISE & HEALTH, UNIVERSITY OF TRÁS-OS-MONTES AND ALTO DOURO, VILA REAL. CENTRO DE INVESTIGAÇÃO EM DESPORTO, SAÚDE E DESENVOLVIMENTO HUMANO, CIDESD, VILA REAL

It is acknowledged that the defensive process has an important role in a football team success (Carmichael & Thomas, 2008; Bosca, Liern, Martínez & Sala, 2009); however, there is a discrepancy in the scientific literature on defensive process when compared with the offensive process. The detection of invariant behaviour is one relevant methodological process to football analysis, pointing out the Theme software possibilities to recognize temporal patterns of invariant behaviour, even though this is a recent procedure in the scientific literature (James, 2006). Therefore, the main purposes of this study were the development and validation of an "ad hoc" observational instrument, which will allow the defensive process of successful teams to be analyzed through t-pattern analysis. The methodology of instrument conception consisted in deductive-inductive procedures with special reference to the literature review, the consulting of a panel of experts consisting of coaches (UEFA level IV) and researchers to find out what performance indicators should be included in the instrument and content validation. The 'ad hoc' observational instrument (ObsPD) was created combining field formats and categorical systems, formed by five vertebrate criteria and the respective observed behaviours for each of these criteria (Martins, 2010). The instrument reliability was calculated by the intra and inter observer concordance, calculated through Cohen's K (using SDIS-GSEG software) and showed reliability levels higher than 0.9 for all criteria (Martins, 2010) and a K value greater than 0.75 is considered excellent (Bakeman & Gottman, 1997). The instrument reliability results ensure that subsequent studies using the ObsPD are based on data obtained from a

high reliability instrument. References Bakeman, R., and Gottman, J. M. (1997). Observing behavior. An introduction to sequential analysis, 2nd ed. Cambridge: Cambridge University Press. Martins, N. ### **NOTATIONAL ANALYSIS OF TACTICS USED BY CANOE POLO NATIONAL TEAMS DURING THE EUROPEAN AND WORLD CHAMPIONSHIPS SEMIFINAL AND FINAL MATCHES, FROM 2006 TILL TODAY**

VASTOLA, R., SIBILIO, M., DI TORE, S., SGAMBELLURI, R.

UNIVERSITY OF SALERNO

**Introduction** The tactic preparation of athletes depends on the learning level of drills (actions and methods on how to fulfill the tactics), tactical projects (attack, counter-attack, zone defense and pressing) and technical / tactical trainings (individual and team) of sports tactics. Platonov stated "... the structure of tactical preparation depends on strategic aims that determine main directions of sports competitions...". Canoe polo is a game with different tactical projects where we can simply identify two macro-areas: the pressing and the zone game. The current preparation of canoe polo national teams and clubs is not supported by sufficient information to ensure a rational training planning. **Aim** The purpose of the research is to quantify the average time per match where the teams play the pressing and the zone systems, and to highlight any tactical elements that can determine the choice between the two game strategies. **Methodology** This type of research is observational and has used a video analysis, realized by "Dartfish", by scanning semifinals and finals World and European Championships matches, from 2006 till today, with the aim of recording the average game time when the teams apply the pressing or zone game system, and other tactical elements that can determine the choice between the two game strategies. **Results** The research shows that the 70% of game time is used by the teams applying the zone system. The tactics predilection toward this type of solution probably cause the least energy expenditure and a lower percentage of losing the match, except for the male Dutch team, where in international events, won more medals than any other national teams by mainly use the pressing system. **Conclusions** Analysis of matches has shown that the pressing system is used primarily at the end of the second half of the match by the team at a disadvantage. Issue of further researches can be the evaluation of the energy expenditure in the pressing game and the correlation of this strategy in relation to the match results.

### **A COMPARISON OF THE DISTANCE FROM THE GOAL LINE TO THE LESS ADVANCED OUTFIELD PLAYER BETWEEN FIVE SPANISH FIRST DIVISION SOCCER TEAMS**

ZUBILLAGA, A.1, CARO, O.2, RUIZ-RUIZ, C.3, FERNANDEZ-GARCIA, A.2, FRADUA, L.2

1.UNIVERSIDAD DEL PAIS VASCO - EUSKAL HERRIKO UNIBERTSITATEA, 2.UNIVERSITY OF GRANADA, 3. UNIVERSITY OF SEVILLE

**Introduction** An outcome like the distance from the goal line to the less advanced outfield player can be used to describe a team's pattern of play (Carling et al., 2005). Teams using an offensive style may play closer to the opposing goal whereas those using a more defensive style may play closer to their own goal. Therefore, the aim of this study was to analyse differences in this tactical variable between four soccer teams. **Methods** A multiple-camera player tracking system (AMISCO Pro, Sport-Universal Process, Nice, France) was used to record the existing distance from the goal line to the less advanced outfield player of the analysed team (metres). A total of 25 matches, 5 per team, of the First Spanish Division were analysed. The matches were recorded and digitalized and the player's position and movements were registered with a frequency of twenty-five records per second (see Zubillaga et al., 2007). A total of 17546 data were collected. **Results** A one-way ANOVA revealed that the distance from the goal line to the less advanced outfield player was smaller in team 1 ( $28.50 \pm 12.89$ ) than teams 2 ( $30.40 \pm 12.93$ ), 3 ( $29.72 \pm 12.98$ ), 4 ( $29.72 \pm 12.75$ ) and 5 ( $29.65 \pm 12.53$ ) ( $P < 0.001$ ). Also this distance was greater in team 2 than teams 3, 4 and 5 ( $P < 0.05$ ). **Discussion** The distance from the goal line to the less advanced outfield player was found as a tactical variable able to discriminate between teams. These different distances from outfield players to their own goal may be a consequence of teams' defensive or offensive minded styles of play. Future studies could analyse whether playing closer or farther away from the own goal is related to a good or bad team performance. **References** Carling C, Williams AM, Reilly T. (2005). ### **EFFECTS OF SCORE-LINE ON TEAM STRATEGIES BEFORE AND AFTER GOAL SCORING IN ELITE SOCCER**

LAGO PEÑAS, C., CASAIS, L.

UNIVERSITY OF VIGO

**INTRODUCTION** Given that soccer is dominated by strategic factors it is reasonable to suggest that performance demands vary according to the status of the score-line. The aim of this study was to investigate differences in team strategies in an elite soccer team in the 5 minutes before a goal was scored and the 5 minutes after by analysing technical, tactical and physical performances. **METHODS** In total 100 goals scored in 50 matches of the Spanish Soccer League were analyzed using a multiple-camera system (AMISCO Pro, Nice, France). Data were collected for score line status of the match, % possession, zone of play (defensive 1/3, middle 1/3, attacking 1/3), distance covered, time spent in five different categories and the frequency and outcome of six technical indicators. Data were analyzed using an independent t-test and a linear regression. **RESULTS** Distances covered at submaximal or maximal intensities ( $>19.1$ ) and time spent in the attacking zone were higher in the 5 minutes before scoring a goal than for the overall half of the match in which the goal was scored. Moreover, there were differences in the frequency and outcome of the technical indicators. **DISCUSSION** Several studies (i.e. O'Donoghue and Tenga, 2001; Lago et al, 2010) have investigated the effect of score-line on aspects of soccer performance by comparing play in the whole time where the score was level with play where a team was winning or losing. However, it has been suggested (Carling et al, 2005) that overall changes in behaviour could be analysed in more detailed if the game was split into 5 minutes segments. According to other studies (i.e. Redwood-Brown, 2008) the current study has revealed differences in team strategies and performance profiles before and after goals are scored when compared to the average for the half of the match in which the goal was scored. The results emphasize the importance of accounting for match status during the assessment of tactical, technical and physical aspects of soccer performances. **REFERENCES** Carling C, Williams AM, Reilly, T. ### **ANALYSIS AND PREDICTION OF TRAINING EFFECTS WITH ARTIFICIAL NEURAL NETWORKS**

HAAR, B., ALT, W.

UNIVERSITY OF STUTTGART

**ANALYSIS AND PREDICTION OF TRAINING EFFECTS WITH ARTIFICIAL NEURAL NETS** Haar, B.1, Alt, W.1 1: inspo (Stuttgart, Germany) **Introduction** Mathematical models attempt to describe and predict the effects of exercise on performance (Banister et al., 1975; Perl et al., 2001). Considerable weaknesses of these modelling approaches are inherent simplifications that question their capability for performance prediction. These simplifications include the prerequisite to aggregate training strain into a single variable and are not in accordance to the complex training process. Artificial neural networks (ANN) are non-linear, multivariate statistical data models to describe and predict complex input and output relationships. Therefore, it is the aim of this study to prove the concept of analysing and predicting training effects with ANN. **Methods** Three well-trained triathletes participated in this study (2 male, 1 female, mean VO<sub>2</sub>max = 3,77 l/min). Training loads were recorded daily by collecting training duration and heart rate in four categories (running, cycling, swimming and strength training) over a three months period. The effects of stress and recovery were also considered. For this purpose psychological assessment was done by means of RESTQ-Sport (Kellmann & Kallus, 2000). VO<sub>2</sub>max was measured as performance output every third day. Exercise testing was conducted as a ramp test on a cycling ergometer and measuring expired gases. A back propagation net was trained for each athlete. Sequenced values of the performance time series were used as autoregressive input to predict performance. Training loads and psychological variables were used as exogenous input data. The ANN output was VO<sub>2</sub>max. **Results** A very good model adaption was achieved for all three athletes (mean  $r=0.94 \pm 0.01$ ;  $P<0.001$ ). Model prediction over a 12 day period was still acceptable. The average Mean-Absolute-Error (MAE) was  $0.18 \pm 0.10$  l/min. **Discussion** Analysis and prediction of training effects with ANN seems to be a quite powerful method. The multivariate model can take multi-faceted factors that affect performance development into account. This means a step in increasing the model complexity that should lead to a better model behaviour. **References** Banister EW, Calvert TW, Savage MV, Bach A (1975). *Austr J Sports Med*, 7, 170-176. ### **A METHOD FOR CALCULATING PROBABILITIES IN BALLGAMES ACCORDING TO SCORES DURING THE MATCHES USING A SPREADSHEET**

HIROTSU, N.

JUNTENDO UNIVERSITY

**Introduction** The probabilities such as winning probability in ballgames according to scores have not been easy to calculate. In general, the calculation needs an assistance of computer and a special knowledge of computer programming. In this paper, we propose a simple method for calculating the probability of ballgames reaching scores of  $i-j$  and the probability of winning from scores of  $i-j$  under  $n$ -point-up scoring system such as tennis, using a spreadsheet which makes it possible to obtain these probabilities without any special knowledge of computer programming. Here, we also propose a method for calculating the probability of reaching situations where a team leads by  $d$  points and the probability of winning the match when the team leads by  $d$  points, in terms of games continuously played such as soccer. **Method** We used mathematical formulations which represent the progress of the score under  $n$ -point-up scoring system (e.g. Sadovskis, 1993; Schutz, 1970). We also used formulations which expresses the progress of the scores in a game which is played continuously in a limited time. (e.g. Hirotsu and Wright, 2002). We demonstrate how to calculate these probabilities using a spreadsheet. In practice, these probabilities are obtained basically just by 'copy' and 'paste' procedures after inputting the formulation into cells. **Results** We applied this method to tennis, table tennis, badminton and volleyball, which are played under  $n$ -point-up scoring system. We also applied it to soccer, handball, basketball and rugby, which are played continuously in a limited time. For example, in terms of tennis, just by setting the probability to get a point by a server as 0.6 in a cell, we can obtain the probability to get a game as 0.736 by the proce-

dures on a spreadsheet. By formulating the hierarchy of the point system, we can also easily calculate the probabilities of winning a set or a match. Discussion As an application of this method, we calculated the winning probability and the number of plays in a volleyball game, not only under the rally-point system, but also under the side-out system. Using this method, we easily got the duration of the game for both systems. For example, assuming that one series of plays starting off with a service takes 0.4 minutes and the probability for each team to get a point from its service is 0.3, the duration of the game is  $74 \pm 9$  minutes under the rally-point system and  $129 \pm 39$  minutes under the side-out system. Further, also as an extension of this method, we can calculate at anytime in the course of the match the probability of winning a match, just by inputting 1 into a cell. The optimal timing of tactical changes is also calculated in a spreadsheet, under the formulation shown in Hirotsu and Wright (2002). References Hirotsu, N. and Wright, M. (2002) Journal of the Operational Research Society, 53, 88-96. Sadovskii, L.E. and Sadovskii, A.L. (1993). ## A STRUCTURAL MODEL OF THE MATCH DYNAMICS IN INVASION TEAM GAMES

LAMAS, L.I, OTRANTO, G.2, UGRINOWITSCH, C.1, BARRERA, J.3

1: EFEE-USP (SAO PAULO, BRAZIL); 2: IME-USP (SÃO PAULO, BRAZIL), FFCLRP-USP (RIBEIRÃO PRETO, BRAZIL)

Introduction The dynamics of the match in invasion team games (ITG) defines a complex context with two adversary teams imposing several constraints to each other for obtaining the ball possession and score. However, a better comprehension of the ITG opposition still requires a model that describes the match cooperation/opposition processes, its regulatory parameters (e.g. team's strategy) and its integration with other competition processes (e.g. training) (Lebed, 2007). Thus, our aim is to present an ITG model with its parameters and regulatory processes. Methods The ITGs were modeled as dynamical systems regulated by control fluxes and data fluxes in accordance with the control-system integration principles of the control theory (Shinners, 1998). In our multi-level model a subsequent layer describe the most relevant processes of the previous layer. The model was logically tested with applications to different sports. Simulation procedures are being organized. Results The dynamical structure of the match was satisfactorily modeled in six hierarchical layers: 1) Competition: its processes, feedback mechanisms and three main interfaces: a) team's strategy-training, b) team's strategy-match, c) match-match analysis; 2) Match: two teams, with respective strategies, preparing to confront each other. Controllers from both teams are the first two processes of the control and data fluxes and its outputs are integrated to produce the final adjustments for the confront occurrence; 3) Controller: controller structures of both teams compute the fluxes provided by the match and a new strategy sub-set is generated. The new strategy generates data specification for all players' action; 4) Match navigation: player's action (navigation) based on controllers' specifications; 5) Match planner: adaptation of the team's strategy to the individual plan of each player describing procedures for synchronizing their actions; 6) Epicenter: actions of players directly involved with the ball. Discussion The model of the match presented integrates extrinsic control (team's strategy operated by the technical commission), the intrinsic control defined by the players' individual decisions and the coordination between both for the collective action. Hence, the model shades some light into the comprehension of the behavior's regulations in the match opposition. Moreover, provides support for a more structured match analysis and contributes for defining more precise training focuses by the coaches. References Lebed, F. ## ANALYSIS OF PLAYER WORKLOADS FOR DEFENSIVE OUTLETS AT THE CHAMPION'S TROPHY INTERNATIONAL FIELD HOCKEY TOURNAMENT.

MORGAN, S.I, BARNES, C.I, WILLIAMS, M.2

AUSTRALIAN INSTITUTE OF SPORT\* AND AUSTRALIAN CATHOLIC UNIVERSITY\*\*

Introduction For team invasion sports, adopting a strategy that requires the opposition to work relatively harder will generally be advantageous. However, it is often difficult to quantitatively measure team or player performances with sufficient accuracy to make meaningful comparisons. Although it is now common-place to use a variety of methods for tracking players during field sports (e.g. GPS, RF tracking), non-invasive methods based on video recordings have a number of advantages; in particular the possibility of simultaneously tracking all players on both teams. In this study we utilised an automated video-tracking methodology to estimate relative positional workloads for teams involved in the "Champions Trophy" hockey tournament, held in Australia in 2009. This data was then analysed using the concept of Specific Power to obtain an accurate surrogate for player and team workloads. Competing teams represented the top six field hockey nations globally. Methods A total of 18 matches were played, from which 42 defensive outlet plays were chosen for detailed examination. Output from a group of five cameras, each with a partial field of view of the game, was synthesised into a single whole-field view from which (x,y) information was obtained on a frame by frame basis (25 Hz). From these derived coordinates the player velocity could be obtained for each player on the field. Plotting the maximum speed sustained against its duration produces a characteristic speed-duration curve for each position. This methodology was used to examine the relative workloads of the teams (attacking and defending) under each of two defensive strategies. One was defined as a "fall back" strategy, in which defending players, having lost possession, fall back into their own half; whereas the second strategy (defined as a "press") represented the strategy of immediately challenging the (now) attacking team in their own half, with the objective of creating an attacking error, reversing the original turnover. Results In overall terms, the attacking/out letting team generally works at higher speeds than the defending team, regardless of the defensive strategy. But, imposing a press on the out-letting team does further increase the speed exhibited by players on most lines in the out-letting team, excluding deep defenders. Discussion There is a moderate increase in speed required of the defending team during a press, and the duration of those efforts is also longer in a press. The increase in work rate suffered by the pressing team is largely borne by the defensive lines, but this is equal to the additional load on the attacking AMF and strikers. Notwithstanding the additional work cost to the defending team, the average duration of the defensive outlets is more than twice as long for a fall away as for a press: any decision about relative workloads on players should take this into account. Also, there is a clear outcome benefit to the defending team in pressing.

## OLYMPIC WINNING PERFORMANCES IN ATHLETICS AND SWIMMING: A COMPREHENSIVE ANALYSIS

STEFANI, R.

CALIFORNIA STATE UNIVERSITY, LONG BEACH

OLYMPIC WINNING PERFORMANCES IN ATHLETICS AND SWIMMING: A COMPREHENSIVE ANALYSIS Stefani, R.T., CSULB (Long Beach, California, USA), Stefani@csulb.edu Introduction Athletics and swimming comprise over 25% of the 300 medal events in the 2012 London Olympics. The percent improvement per Olympiad (%/O) was calculated in those sports for all comparable winning performances of the

modern Games. Charts and photographs are used throughout to enhance the presentation. Overall and Individual Results For athletics events, the average %I/O was 0.7% for running, 1.5% for jumping and 2.9% for throwing. The average for swimming was 1.9%. The best individual %I/O were 6.2% in running by Lasse Viren (FIN, 1972, 5 k), 10.3% in jumping by Bob Beamon (USA, 1968, long jump, still the Olympic record), 17.4% in throwing by Gisela Mauermayer (GER, 1936, women's discus) and 10.2% in swimming by Andrew "Boy" Charlton (AUS, 1924, 1500 m). Comparing 2004 winners with those of 1924, Justin Gatlin would be 7.1% faster than Harold Abrahams at 100 m, Jeremy Wariner would be 7.6% faster than Eric Liddell at 400m, Stefano Maldini would be 19% faster than Albin Stenroos at the marathon and Grant Hackett would be 27% faster, lapping Boy Charlton 4 times in the 1500m swim. Results by Olympics For athletics, the highest %I/O was in 1900 (10.9%). Values peaked before WWI, dropped after that war, rebounded in 1924, peaked before WW2, dropped after that war, rebounded in 1952, remained high through the Cold War, dropped in 1980 and 1984 due to boycotting and then rebounded in 1988 when Ben Johnson of Canada was disqualified for doping in the men's 100 m run. Following a crackdown on performance enhancing drugs, 2/3 of the 1988 winners would still have won in 2000 and 1/2 would still have won in 2008. %I/O rebounded to 0.65% in 2004 and 0.34% in 2008. In swimming, %I/O values remained high through two world wars from 1912 through 1976. Values declined due to boycotting in 1980 and 1984, rebounded in 1988 and dropped in 1992 and 1996 as doping controls were enhanced. The values of 1.3% in 2000 and 1.8% in 2008 are unusual only as compared to the last eight Games but were commonplace before then. The importance of swim suits is overstated in that drag is measured passively as compared to suits not used in competition. Results by Gender In athletics, as opportunities and training methods began to catch up to those of men, women improved about 1% more than men from 1900 to 1988. After 1988, women improved a bit less than men, equalizing %I/O for both genders at 1.3% for all events. Similarly in swimming, women improved 0.6% more than men per Olympiad from 1912 to 1976, after which improvement was at the same rate as for men. Both genders have improved at about 1.9% for all events. Estimated Great Britain Medal Count in 2012 In the last 12 fully attended Games, the host nation earned 13 more medal at home than four years before. Great Britain should thus win 47 + 13 or 60 medals at London in 2012.

#### THE EMPLOYMENT OF ALTERNATING INTERMITTENT VISION DURING GOAL-DIRECTED AIMING

HANSEN, S.

*NIPISSING UNIVERSITY*

THE EMPLOYMENT OF ALTERNATING INTERMITTENT VISION DURING GOAL-DIRECTED AIMING Hansen, S.1, Hallam, M.2, Bennett, S.J.2, 1: Nipissing University (Canada), 2: LJMU (United Kingdom) Introduction Humans are capable of integrating alternating monocular visual samples to gain information needed for complex tasks such as one-handed ball catching (Olivier et al, 2000). However, deterioration in performance occurs when an inter-ocular delay is added between monocular visual samples (Bennett et al, 2000). Studies investigating reach-to-grasp tasks have also revealed that humans have difficulty integrating alternating monocular visual samples when there is an inter-ocular delay (Hansen et al, 2011; Wilson et al, 2008), resulting in a lengthened movement time and larger grip apertures to compensate for a reduced binocular percept. The current experiment was designed to further examine the apparent inability to integrate alternating monocular samples by using a manual aiming task that did not require control of a grip aperture, but still required a precise action. Methods Participants aimed at targets of three distances (250, 300 or 350mm). Liquid crystal goggles were used to provide the binocular, monocular, or three alternating monocular vision conditions. In the alternating conditions, 25ms monocular samples were provided to the right and left eye without a delay (0 ms), or with a delay of 25 or 50ms. Participants completed 150 randomly ordered trials, 10 in each of 15 conditions. A 2D digitizing tablet recorded the movements. Results An inter-ocular delay of 25 or 50ms resulted in longer movement time ( $F(4,44)=25.23$ ;  $p<0.001$ ) and time to reach peak velocity ( $F(4,44)=23.30$ ;  $p<0.001$ ) than those observed in the other conditions. Although there were main effects of target distance for constant error, there were no main effects or interactions involving vision condition. However, analysis of peak velocity revealed a significant interaction of vision condition and target ( $F(8,88)=3.44$ ;  $p<0.002$ ). Participants produced a lower peak velocity and failed to scale their velocity to the target distance when there was an inter-ocular delay. Discussion As expected, aiming accuracy was not influenced by visual condition. This required participants to compensate for the disrupted binocular percept in alternating monocular conditions by reducing limb velocity and consequently increasing the time to complete the action. The current results parallel studies of alternating monocular vision and grasping (Hansen et al., 2011; Wilson et al., 2008) and thus support the notion that humans are intolerant to alternating monocular vision with an inter-ocular delay. #### COMPARISON OF THE EFFECTS OF SELF-CONTROL AND INSTRUCTOR-CONTROL FEEDBACKS ON PERFORMANCE AND FORCE-PRODUCTION TASK LEARNING AFTER GOOD, POOR, AND GOOD-POOR ATTEMPTS

AHMADI, P., AZIZI, M.

*ISLAMIC SHAHRE-RAY AZAD UNIVERSITY*

Introduction Improved performance have been shown if the subjects receive feedback both for good and poor attempts; by this feedback subjects will be both encouraged and informed about their errors (Chivacowsky 2002). Considering self control feedback (Janella 1997) and previous research in regard to positive and negative feedbacks (Chivacowsky2002), this study is aimed to compare the effects of self-control and instructor-control feedbacks on performance and force-production task learning after good, poor, and good- poor attempts. Methods 60 subjects were randomly divided into four groups: self-control feedback, instructor-control feedback after good, poor, and good-poor trials groups. Acquisition phase include 6 series of 12 attempts. All participant produced 10 kg force in acquisition phase. They couldn't see the result. After 24 hours, subjects performed a retention and transfer tests without feedback. To analyze data, Factorial analysis of variance with repeated measure was used. Results In the acquisition phase significant improvements occurred in the performance of the four groups. However, there was no significant difference between the groups. Performance of the self-control feedback group after good, poor, and good-poor attempts was significantly improved in comparison with instructor-control feedback group. No significant difference was observed between instructor- control groups. Discussion It seems that each of instructor-control conditions has its own specific benefits on learning, and this lead to the similar learning. Chivacowsky, S., & Wulf, G. (2002). ### INCREASING CONTEXTUAL INTERFERENCE EFFECT ON GOLF PUTTING TASK

MENDES, R., DIAS, G.

*ESCOLA SUPERIOR DE EDUCAÇÃO DE COIMBRA - COLLEGE OF EDUCATION (PORTUGAL)*

Mendes, R.I, Dias, G. 2 1: ESE-IPC (Coimbra, Portugal), 2: FCDEF-UC (Coimbra) Introduction Porter and Magill (2005, 2010) advocate that can be beneficial to promote a gradual increase of Contextual Interference (CI) in acquisition in order to achieve positive effects on learning, especially in retention and transfer. The purpose of this study was to investigate the increasing CI effect on learning a golf putting task. Methods Forty inexperienced golfers undergraduate students (19,7±1.9 years old) were randomly assigned to one of four groups: blocked, serial, random and increasing CI practice schedules. They putted 126 trails in acquisition (3 distances to hole: 2, 2.75 and 3.5 meters) in a artificial indoor golf carpet, 30 trials in a random order in retention test and, in the transfer test 20 trials: T1 - 10 at 2.5 meters and 10 to T2 - 2.5 meters with 10 degrees of deviation (angle) from the starting point towards the hole. Absolute error (AE) a variable error (VE) were analysed using separate analyses of variances for acquisition (4 practice conditions x 9 blocks of trials) with repeated measures on the last factor and One-Way ANOVAs for retention and transfer tests. The Tukey HSD test was applied to the Post hoc analysis of data. Results It's observed in AE and VE a superiority of performance of increasing CI group on transfer test. However weren't significant differences between the four conditions in the transfer distance test,  $F(3,44)=0.535$ ,  $p=0.66$  and transfer angle test,  $F(3,44)=1.225$ ,  $p=0.31$ . Discussion Mendes & al. (2008) found better results on learning by effect of increase CI on a putt task. The effect of increasing CI was not found in this experiment. According to Guadagnoli and Lee (2004) several factors may constrain the effect of CI in ecological and field tasks as, for instance, the organization and amount of practice or the specificity and task complexity. It's necessary investigate the effects of these variables with the increasing CI practice References Guadagnoli MA, Lee TD (2004). Challenge point: a framework for conceptualizing the effects of various practice conditions in motor learning. *J Mot Behav.*, 36, 2, 212-224. Mendes R, Martins R, Dias G (2008). ### GOLF PUTTING: PROCEDURES AND DATA ANALYSIS

MENDES, R., DIAS, G., COUCEIRO, M., LUZ, J., FIGUEIREDO, C.

*ESCOLA SUPERIOR DE EDUCAÇÃO DE COIMBRA - COLLEGE OF EDUCATION (PORTUGAL)*

GOLF PUTTING: PROCEDURES AND DATA ANALYSIS Mendes, R.I, Dias, G.2, Couceiro MS.3, Luz JM.3, Figueiredo CM.3 1: ESE-IPC and CIPER (Coimbra and Lisboa, Portugal), 2: FCDEF-UC (Coimbra), 3: ISE-IPC (Coimbra) Introduction The coordination and control in the practice of golf putting is an individual process that is different for each subject depending on their profile and characteristics (Pelz, 2000; Hume et al. 2005). Like other motor skills, the intra and inter-individual performance resulting from the execution of this movement is a "fingerprint" (i.e., "signature") that is unique to each individual (Davids et al., 2008). The aim of this study was to present the experimental design and methodological aspects in the analysis of the effects of variability in golf putting performance of novice golf players. Methods Three male subjects, all right-handed and without previous experience related to the practice of Golf, performed three putts to 2m, 3m and 4m. The ball's trajectory and the putter movement were automatically analyzed based on visual detection and parameter estimation, using the Matlab software to determine the amplitude, velocity and acceleration of the putting execution, based on the respective video recordings. Results The results show that putter's trajectory during the movement is similar to a sinusoidal function. When a player has a radial error different than zero, the tendency is to raise the amplitude in position, velocity and acceleration of the putter in the second trial, in order to correct that error. Anyway, exceptions to this situation occur, when the subject can reduce or even eliminate the radial error in the second attempt, tends to maintain or raise the amplitude in position, velocity and acceleration of the putter. The available data confirm that golf's putting is a complex movement and differently executed from subject to subject. Discussion The intra-and inter-individual feature that results from putting represent a "fingerprint" that is unique to each individual. Experimental results clearly show, when considering different trials of every player, that each of them has a typical and distinct game style, a "fingerprint" (i.e., signature), confirming conclusions from studies mentioned in the introduction (c.f., Pelz, 2000). It becomes imperative that this movement is analyzed not only from the quantitative point of view, from the perspective of quantifying the error, but also from a qualitative point of view that focuses on the measures of the process variables, i.e., the closest approach of dynamic (c.f., Davids et al., 2008). ### THROWING VARIABILITY AND ACCURACY UNDER INSTABILITY CONDITIONS IN YOUNG TEAM-HANDBALL PLAYERS.

MORENO, F.J., GUTIERREZ, O., URBAN, T.

*MIGUEL HERNANDEZ UNIVERSITY OF ELCHE*

Introduction Precision and ball speed at throwing are two very important conditions in team-handball, but this task is carried out into a wide variability depending on the way the thrower assembles the arm. Previous studies analyzed relationship between precision and ball speed (van der Tillaar & Ettema 2006). Different task constraints have been studied in relation to speed and accuracy of human movement (Davids, Bennet and Newell, 2006). The aim of this study was to analyze the effect of unstable conditions at throwing and its relation to movement variability. METHOD Twenty-five young handball players performed thirty-two throws on the floor and on unstable surface (Bosu). Kinematic variables from hands, arm and hip were collected (Polhemus Liberty 240Hz update rate), ball speed (RS3600) and accuracy were recorded to determine performance. Correlation analysis was carried out to analyze the relationship between kinematics, movement variability and performance. Repeated measure ANOVA was carried out to compare unstable conditions effects. RESULTS Data did not offer concordance between ball speed and precision of throwing. Significant relations were found between hand rotation degree ( $p<0.50$ ), hip ( $p<0.01$ ) and amplitude of movement ( $p<0.01$ ) with quantity of error. Also relations were found between amplitude of movement and ball speed ( $p<0.01$ ) and variability of the ball speed as well as variability of the range of movement with

quantity of error. Unstable conditions did not affect ball speed and precision of throws. **DISCUSSION** As in this research, previous studies have not found the ball speed-precision trade-off in handball players (van der Tillaar & Ettema, 2006 and Párraga, Sánchez & Oña, 2001). Despite the fact variability is an inherent feature in human movements, and there is not a unique way to perform a throw, we have found some kinematic profiles related to better performance. Lower hip rotation and shorter movement amplitude correlated to higher ball speed and accuracy and lower variability at ball speed. Handball players exhibited higher variability under unstable conditions but it did not affect to performance. As conclusion, accuracy is not related to ball speed, variability is not clearly related to performance and shorter movements are faster and more accurate in handball throws. **REFERENCES.** Davids, K., Bennett, S. & Newell, K.M. ## **ASOCIATION BETWEEN MOTOR COORDINATION AND ACADEMIC ACHIEVEMENT IN PORTUGUESE ELEMENTARY SCHOOL CHILDREN**

LOPES, L.1, SANTOS, R.2, SARAIVA, J.P.1, LOPES, V.3, PEREIRA, B.1

1. INSTITUTE OF EDUCATION, UNIVERSITY OF MINHO (CIFEPEC) 2. MAIA INSTITUTE OF HIGHER EDUCATION (CIDESD) 3. POLYTECHNIC INSTITUTE OF BRAGANÇA (CIDESD)

**Introduction** Several studies have addressed the relations between physical activity (PA), fitness and academic achievement (AA), however, no investigation has linked motor coordination (MC) and AA. We aimed to evaluate the relationship between MC and AA in a sample of Portuguese children aged 9-12 years. **Methods** This is a 2009/2010 school-based study with 596 urban children from the north of Portugal. AA was assessed using the Portuguese Language and Mathematics National Exams. MC was evaluated with the Körperkoordination Test für Kinder(1). Cardiorespiratory fitness was predicted by a maximal multistage 20m shuttle-run test of the Fitnessgram Test Battery(2). Body weight and height were measured following standard procedures. Socioeconomic status was based on annual family income. Logistic Regression was used to analyze the influence of MC on AA. Results 51.6% of the sample exhibited MC disorders or MC insufficiency and none of the participants showed very good MC. In both genders, children with insufficient MC or MC disorders exhibited a lower probability of having high AA, compared with those with normal or good MC ( $p < 0.05$  for trend for both) after adjusting for cardiorespiratory fitness, body mass index and socioeconomic status. **Discussion** Children of both genders with lower MC had lower odds of having high AA, after adjusting for potential confounding factors. Our results highlight the need of providing children opportunities to engage in structured and unstructured PA that requires different motor skills since MC in childhood may support AA. **References** 1.Schilling F. ## **DIFFERENT LEVELS OF VARIABILITY VERSUS SPECIFICITY OF PRACTICE APPLIED TO INCREASE THE PERFORMANCE UNDER STATICS TASK CONSTRAINTS.**

MORENO, F.J., PELAEZ, M., URBAN, T., REINA, R.

MIGUEL HERNÁNDEZ UNIVERSITY.

**Introduction** Variability has usually been considered as an index of error, however, actually some studies have shown that motor variability allows exploring the environment and it can be useful for learning (Riley y Turkey, 2002; Davids et al., 2003). Therefore, increased variability during motor learning could be considered for a more adequately exploring behavior and increase task effectiveness (Davids, et al. 2003). This study examines the effect of different levels of variability of practice on a closed motor skill. **Methods** Thirty nine participants (18 male, 21 female) took part in this study. The participants were asked to perform series of throwing a ball with the right hand to a target located at 1.65 meters distance in front of them. After an initial test of eighty throws, the participants were divided in five groups. Four levels of variability of practice were applied to four groups along eight sessions (one per day) of 160 throws each of them. One control group did not practice. A final test and three retention tests (4 days, 2 weeks and 4 weeks) were carried out for the five groups. Kinematic variables were collected by Polhemus Liberty sensors attached to performing arm and hip (240Hz). Ball bounces were video recorded to calculate radial error. A repeated measures ANOVA was conducted to estimate the effects of training on accuracy. Result Repeated measures ANOVA showed significant differences for the radial error ( $F(4,24) = 20.86$ ;  $p < 0.001$ ;  $\eta^2 = 0.47$ ) and the standard deviation of radial error ( $F(4,24) = 21.21$ ;  $p < 0.001$ ;  $\eta^2 = 0.47$ ). No significant differences were obtained for group interaction. Nevertheless, all intervention groups improved (r1) their performance according the following ranking: level 1 ( $-3.34 \pm 2.56$ ), level 3 ( $-2.43 \pm 3.05$ ), level 2 ( $-1.89 \pm 2.38$ ) and consistency ( $-1.51 \pm 2.03$ ). At the post- and retention test, a Scheffé pos-hoc analysis showed significant differences between control group and variability level 2 group ( $p < 0.05$ ). Significant differences were also obtained between control and level 2 of variability groups in the SD radial error ( $p < 0.05$ ) in the post-test. **Discussion** Practice increased accuracy. Low-impact variability of practice (group 2) showed higher improvement in throwing accuracy. The higher level of variability of practice (group 4) did not increased performance variability in final test or in retention tests. The results suggest the effective use of variability to enhance the performance under static task constraints. **References** Riley MA, Turvey MT. (2002). *Journal of Motor Behavior*, 34: 99-125. ## **THE INFLUENCE OF TIME-SCALE CHANGES IN BASKETBALL FREE-THROW ON ACTION ANTICIPATION**

UCHIDA, Y., HONDA, M.

WASEDA UNIVERSITY

[Introduction] Recent neurophysiological studies have reported the presence of a human motor mirror system providing feedback of movement simulation to the observer (Cross et al., 2006). In addition, at the psychophysical level, elite basketball players predicted the basket shot's fate by reading the body kinematics (Aglioti et al., 2008). However, the influence of changes in the variable of the time factor of an observed movement on such stimulation has not been clarified. Therefore, this study aimed to examine the influence of time-scale changes in movement during a basketball free-throw on action anticipation, and differences in eye position, involved in these changes, by simultaneously conducting eye-tracking measurement. [Methods] Six male basketball team members ("players"), aged  $21.8 \pm 0.4$ , and 6 males without experience of playing basketball ("watchers"), aged  $22.3 \pm 2.3$ , were studied. Images of 10 successful and 10 unsuccessful throws, giving a total of 20 free-throws, recorded from shooting to the peak of the throw, were randomly presented to subjects at 3

different speeds (slow, normal, and fast). The mean rates of correct predictions of the results were calculated by group. Eye position during observation was measured using an eye tracking system to examine rates of fixation within 3 regions (lower and upper body, and ball-tracking) of the image. [Results] The correct prediction rate was significantly higher in the players than in the watchers when watching the images at normal speed ( $p < 0.01$ ). Analysis of the simultaneously recorded eye position data revealed that the players' fixation rate was highest in the lower body region, followed, in this order, by the upper and ball-tracking regions. In contrast, the watchers' eye position was not observed in the lower body region, and their fixation rate was higher in the ball-tracking than in the upper body region. When watching the images at slow and fast speeds, a similar tendency in the fixation rate was observed in both groups, although the players' correct prediction rates significantly decreased ( $p < 0.01$ ). [Discussion] When watching the images at normal speed, the players' correct prediction rate was significantly higher as a result of their eye position being focused on the lower body region. The factors essential for mental imagery which is a process contributing to the prediction of throw results are involved in this region. The players' correct prediction rates varying among different speeds despite their similar eye position suggest that the variable of the time factor may be associated with mental imagery. Based on these results, it may be concluded that the speed of a movement, similar to that necessary for the observer to actually execute it, facilitates mental imagery and anticipation of the outcome. ### **EFFECT OF COMBINING HIGH FREQUENCY OF KNOWLEDGE OF PERFORMANCE WITH SELF ESTIMATION OF ERROR IN THE LEARNING OF BASKETBALL SHOOTING BY CHILDREN**

TEIXEIRA, L.A., SILVA, L.C., PEREIRA, C.F.

UNIVERSITY OF SÃO PAULO

**Introduction** The present study aimed at assessing the effect of combining high frequency of knowledge of performance (KP) with self estimation of error in the learning of basketball shooting in children. **Methods** Participated of the study 40 males and females in the age range of 10-12 years. They were assigned to the following experimental groups: error estimation associated with KP in all trials (EST100-KP100), no error estimation associated with KP in all trials (EST0-KP100), error estimation in all trials associated with KP in 33% of the trials (EST100-KP33), and no error estimation associated with KP in 33% of the trials (EST0-KP33). During task acquisition, the children executed 50 trials from a single position. Performance in the shooting was filmed and evaluated offline for the periods before, immediately after and one day following the practice trials. Performance was evaluated on the basis of qualitative analysis of movement pattern. **Results** Results showed that all groups improved performance with practice, but no between-group difference was detected in the immediate posttest. In retention we found that high frequency of error estimation associated with high frequency of KP led to the best results of learning, with EST100-KP100 group achieving significantly higher scores in comparison with the EST0-KP100 and EST100-KP33 groups. **Discussion** These results indicate that self evaluation by children associated with abundant extrinsic information about their errors potentialize the beneficial effect of KP without creating dependence on that information in the learning of complex motor patterns by children, as those characteristic of sport actions.

### **SIGNIFICANCE OF SKIN CONDUCTANCE RESPONSES REVEALED BY GO/NO GO MOTOR TASK.**

YONEDA, T.1, BAN, Y.2, KITO, T.1, KIMURA, M.3, SAKURABA, K.1

1JUNTENDO UNIVERSITY, 2JUNTENDO UNIVERSITY DOCTORAL PROGRAM, 3TOKYO INSTITUTE OF POLYTECHNIC

**Introduction:** Skin conductance response (SCR), a non-invasive method that measures the activity of sweat glands enhanced by sympathetic nerves, has been regarded as an excellent reflector of sympathetic nerve activity<sup>1)2)</sup>, although the neurogram, an invasive method, is regarded as the conclusive method to study the activity of autonomic nervous system. Somato-autonomic linkage has been discussed in peripheral circulation during exercise. It has been postulated that central motor command of the muscular system must have an effect on sympathetic nerve activity in sustained isometric force exertion<sup>3)4)5)6)7)</sup>. To investigate the intrinsic quality of the central command on the autonomic nervous system, a GO/No GO ballistic force task was adopted in this study. The GO/No GO motor task was chosen to provide a means for judging whether a descending neural volley is constructed only by neural components for a motor plan, or also by components for motor output. **Introduction** of the ballistic contraction to the study of autonomic activities during movement could provide a means to argue for the dependence of cortical command in collateral nervous functions, since it would put away the feedback component in related neural circuits. **Methods:** Twelve volunteers participated in this study. They sat on a stable chair and performed isometric hand grip force as fast as possible as a GO/No GO RT task. Force targets were set at three grades (10, 30, 50 %MVC) displayed on a monitor screen. SCRs were recorded from the contra-lateral index finger. **Results & Discussion:** SCR changes appeared in both GO trials and No GO trials. However, when changing the SCR amplitudes of GO trials, exerting force conditions were far higher than those of No GO trials. Furthermore, SCR amplitudes of GO trials increased depending on force amplitude exerted. Different SCR responses between trial conditions and force—dependent SCR change were observed. The results suggest that cortical motor programs including the plan and the neural output must have effects on sympathetic nerve activity as the central command. **References:** 1) Tranel, D. and Damasio, H. ### **A STUDY OF INTEGRATION OF VISUAL, AUDITORY AND SOMATOSENSORY INFORMATION USING A HAPTIC DEVICE**

KAWABATA, S.1, KAWABATA, T.1, YAMADA, M.1, YANAGIDA, S.1, NURUKI, A.1, YUNOKUCHI, K.1, ROTHWELL, J.2

1: KAGOSHIMA UNIV (KAGOSHIMA, JAPAN), 2: UCL (LONDON, UK)

**Introduction** We use categories of sensory information in order to process external information. There are many studies investigating sensory interactions, but the haptic effects on other senses have not been sufficiently studied. The aim of this study was to measure how the brain integrates visual, auditory and tactile information using a haptic device. **Methods** We used a behavioral task based on the observation that when two identical visual objects move toward each other, they overlap and then continue their original motion (Bushara et al., 2003). Haptic, auditory or haptic and auditory stimulation was presented at various times relative to visual objects overlapped (100-, 200-, 300-, 400-ms before, after, or at the same time as visual objects overlapped). Subjects may perceive the objects as either bypassing each other or colliding and reversing their motion direction. We worked out the colliding rates of subjects for each presented time and for each presented sense type. **Results** The colliding rates when haptic stimulation was presented were higher than when auditory stimu-

lation was presented. However, the colliding rates when haptic and auditory stimulation was presented were the highest in other senses. Moreover, the rates were the highest when stimulation presented at around the time when two identical visual objects overlapped. Moreover, the rates were higher when stimulation was presented before they overlapped than when stimulation was presented after they had overlapped. Discussion Our results showed that timing of the stimulus presentation and type of stimulus presentation are important factors for interaction between different senses. ### PP-BN09 Coaching: Monitoring and Preparation for Sport

#### THE CENTRALIZED PREPARATION OF BRAZILIAN WOMEN ARTISTIC GYMNASTICS TEAM

OLIVEIRA, M.S., NUNOMURA, M.

UNIVERSITY OF SAO PAULO

**Introduction** Over two Olympic cycles, 2001-2004 and 2005-2008, the Brazilian Women Artistic Gymnastics (WAG) team obtained the best results in its history. This success was attributed to the infrastructure of the Centre of Excellence (located in Curitiba), the implementation of centralized training program (SMOLEUSKIY; GAVERDOUSKIY, 1996) and the leadership of a renowned foreigner coach. However, we found out several problems caused by this model imported from the Sovietic Union (ARKAEV; SUCHILIN, 2004), as it was not adapted to the Brazilian AG context. Therefore, the aim of this field study was to discuss the centralized preparation of Brazilian WAG team. **Methods** We interviewed 34 WAG coaches who are coaching at the competitive level in 29 institutions in Brazil and have been competing nationally and some internationally. For data treatment we used the Content Analysis (BARDIN, 2008). **Results and discussion** The positive aspects of the program are mainly related to the physical infrastructure of the Centre of Excellence, human resources available to the gymnasts, and the financial support. Despite the aforementioned positive aspects, the negative ones seem to have more significance due to the greater number of categories and unity of analysis (BARDIN, 2008). The coaches said that there was a lack of recognition and depreciation of the Brazilian coaches. Another problem was the departure of the best gymnasts from their institutions to the Centre of Excellence. This aspect discouraged the clubs to invest in AG and, therefore, was prejudicial to the other gymnasts, coaches and AG in general. The coaches also said that the gymnasts who were not selected or successful in joining the centralized training program felt discouraged, without motivation and goals in the sport and dropped out. All these negative aspects weakened the process of development of the future generations of gymnasts in the country. **Conclusion** Besides the negative aspects, we believe that the implementation of the centralized preparation of the team was a significant experience for all involved with AG. From this initiative and its outcomes and impacts, it is important to reflect and rethink the format and concepts that led to this program. Undoubtedly the centralized preparation of the team showed its effectiveness through the improvement of competitive results. On the other hand, it revealed several problems that need to be improved to better contribute to an equitable growth and development of WAG in Brazil. **References** ARKAEV, L.; SUCHILIN, N. #### PREPARING AN EXPEDITION - PERFORMING IN DUSTY ENVIRONMENTS

FERNANDO, C., LOPES, H., VICENTE, A.

UNIVERSITY OF MADEIRA, UNIVERSITY OF BEIRA INTERIOR, CIDESD

**INTRODUCTION** When preparing and organizing an expedition it is important to understand how the performance of the participants will be influenced by the conditions in which they will have to act and take decisions. We continue here the studies we made (Fernando et al., 2010) with cold and mud and how this conditions influence decisions, even very simple decisions. To easier compare the results we keep, as possible, the same methodology. Dust is present in lot of sport environments, mainly in Open Spaces Sports and in Environments Adaptation Sports, and even, Sometimes in collective Outdoors Sports. **METHODS** To a sample of 15 people aging between 21 and 27 years, we presented on a paper a test of 60 arithmetical operations (additions, subtractions, divisions and multiplications), with numbers equal or inferior to 5, distributed randomly. They should perform these arithmetical operations with two sorts of objectives: 1- first of all to make no mistakes; 2 - to do it as quickly as possible. The sample was divided in two groups of 7 and 8, randomly. One group, group A, answered to the test, always the same test, first comfortably sitting at a table, indoors, and then after having been exposed to win and dust for 5 minutes, in a temperature of about 22 degrees C, in a "tunnel of dust". The other group, group B, did the same thing but in reverse order. So, after to do the first test, they had an hour for a hot shower and then answered to the same test in the same comfortable situation indoors. Everybody was using practice suits and when exposed to dust were wearing protection glasses. We've measured the time of each participant and the total of errors committed by all the members of each group. **RESULTS** Group A - the average of the time in adverse conditions was 23% higher than indoors in comfortable conditions. Distribution results had a much wider distribution in the outdoors situation. While in indoors conditions there where practically no errors (less than 3.5% of the total), in adverse conditions there where 15% of errors. Group B - the average of the time in adverse conditions was 25% higher than indoors in comfortable conditions. Distribution results had a much wider distribution in the outdoors situation. While in indoors conditions there where practically no errors (less than 2% of the total), in adverse conditions there where 20% of errors. **DISCUSSION** Performance was influenced by dust in the clothes and over the body so we must know what to expect and the influence it can have in the activities. This knowledge is an essential instrument to organize and plan an expedition. **REFERENCES** Fernando, C., Vicente, A., Lopes, H. & Almada, F. (2010). 15th ECSS, 473-474.

#### PREPARING AN EXPEDITION - PERFORMING IN A WARM AND SWEATING ENVIRONMENT

LOPES, H., VICENTE, A., FERNANDO, C.

UNIVERSITY OF MADEIRA, UNIVERSITY OF BEIRA INTERIOR, CIDESD

**INTRODUCTION** To prepare and organize an expedition, for instance in the mountain or at the sea, it is important to understand how the performance of the participants will be influenced by the weather conditions in which they have to act and take decisions. It is not only the physiological reaction that we have to understand, it's also important to know how much conditions will influence decisions, even very simple decisions. With this study we complement similar works in cold, muddy and dusty conditions (Fernando et al., 2010). So we

keep the methodology used as similar as possible in order to enable comparing data and results. **METHODS** To a sample of 18 people aging between 18 and 25 years, we presented, on a paper, a test of 60 arithmetical operations (additions, subtractions, divisions and multiplications), with numbers equal or inferior to 5, distributed randomly. They should perform these arithmetical operations with to sorts of objectives: 1- first of all to make no mistakes; 2 – to do it as quickly as possible. The sample was divided in two groups of 9, randomly. One group, group A, answered to the test, always the same test, first comfortably sitting at a table, indoors, and then, after a light 15 minutes walk with temperatures of about 27 degrees C, outdoors and wearing heavy winter clothes. The other group, group B, did the same thing but in reverse order. So, after the walk (that they did together with group A), they had an hour for a shower and then answered to the same test in the same comfortable situation indoors. We've measured the time of each participant and the total of errors committed by all the members of each group. **RESULTS** Group A - the average of the time in adverse conditions was 19% higher than indoors in comfortable conditions. Distribution results had a much wider distribution in the outdoors situation. While in indoors conditions there were practically no errors (less than 1% of the total), in adverse conditions there were 14% of errors. Group B - the average of the time in adverse conditions was 24% higher than indoors in comfortable conditions. Distribution results had a much wider distribution in the outdoors situation. While in indoors conditions there were practically no errors (less than 1% of the total), in adverse conditions there were 12% of errors. **DISCUSSION** When practicing for an expedition people must consider not only the performances that must be useful during the raid, but also should take in account the conditions that can occur and the difficulties that will result from them. Even a heavy sweat in a walk as short as 15 minutes can have influence in the way people answers to a very easy test, altering the performance. **REFERENCES** Fernando, C., Vicente, A., Lopes, H. & Almada, F. (2010). 15th ECSS, 473-474.

## PREPARING AN EXPEDITION - PERFORMING IN A MUDDY ENVIRONMENT

VICENTE, A., FERNANDO, C., LOPES, H.

UNIVERSITY OF BEIRA INTERIOR, UNIVERSITY OF MADEIRA, CIDESD

**INTRODUCTION** We've studied and presented last year in this Congress how cold and rain could retard decisions, even very simple decisions, and how important it was to know the importance it can have in it's preparation (Fernando et al., 2010). It is important to understand how the performance of the participants will be influenced by mud and how it can change the way they take decisions, by being unpleasant (or pleasant). Mud is present in situations of outdoors collective sports (for instance football), in open spaces sports (like walking raids, etc.) and in environments adaptation sports (as rappelling, etc.). Developing this kind of studies will allow us, in the future, to compared the influences of different sorts of conditions in the practice and in the performance in those types of sports. We will follow a similar methodology in all these studies to keep it easier to compare the results. **METHODS** To a sample of 12 people aging between 15 and 23 years, we've presented on a paper a test of 60 arithmetical operations (additions, subtractions, divisions and multiplications), with numbers equal or inferior to 5, randomly distributed. They should perform these arithmetical operations with two sorts of objectives: 1- first of all to make no mistakes; 2 – to do it as quickly as possible. The sample was divided in two groups of 6 randomly. One group, group A, answered to the test, always the same test, first comfortably sitting at a table, indoors, and then, after playing for five minutes in a muddy pool, in an environment temperature of about 25 degrees C, outdoors. To answer to the test, people came out from the pool and could use towels to clean the hands. The other group, group B, did the same thing but in the reverse order. So, after being in the mud pool and doing the first test, they had half an hour for a hot shower and then answered to the same test in the same comfortable situation indoors. Everybody was using practice suits. We controlled the time of each participant and the total of errors committed by all the members of each group. **RESULTS** Group A - the time average in adverse conditions was 45% higher than indoors in comfortable conditions. Distribution results had a much wider distribution in the outdoors situation. While in indoors conditions there were practically no errors (less than 1% of the total), in adverse conditions there were 17% of errors. Group B - the time average in adverse conditions was 34% higher than indoors in comfortable conditions. Distribution results had a much wider distribution in the outdoors situation. While in indoors conditions there were practically no errors (less than 1% of the total), in adverse conditions there were 25% of errors. **DISCUSSION** We found a similar conclusion to the previous study, however in more profound degree. It is essential to take into account the conditions that can occur and the difficulties that result from them. **REFERENCES** Fernando, C., Vicente, A., Lopes, H. & Almada, F. (2010). 15th ECSS, 168.

## OPTIMIZATION TECHNICAL TRAINING LEVEL JUNIOR TEAMS

MIHAILA, I., GHERVAN, P., IANCU, A., POPESCU, C., STANCU, M.

UNIVERSITY OF PITESTI, STEFAN CEL MARE UNIVERSITY SUCEAVA, VALAHIA UNIVERSITY TARGOVISTE, UNIVERSITY OF PITESTI, UNIVERSITY OF PITESTI

**Introduction** In the game of handball technique is currently the base, which constantly develops and improves the game, being more dynamic factor in raising the level of handball at increasingly high all over the world. There handball teams and players that do not possess the perfect elements and techniques required by the motor structure of the game, absolutely necessary for achieving victory and sporting performance. **Methods** The research was conducted during a competitive year (2009/2010) to a group of junior level II (15-17 years) of a school sports club. At the beginning and end of components research group under study have passed a series of control samples for testing the level of technical skill, the results and differences are interpreted in terms of statistics. Between the two tests was driven by a series of specific exercises to improve technical training. **Results** Samples of control subjects and the results passed the two tests were: the wall passes: initial testing  $23,43 \pm 2,24$ , variability coefficient 9,58%; final test  $27,86 \pm 2,03$ , variability coefficient 7,30%,  $p < 0,05$ ; specific test: initial testing  $47,85 \pm 2,91$ , variability coefficient 6,08%; final test  $42,88 \pm 2,62$ , variability coefficient 6,12%,  $p < 0,05$ ; dribbling 20 m: initial testing  $13,28 \pm 0,98$ , variability coefficient 7,35%; final test  $11,45 \pm 0,93$ , variability coefficient 8,08%,  $p < 0,05$ ; in slalom dribbling: initial testing  $16,01 \pm 0,99$ , variability coefficient 6,17%; final test  $13,96 \pm 0,96$ , variability coefficient 6,6%,  $p < 0,05$ ; small marathon: initial testing  $65,03 \pm 2,26$ , variability coefficient 3,48%; final test  $60,77 \pm 2,22$ , variability coefficient 3,66%,  $p < 0,05$ . Record the differences statistically significant ( $p < 0,05$ ) in all samples between initial testing and final inspection. **Conclusions** Technology is driving that shapes the structure of the game of handball, and the effectiveness is directly proportional to the performance capability of each team (player) in the party. The proposed program for improving the efficiency of technical training was expected from the results in both control samples and the method of the tactical action game. **Reference** Dupont G., Bosquet L., (2007), *Méthodologie de l'entraînement*, Ellipses edition, Paris Mihaila I., Popescu C., (2009), *Handbal indrumar practico-metodic*, Ed. ## PREPARATION OF YOUNG SPORTSMEN TO THE PROFESSIONAL CAREER.

LIKHACHEV, O.

SMOLENSK STATE INSTITUTE OF PHYSICAL CULTURE

PREPARATION OF YOUNG SPORTSMEN TO THE PROFESSIONAL CAREER. Likhachev O. 1; Fomin S. 2; Fomin A. 1. 1: Smolensk State Academy of Physical Culture, Sports and Tourism (Smolensk, Russia); 2: Russian State University of Physical Culture, Sports and Tourism (Moscow, Russia). Introduction. Nowadays, at the stage of economic and political changes in Russia, aggressive professionalization and commercialization of sport games is being observed. This is not just national, Russian phenomenon. There are similar tendencies in sport development in other countries. Professional sportsmen admittance to amateur sports last stronghold – participation in Olympic Games – is the basic stimulus of movement in this direction. Methods. The aim of the work is: the search of reserves and conditions which are necessary for successful preparation of qualified young sportsmen for professional basketball. For this purpose we used questionnaires, study of scientific and methodological works, periodicals and documents. 168 basketball players at the age of 17-20 and 57 coaches working with young sportsmen in different teams, which were in the first and top professional leagues of Russia basketball championship took part in questionnaires. Discussion. As a result of questionnaire it turned out that according to trainers they can't succeed in achieving the responsible attitude of young sportsmen to the training without any assistance as they haven't formed the responsible attitude to their sportive career yet. As a result while transforming from junior to adult teams we have big unjustified losses of talented sportsmen who weren't taught to work without any assistance. At the same time there aren't any special interseason training camps in Russia yet. Analogical results were obtained as a result of the questionnaire of young basketball players and the trainers of the student teams (the participants of the student league of Russia). According to them most of the students aren't ready to tough competition for the place in the team. After holidays the sportsmen practically aren't ready for the season, they have extra mass of the body, they practically lost the acquired level of technical and physical form during the last season. Results. The increased level of sport results in world sports, the wide professionalization of basketball and other sport games led to the necessity of specialized training of young sportsmen in the interseason period. At the same time the formation of the motives of the active preparation of young sportsmen without any assistance in the inter-season period acquires the paramount importance.

## APPLICATION OF CIRCULATING WATER CHANNEL FOR MONITORING AND EVALUATING PADDLING SKILL IN ELITE JAPANESE KAYAK ATHLETES

FUNATO, K., MATSU, A.

NIPPON SPORTS SCIENCE UNIVERSITY

APPLICATION OF CIRCULATING WATER CHANNEL (CWC) FOR MONITORING AND EVALUATING PADDLING SKILL IN ELITE JAPANESE KAYAK ATHLETES FUNATO, K.1 and MATSUO, A.2 1:Laboratory for Human Movement Sciences, Nippon Sport Science University (Tokyo, Japan) , 2 Japan Institute of Sports Sciences (Tokyo, Japan) Introduction In order to improve athletic performance of kayak paddling, circulating water channel (CWC) has newly constructed in Japan Institute of Sports Sciences (JISS). This study was designed to develop new training methods using CWC with monitoring mechanical variables such as propulsion force and rolling angle as well as comparing the physiological responses. Methods A rowing tank equipped with CWC was newly developed for both research and training of canoeing and rowing. Length, width and depth of the open channel in CWC were 10.0m, 2.5m and 0.6m, respectively. (respective size of the rowing tank were; length: 22.1m, width: 8.1m and height: 5.0m). Functional performance of the CWC were as follows; maximum velocity of the flow: 5.5m/s, uniformity of the flow:  $\sim \pm 5\%$  and maximum wave height:  $\sim 50\text{mm}$ . Bow of kayak boat was attached to the supporting guide system which measures propulsion force ( $F_y$ ) caused by paddling as well as rolling angle of the boat ( $\theta_r$ ). Subjects were national elite canoeing athletes (5males and 2 females, aged from 21-27). They performed interval training in the flow as to maintain the position of the boat at the water velocity of 3.5 to 5.5m/s. During interval paddling trials, simultaneous HR and  $\text{VO}_2$  were measured by K4b2 system (Cosmed, Italy). Results and Discussion Using newly developed system, definite boat propulsion force as well as three different angles (pitch, yaw and roll) were able to obtain and these parameters were useful information for monitoring kayak paddling skill. Relationship between rolling angle ( $\theta_r$ ) and propulsion force  $F_y$  (vertical axis) was obtained for different levels of Japanese kayak paddlers. National elite athletes were superior in  $F_y$  magnitude and  $\theta_r$  balance than these from collegiate athletes. Different instantaneous  $\theta_r$  (horizontal axis) and  $F_y$  (vertical axis) relations were characterized among athletic level, which the highest performer indicated clear eight figured shape in  $\theta_r - F_y$  curve. Conclusions Paddling skill for accelerating the kayak boat more effectively can be evaluated from the relationship between rolling angle and propulsion force. Circulating water channel simulation system for kayak paddling is useful for improving the athletic performance of the athletes.

## THE EFFECT OF DIFFERENT REST INTERVAL LENGTHS ON THE SUSTAINABILITY OF REPETITIONS DURING RESISTANCE TRAINING FOR LOWER LIMB

HASHEM, E.M., TAMMAM, A.H.

FACULTY OF PHYSICAL EDUCATION, TANTA UNIVERSITY, EGYPT

Introduction There is a lack of research that investigate the relationship between rest interval length and the sustainability of repetitions when training with loads designed to develop muscular endurance for similar muscle groups. So this study aimed to compare the effect of 3 different rest interval lengths (1-min (RIL1), 2-min (RIL2), or 3-minute (RIL3)) on the sustainability of repetitions (knee extension, leg curl, seated leg press, and squat) over 5 consecutive sets performed with a 15 repetition maximum (RM)- load. Methods Fourteen experienced, resistance-trained males volunteered to participate in the study (age,  $25.6 \pm 4.1$  yr; weight,  $78.8 \pm 7.1$  kg). All subjects were tested weekly over a period of 4 weeks. During the 1st testing session, 15 repetition maximum (RM)- load for 4 lower limb exercises performed in a set manner were determined for each subject. During the next 3 testing sessions, 5 consecutive sets of the exercises were performed to voluntary exhaustion. The 3 testing sessions differed only in the length of rest interval between sets and exercises RIL1, RIL2, or RIL3 with a random order to testing sessions. Results - For all exercises, results demonstrate significantly decline in repetitions completed between the first set and each subsequent set thereafter ( $P=0.000$ ). - Between RIL1 and RIL2 condition a significant differences in the ability to sustain repetitions occurred for leg press and squat ( $P=0.013$ ,  $0.024$ ) respectively. Whereas differences were not significant for leg curl and knee extension ( $P=0.461$ ,  $0.055$ ) respectively. - Between RIL1 and RIL3 condition a significant differences in the ability to sustain repetitions occurred for all exercises ( $P<0.05$ ). - Between RIL2 and RIL3 condition a significant differences in the ability to sustain repetitions occurred for knee extension, leg press, and squat ( $P=0.019$ ,  $0.023$ , and  $0.031$ ) respectively. Whereas differences were not significant for leg curl ( $P=0.297$ ). Discussion This study has shown that the repetitions has decline between the first set and each subsequent set there-

after, irrespective of the rest condition. This result suggest that when training for similar muscle groups (lower limb); the rest interval length must be long enough ( $\geq 3$  minute) to sustain a high number of repetitions over consecutive sets, or decrease the intensity to sustain repetitions. References Fleck S.J., and W.J. Kraemer. Designing Resistance Training Programs. Champaign, IL: Human Kinetics, 1987. Willardson, J.M., and L.N. Burkett. The effect of rest interval length on bench press performance with heavy versus light loads. J. Strength Condi. Res. 20:396–399. 2006.

### THE RELATIONSHIPS BETWEEN PHYSICAL STRENGTH AND ANTHROPOMETRIC FACTOR IN THE PERIOD OF THIRTY YEARS

SASAKI, T., TSUNODA, K., HOSHINO, H., TAKEDA, H.

HOKUSEI GAKUEN UNIVERSITY

Introduction Since 1975 we have executed the test to the new students and second grade students in Hokusei University. The physical strength of students has changed awfully during thirty years. The physical strength of students ought to relate to the rest of life. The purpose of this study is to reveal the way to solve the health problem in students. Methodology We have executed the test as seven items: These items are back strength, grip strength, side step, step test, forward flexion, trunk extension and vertical jump. The body height and weight as anthropometric factors have been measured for comparing the physical strength. The tests and measurement have executed at every April of the new school year. Results The body height in Japanese students has increased and reached plateau at 1995. On the other hand some items that are muscle strength and endurance capacity have decreased after the body height has reached the plateau. The flexibility also has decreased continuously. The muscle strength has reduced in particular. Discussion The health and ability of current students ought to strongly relate to the rest of their life. Therefore, the reduction of the physical strength in young adult is the main subject that has to be solved by the physical education. The reduction of muscle strength could be solved by physical education program in particular. It is important to increase the chance of physical activity in Japanese young adults.

### ESTIMATION AND VALIDITY VERIFICATION OF 1-RM ON BENCH PRESS, BACK SQUAT, LEG CURL AND LEG EXTENSION FROM 7-10RM, BASIC FITNESS AND ANTHROPOMETRIC VARIABLES FOR KOREAN ADULT MALE

LEE, B.K., SHIN, J.M.

SANGMYUNG UNIVERSITY

Introduction 1-RM is most useful item for strength training, so many equation for 1-RM were reported. Estimation of 1-RM were vary according to training level, age, anthropometric variables, and human race, etc. The purpose of this study were to develop and verify 1-RM prediction equation of leg curl and leg extension from anthropometric variables and 7-10RM. Methods Trained adult males of development group and verification group were measured 1-RM, anthropometric variables, and 7-10 RM(Barchle et al., 2000). This study was summarized and modified Lee et al.(2009), and Lee(2006). Results, Discussion As a results of regression analysis, The equation of bench press was  $y = -1245.954 + 1.092 * \text{right grip strength} + 0.331 * \text{standing long jump} + 2.858 * \text{circumference of upper arm}$  ( $p < .01$ ). The equation of back squat was  $y = -166.046 + 6.289 * \text{circumference of upper arm} + 0.410 * \text{standing long jump} - 0.340 * \text{circumference of chest}$  ( $p < .01$ ). The 7-10RM equation of LC was  $y = 29.946 + 0.821 * 7\text{-}10\text{RM}(\text{kg})$  ( $p < .01$ ), the equation of anthropometric variables was  $y = -48.838 + 2.428 * \text{thigh girth}(\text{cm})$  ( $p < .01$ ). The 7-10RM equation of LE was  $y = 4.275 + 1.255 * 7\text{-}10\text{RM}(\text{kg})$  ( $p < .01$ ), the equation of anthropometric variables was  $y = -4.411 * \text{weight}(\text{kg})$  ( $p < .05$ ). As a results of verification, there were no significant difference between measured 1-RM and predicted 1-RM for bench press and back squat. The equation of bench press and back squat were a little overestimate 1-RM. Both LC and LE, there were no significant difference, and high correlation between measured 1-RM and estimated 1-RM from 7-10 RM. The equation of 7-10 RM equation has a good validity, but the equation of anthropometric variables has a limitation to apply. Conclusion It was concluded that the satisfied 1-RM equation of bench press and back squat were made by anthropometric and basic fitness variables only for trained adult males. And both LC and LE, the satisfied 1-RM equation were made from submaximal strength(7-10 RM), except anthropometric variables. for trained Korean adult males. References Barchle TR, Earle RW (2000). Essentials of strength training and conditioning. 2nd Ed., Champaign, IL. Human Kinetics. Lee BK, Lee DK (2009). Estimation of 1-RM on Leg Extension and Leg Curl from Submaximal Strength and Anthropometric Variables for Adult Male, Kinesiology, 11(3), 21-30. Lee BK (2006). Development and verification 1-RM prediction equation of bench press, back squat and dead lift by anthropometric and basic fitness variables for adult males, Korea Sports Research, 17(6), 275-285.

### THE BODY- MIND IMPACT OF SINGLE 30-MINUTE DUNKING FEET, NECK, SHOULDER AND FEET MASSAGE

CHENG, CH.M.1, CHANG, K.M.2, TING, W.CH.3

1 : KUAS (KAOHSIUNG, TAIWAN), 2 : TJUIPINGTONG, TAIWAN), 3 : CSU (KAOHSIUNG, TAIWAN)

Introduction In Traditional Chinese Medicine (TCM), meridian point massage is a popular form of therapy island wide in Taiwan. The aim of this study was to investigate the emotional, physical, and mental impact of 30 minutes of feet dunking, neck and shoulder as well as foot massage. Methods Fourteen subjects participated in this study, in the relative humidity 36-37%, at room temperature 26 °C, after the dunking feet and neck massage for 10 minutes, with twenty minutes of feet massage. The impacts evaluated by using Positive and Negative Affect Scales (PANAS), Profile of Mood State Scale (POMS) and Foot Massage-Induced Feeling Inventory (FMFI). All of the data were showed with Mean  $\pm$  SD, and analyzed with Windows Excel 2007 software package for Paired t-test and the significance level was .05. Results The negative affect domain of PANAS has a significant difference before and after massage from score of  $15.6 \pm 6.8$  decreasing to  $11.7 \pm 2.5$ . There were no significant differences before and after massage treatment, except the dimension scores of self-respect and vitality, the other dimensions showed significant difference in fatigue, nervousness, confusion, anger and depression of POMS. It increased the scores of activity recovery domain and decreased the scores of physical exhaustion of FMFI. Discussion Based on the results shown above, the neck, shoulder and feet massage has a significant impact for personal body-mind reflection due to evaluated by the scientific survey scoring. Owing to the negative affect score decreasing in PANAS, and reducing score of fatigue, nervous, confusion, anger and depression in POMS, and increasing the scores of activity recovery domain and decreasing scores in the physical exhaustion of FMFI, the conclusions of this study are that dunking feet, neck, shoulder and feet massage is conducive to reducing physical fatigue and exhaustion effects, but within a short period (30 minutes) can't immediately affect the positive emotional state. Future research is obviously required, but this is an exciting first step. We are hopeful that future research will provide more detailed results which may differentiate views from on another. Such as, subjects participated in this study by 30 minutes a day, lasting for 3 months. Then we can

inspect the impacts between initial and three months later. References Cheng J C M, Ting W C, Chang K M. (2011). Program of ICHPER.SD Asia Congress 2011, 128, Taipei, Taiwan.

### PP-BN10 Biomechanics: Balance and Coordination

#### RELIABILITY OF STATIC AND DYNAMIC BALANCE TESTS IN HEALTHY YOUNG ADULTS WITH A NEW METHOD OF ANALYSIS

FEIJOO DIEZ, D.

UNIVERSITY OF LAS PALMAS DE GRAN CANARIA

The assessment of balance is rather complex, since balance depends of the integration and coordination of many function. At present, most of the test proposed to assess static and dynamic balance show low reliability due to very high individual variation. Thus, new procedures and method of analysis should be developed to assess balance more reliably. Therefore the aim of this study was to design a new balance test-battery to assessed static and dynamic balance with high reliability. Methods. Twenty-three physical education students (mean  $\pm$  SD) age:  $23 \pm 3$  years, body mass:  $69 \pm 8$  kg were tested in two different days, two-week apart. Each testing day the subjects performed to trials of six different test consisting on: 1) One-leg standing on the jumping leg (JL; main propelling leg when jumping) with eyes open; 2) One-leg standing with the contralateral leg and eyes open; 3) One-leg standing on JL with eyes closed; 4) One-leg standing with the contralateral leg and eyes closed; 5) One-leg standing on jumping leg while executing a precision task with the dominant arm extended, consisting on taping on numbers marked on table 1 meter away in front of the subject in a standardized order; and 6) the same protocol of test 5, but standing on the contralateral leg. Each trial lasted 30 seconds and was performed on a Force Platform Kistler. Each day the same test was repeated twice, separated by a 30 min rest period. The mean and the best of the two trial performed each day was taken as representative for further analysis. Measurements. The reliability of each test was assessed calculating the ICC between the mean of testing day 1 and the mean of testing day 2 for the "Mean result" analysis. The best of testing day 1 and the best of testing day 2 were selected for the "Best result" analysis. The following variables were calculated: a) root-mean-square (RMS) medio-lateral (ML) velocity of the CP; b) root-mean-square (RMS) antero-posterior (AP) velocity of the CP; c) Mean CP speed; d) Sway Area; e) Mean Peaks; f) mean distance; g) Mean frequency ML; h) 95% Power frequency ML; i) Mean frequency AP; j) 95% Power frequency AP. Results. The ICCs for inter-item reliability of the CP-SPEED showed fair to excellent reliability for "Mean result" analysis (ICCs between 0.66 and 0.95) and excellent for "Best result" analysis (ICCs between 0.87 and 0.97). Only in test number 4, the reproducibility of the CP-SPEED was low. The rest of the parameters showed good to excellent reliability. Differences between methods of analysis were found, where the "Best result" analysis was the optimal method to assess the balance. Jumping and contralateral legs were similar. However, we found one leg with better balance ( $p < 0.05$ ). Conclusions. This study shows that static and dynamic balance can be assessed reliably in young healthy adults using very simple tests performed on a force platform. The analyses performed with the "Best result" method are more reliable than those performed with the "Mean result" method. The tests performed with the eyes open are more reliable than with eyes closed..

#### AGE-RELATED CONTRIBUTIONS OF ANKLE MUSCULAR COORDINATION TO POSTURAL EQUILIBRIUM

OGISO, K., FUJIKI, T., MOGAMI, T.

KOGAKKAN UNIVERSITY

Introduction Ankle joint muscles generally commence contracting first to restore the equilibrium when sway perturbations were applied during upright stance (Horak and Nashner, 1986). Aging reduces the ability to control the posture (Woolacott et al., 1986) and increases the instability elevating fall incidence. Therefore, this study examined two aspects of postural control: relationships to control ability of the ankle joint, and to age. Methods Eight older adults (Egroup,  $71.1 \pm 5.1$  yr), seven young adults (Ygroup,  $21.9 \pm 0.3$  yr) and eight boys (Bgroup,  $11.2 \pm 1.5$  yr) volunteered in this study. They performed two different motor tasks after maximum plantar flexion (MPF): attempts to track and maintain target positions (P task), and attempts to track and maintain target force (F task) for fifty seconds. They were requested to do the tasks as quickly and precisely as possible. The target values were displayed on a monitor and changed every five seconds. Differences between the target values and actual values exerted by the subjects (T-A difference) were calculated to evaluate the control ability. After the tasks, the subjects maintained upright stance as still as possible on a force plate for sixty seconds. Path length (PL), rectangular area, RMS area and environmental area were calculated from distance traveled by the center of pressure. EMG activities were recorded from soleus, gastrocnemius lateralis and medialis, and tibialis anterior muscles. Results Egroup showed larger T-A difference than the other groups in both plantar- and dorsi-flexion in P task. Bgroup showed larger T-A differences in F task. Ygroup showed the largest MPF force and the smallest postural sway. Close relationships were observed between T-A difference and MPF force, and between time when reached the target value (TRT) and PL per second in Egroup. Ygroup showed close relationships between T-A difference and RMS area. The shorter TRT in P task, the smaller T-A difference was in Bgroup. Subjects who showed large T-A difference tended to show co-activation of synergist and antagonist muscles and unclear EMG activity patterns. Discussion Older adults were difficult to control the position quickly and precisely, which influenced the postural equilibrium. This characteristic depended on the muscle strength are consistent with earlier reports of declines in muscle strength (Reimers et al., 1998) and sensory capabilities (Thelen et al., 1998). On the other hand, children secured the postural stability by quick control of the position. References Horak FB, Nashner LM. (1986). J Neurophysiol, 55(6), 1369-1381. Woolacott MH, et al. (1986). #### DYNAMIC BALANCE CONTROL OF THE BASEBALL PITCHER'S TRAIL LEG AND STRIDE LEG

LIN, W., CHENG, J.

NATIONAL CHIAYI UNIVERSITY

Introduction The trail leg and stride leg perform single-leg standing to support the body weight respectively while pitching. To the overall dynamic balance control in baseball pitching, the relative contributions of each leg are different during individual pitching phases. However, the difference between each leg in dynamic balance control is still unknown. Therefore, the aim of this study was to compare the dynamic balance performance between trail leg and stride leg in pitchers. Methods Seventeen college baseball pitchers (age =  $19.9 \pm 1.4$

years, height =  $178.2 \pm 6.6$  cm, weight =  $77.4 \pm 10$  kg) participated in this study. The star excursion balance test (SEBT) and Biodex balance system (BBS) was used to evaluate the dynamic balance. All participants' excursion distances in anterior (ANT), posteromedial (PM), and posterolateral (PL) directions were measured and normalized to leg length in SEBT. The BBS test mode was set to athletic single leg stability (level six) and the anterior-posterior stability index (APSI), medial-lateral stability index (MLSI), and overall stability index (OSI) were collected during the measurement. The paired t-test was used to compare the MLSI, APSI and OSI and the normalized reach distances in ANT, PM, and PL directions between stride legs and trail legs. Results The significant difference between stride leg and trail leg was found in OSI ( $p < 0.05$ ) and the normalized reach distance in PL direction ( $p < 0.05$ ). The results showed the dynamic balance control of the trail leg is significant better than the stride leg. Discussion The OSI is a composition index of the APSI and MLSI and the reliability of OSI measures is higher than the reliability of both the MLSI and APSI measures (Arnold & Schmitz, 1998., Cachepe et al., 2001). Since the normalized reach distance in PL direction showed significant difference between trail leg and stride leg, it is possible that differences from other directions other than AP and ML axes were ignored in the BBS measurement. It is concluded that the overall dynamic balance performance of the trail leg is better than the stride leg in baseball pitchers and there differences between each leg in PL direction. ## DIFFERENCES IN MUSCULAR IMBALANCE RATIO CALCULATIONS USING FUNCTIONAL TEST DATA.

RELPH, N.S., BAMPOURAS, T.M.

UNIVERSITY OF CUMBRIA

**Introduction** Muscular imbalance assessment (MI) is important in identifying increased injury likelihood as well as performance deficit (Impellizzeri et al, 2007). However, use of left /right or strong/weak legs, as well as the reference value used for ratio calculations, can affect the MI value obtained. These different values may mask any MI differences (Zifchock et al, 2008), rendering the tests insensitive to detecting performance changes. Currently, limited comparisons exist between the various calculation methods, while a new calculation method has been proposed (Zifchock et al, 2008). Therefore, our aim was to compare the MI calculations obtained from two functional tests. **Methods** Twenty healthy, physically active young adults (females:  $n=6$ , height  $1.62 \pm 0.03$  m, body mass  $67.8 \pm 5.8$  kg; males:  $n=14$ , height  $1.79 \pm 0.07$  m, body mass  $80.2 \pm 13.3$  kg) performed two trials of the 6m timed and triple jump alternate hops (Reid et al., 2007). The best performance was used for analysis. MI ratios were calculated as (side 1-side 2)/reference value\*100, where reference value was left or right leg or average of the two when calculating left/right ratio, as well as strong or weak leg or average of the two when calculating strong/weak comparison. The symmetry angle (SA, Zifchock et al, 2008) was also calculated for both side combinations. A repeated measures MANOVA was utilised with significance level set at  $p < 0.05$ . **Results** Results indicated no significant effect of test, or interaction between test and side combination ( $p > 0.05$ ). However, significant interactions were found between test-MI ratio ( $p = .001$ ), side combination-MI ratio ( $p = .002$ ) and test-side combination-MI ratio ( $p = .002$ ). Significant effects were found for side combination ( $p = .001$ ) with strong/weak overestimating by 3%, and MI ratio calculation ( $p = .001$ ), with the SA overestimating MI by 9.3% for strong/weak comparisons for both tests and 5.6% and 5.9% for left/right comparisons for 6m and alternate hop, respectively. **Discussion** Our findings indicate that test selection does not affect MI ratio calculations but side combination does. Ratios calculations affected MI values, with the SA significantly overestimating MI ratio compared to all other ratio calculations. In particular, the difference in strong/weak comparisons by the SA could lead to different conclusions on the MI status of an individual. Future studies should examine relationships of ratios to sporting performance as an indicator of the more appropriate MI ratio calculation to be used. **References** Impellizzeri FM, Rampinini E, Maffiuletti N, Marcora SM. ## THE EFFECTS OF UNILATERAL STRENGTH TRAINING ON CONTRALATERAL BALANCE PERFORMANCE

JOSIPA, B., ASIM, B., EROL, K., GREGOV, C.

FACULTY OF KINESIOLOGY, UNIVERSITY OF ZAGREB

**Introduction** Unilateral strength training primarily has ipsilateral effects, whereas its secondary effects are termed as contralateral strength training effects. Studies have shown positive dependence between the lower limb strength and balance in elderly people (Pijnappels i sur., 2008). It is well known that combining strength and balance training has positive effects on balance in young adults (Thorpe and Ebersole, 2008). **Methods** Physically active young women participated in a 4-week progressive isokinetic training. The participants were separated into two groups: trained (15) and not trained group (15). The trained group carried out the con-con ankle and knee joint training on the isokinetic device known as Biodex System 3 at a relatively high speed (ankle-60, knee-180). The single leg balance of both trained and non-trained leg was tested on the Biodex Balance System. Statistical significance of the difference between the initial and final measuring values was assessed by using the two-way repeated measure ANOVA. **Results** The results have shown that the difference between the initial and final measures of the single-leg balance of a trained ( $F_{1,28} = 8.43$ ;  $p = 0.007$ ;  $\eta = 0.231$ ) and non-trained ( $F_{1,28} = 9.25$ ;  $p = 0.005$ ;  $\eta = 0.248$ ) leg in the EXP and CON group is statistically significant. In the experimental group the single-leg balance of the trained (non-dominant) leg was improved by 25.04%, whereas the non-trained (dominant) leg improved its balance by 18.8%. The control group did not demonstrate any change in balance performance. **Discussion** Given the fact that leg extensors and flexors have to be able to produce force very quickly (Izquierdo i sur., 1999) as to preserve and establish balance, it has been assumed that the strength training at relatively fast contraction rate would significantly affect the balance improvement. This research confirmed the above said. Unilateral isokinetic concentric-concentric strength training of extensors and flexors of the lower leg and foot in physically active women does not only result in ipsilateral, but also in contralateral change in balance. These findings open up many possibilities for application of the unilateral strength training not only in sport, but also in different rehabilitation processes. **References** Izquierdo M, Aguado X, Gonzalez R, López JL, Häkkinen K. ## THE EFFECTS OF PILATES TRAINING ON POSTURAL STABILITY AND JUMP PERFORMANCE IN YOUNG DANCER

LEE, A.J.Y.1, WANG, Y.T.2, GUO, S.C.1, LIN, W.H.3

1: NATIONAL HSINCHU UNIVERSITY OF EDUCATION (TAIWAN), 2: NATIONAL TAIWAN SPORTS UNIVERSITY (TAIWAN); 3: NATIONAL CHIAI UNIVERSITY (TAIWAN)

**Introduction** Dance is not only a performing art, but a highly rigorous athletic sport that is one of the most physically and mentally demanding athletic sports in the world (Shah, 2008). For excellent performance, it requires a high level of fine motor control, flexibility, and core stability in dancing. Pilates is a kind of body conditioning exercise which can build joint flexibility, strengthen muscles coordination, and improve movement control. The purpose of this study was to evaluate the effects of Pilates training on postural stability (PS) and jump performance (JP) in young dancers (YD). **Methods** Twenty-six YD were enrolled and obtained permission from their parents as participants, equally and randomly assigned as training group (TG, age: 11±1 yrs, height: 148±5 cm, weight: 38±6 kg) and control group (CG, age: 11±1 yrs, height: 146±6 cm, weight: 36±7 kg). Only the TG received extra 12 weeks of Pilates Mat exercise, 3 times a week, for 40 minutes. The PS was evaluated as Limits of Stability (LOS) by Biodex Balance System. The JP was evaluated by the maximum vertical jump height during the countermovement jump (CMJ) on force plate. Single-factor ANCOVA was used to analyze the differences between groups after training. **Results** 12 weeks Pilates training significantly improved the total (+26%), left (+34%), left-front (+37%), and left-back (+34%) directions LOS and the maximum height of CMJ (+7%) in TG than CG. **Discussion** The main goals of Pilates training are efficient movement, core stability and enhanced performance (Akuthota & Nadler, 2004). With regard to the results of this study, Pilates training were found to be an efficient training method with significant improvements in PS and JP in YD. Previous studies demonstrated that regular Pilates training increase transversus abdominal muscle coordination, which helps maintain better lumbo-pelvic control (Herrington & Davies, 2005), improve the stability of the upper body segments and the coordination of lower extremity limb during running (Lugolarcheveque et al, 2006). A recent study also showed that both transverses abdominis and obliquus internus muscles activity were significantly increase in order to help stabilize or protect the spine (Endleman & Critchley, 2008). In dancers, intact muscular coordination and well-balanced antagonists could be decisive factors for excellent performance and in protection against injury because dancers often have jump and their ankle joints often bear full body weight in an extreme position. It is concluded that regular Pilates training can improve the dynamic PS and JP in YD with the strengthened core strength and improved postural neuromuscular coordination. **References** Akuthota V, Nadler SF (2004). ## COMPARISON OF EFFECTS OF SHORT-TERM HOPPING AND BALANCE TRAINING ON MUSCLE POWER AND FUNCTIONAL FITNESS IN THE ELDERLY: SINGLE-BLIND RANDOMIZED CONTROLLED TRIAL

NAKATANI, T., TERADA, K., SHIRAIISHI, A., NADAMOTO, M., HAYASHI, T.

DEPT. HEALTH AND HUMAN PERFORMANCE

**Introduction** With increasing age, older adults may experience loss of strength and power, which may lead to functional impairments and frailty (Porter et al., 1995; Caserotti et al., 2008). Strength and power training are considered promising interventions for reversing loss of muscle function. The purpose of this study was to compare the effects of short-term hopping and balance training on lower extremity muscle power and functional fitness in the elderly. **Methods** Twenty-six community-dwelling elderly individuals (4 men and 22 women; age range, 63–83 years) were randomly assigned to either the hopping training (HT, n = 13) or balance training (BT, n = 13) groups. Training programs consisted of a 60-min supervised group exercise session held once every 2 weeks at a local welfare center and additional home exercises. The training lasted for 10 weeks. The HT group performed 2–3 sets of normal two-legged hopping at their preferred frequency until they reached the Borg rate of perceived exertion scale of 16 (hard). The BT group performed balance exercise on a foam stability pad or a narrow beam. Outcome measures included peak power output (PP), vertical jump (VJ), rate of force development (RFD) in sit-to-stand (STS), reaction time (RT), timed up and go (TUG), and postural stability. **Results** After the training session, the HT group demonstrated significant increases in the values of PP and RFD in STS (5.3%, 8.7%, respectively;  $P < 0.05$ ) and a decrease in the length of the sway path in a particular unit of time (–16.4%,  $P < 0.05$ ); however, no differences were observed in VJ, RT, and TUG. Furthermore, the BT group demonstrated significant changes in PP (5.1%,  $P < 0.05$ ) and TUG (–8.7%,  $P < 0.01$ ), but no differences in VJ, RT, RFD in STS, and postural stability were observed. The percentage changes in values of RFD in STS and TUG differed significantly between the two groups. **Conclusion** Our results suggested that short-term two-legged hopping training was more effective than balance training in improving lower extremity muscle power and postural stability in the elderly. It appears that hopping training may be recommended as a technique to reduce fall risks, but future studies should examine the safety of the method for the elderly. **Acknowledgment** This study was supported in part by a grant from Tenri University Grants-in-Aid for activities on Academic, Research, and Education. **References** Porter M M, Vandervoort A A, Laxell J (1995) Scand J Med Sci Sports, 5(3), 129-142. ## STUDYING STATIC BALANCE IN ELDERLY WOMEN AFTER AQUATIC EXERCISE

LATIFI, S., SAGHAZADEH, M.

UNIVERSITY OF TEHRAN

**Introduction** Falls causing fatal and nonfatal injuries in the elderly population are well recognized health and socioeconomic problems. One of the main factors in falls, happens with ageing, is the decline of balance ability; it is markedly lower in those who are 60 years old or older. A rapid step is the most important protective strategy, acting to recover balance and prevent a fall from initiating. As the elderly are less fearful of movement in water, exercise in aquatic environment is appropriate for them (Kaneda et al., 2008; Ruoti et al., 1997). **Methods** Thirty healthy elderly women were assigned equally to either experimental (63.6± 2.8 years old) or control group (64.8± 2.6 years old). Total Path Length (TPL) and Area of Center of Pressure (CoP) were evaluated, before and after doing exercise in water, while standing on force distribution using the Zebris FDM measuring system. The experimental group underwent balance program applied for 8 weeks, with three sessions per week, each session lasting 60 minutes. Paired t-test and independent t-test were used respectively to analyze the data within and between groups. **Results** The result of this study indicated that; aquatic exercise promoted significant increases in the elderly women's static balance, as assessed using TPL and Area of CoP with both opened and closed eyes ( $p < 0.05$ ), while, no significant difference was observed in control group ( $P \geq 0.05$ ). Also there were significant differences between control and experimental groups ( $P \leq 0.05$ ). These results show us the aquatic exercise program increases static balance. **Discussion** According to the

results, static balance increased significantly after the aquatic exercise program. This was similar to the results obtained by many other authors (Hara et al., 2007; Lord et al., 1993). These results possibly occurred because fear of falling is less in water, making the elderly willing to experience greater movement variability and errors, furthermore activity in water may facilitate vestibular inputs (Ruoti et al., 1997). ## THE EFFECT OF HIP ABDUCTOR FATIGUE ON LOWER LIMB COORDINATION DURING A CUTTING MANEUVER

TANABE, Y.

UNIVERSITY OF TSUKUBA

**Introduction** The purpose of this study was to assess how sub-maximal fatiguing exercise of the hip abductors affects lower limb coordination. Anterior cruciate ligament of the knee (ACL) injuries are serious and have a significant rate of occurrence in athletes. Nowadays, research has focused on the role of the hip abductors in preventing ACL injuries (Geiser et al., 2010). Previous studies have found that shift to hip abduction and knee abduction during a single leg squat because of their weak hip abductors (Zeller et al., 2003), which is associated with ACL injury. However, the coordination between hip and knee joint has not yet been evaluated under the fatiguing condition. **Methods** Eleven female athletes were investigated. Participants performed six cutting maneuvers at a 90° angle from a 40 cm-high box before and after the fatigue protocol which is repeated hip abduction. The isokinetic dynamometer was used as the fatigue protocol (Jacobs et al., 2007). The speed of the isokinetic resistance was set at 60°/s during concentric hip abduction and at 180°/s during adduction phase. This task was continued until exhausted (Mean repetition 112.2 ± 40.4 reps). Using the surface EMG, the power spectrum in median frequencies of Gluteus medius (Gmed) were obtained during 120 ms from 40 ms before the initial contact. To capture the motion, a ten-camera motion analysis system was used. Coordination graph of hip and knee angle were obtained as same period as the power spectrum data in the frontal and horizontal plane. Results Gmed median frequency was significantly decreased after the fatigue protocol ( $p < 0.01$ ). Hip-Knee coordination graphs showed no significant difference in variability of six trials between pre and post fatigue conditions in both the frontal and horizontal planes. In the horizontal plane, all participants showed increases in internal rotation at the knee joint and external rotation at the hip joint. **Discussion** Despite hip abductor fatigue, it was observed that there is no significant difference in variability of hip and knee coordination within the group. However qualitative Hip-Knee plots showed two characteristic coordination patterns in the horizontal plane between some participants. Most participants showed an increase in external rotation post-fatigue but maintain a similar coordination pattern. On the other hand, some participants showed a gradual change from hip internal rotation to hip external rotation. Kinematic data showed that lower limb alignment did not approach the "point of no return" (Quatman et al., 2010) which was knee-in and toe-out. This may be due to participants adopting a landing strategy that minimizes the likelihood of this point being reached. References Geiser F, O'Connor M, Earl E. ## STUDY ON BODY BALANCE IN HYPERTENSIVE PATIENTS

BANKOFF, A.D.P., ZAMAI, C.A.

UNIVERSIDADE ESTADUAL DE CAMPINAS

**Introduction** This upright position is called the orthostatic or erect position. Consequently, even an everyday behavior such as maintaining an erect position is an intricate task which involves a complex association of sensorial information and motor activity (BANKOFF, 2007). Bankoff (2006) reports an association between balance and postural positions, with postural balance being modified within milliseconds. The association of antihypertensive drugs which are indicated for patients with arterial hypertension is a consummate fact. These drugs are prescribed for ingestion immediately after breakfast. Among the most commonly prescribed drugs are: Hydrochlorothiazide 50mg, Furosemide 40 mg, Methyldopa 250mg, Nifedipine 20mg, Propranolol 40 mg, and Captopril 25 mg. **Methods** The study was performed on three groups of male subjects, namely: group 01 = 15 hypertensive subjects who take antihypertensive medication; group 02 = 09 hypertensive subjects who do not take such medication; and group 03 = 12 non-hypertensive patients. Mean age was 42.7 years. **Instrument Used** The tests were conducted using an Electronic Baropodometer comprised of a modular platform by Physical Support Italy. This device is comprised of platinum electronic sensors covered with an alveolar captor that recognizes plantar support information while preserving natural mobility. Image acquisition is accurate, instantaneous, reproducible and non-invasive. Results The results presented herein show higher values for hypertensive patients who take antihypertensive drugs (group 01) and for non-medicated hypertensive subjects (group 02). The subjects with normal blood pressure (group 03) swayed much less than the other two groups, irrespective of which variable was analyzed (bipedalic or monopodalic posture, eyes open or closed). Thus, it was shown quite clearly that arterial blood pressure and antihypertensive drugs have an influence on body balance in static postures. **Discussion** When a person is standing upright, the body sways forward and backward (Y axis) and side to side (X axis). The neuromuscular activity that prevents the person from losing balance and falling is the body's automatic posture control. As the individual sways along the X and Y axes, his or her visual, somatosensory and vestibular receptors detect those variations and generate compensatory responses in the adequate muscles (Dietz, 1992). ### PP-BN11 Biomechanics: Lower Limb/Foot

#### LOWER LIMB MUSCLES COCONTRACTION DURING PERTURBATIONS ON AN UNEAVEN SURFACE

CARDOZO, A.C., ALMEIDA NETO, A.F., HALLAL, C.Z., MARQUES, N.R.

SÃO PAULO STATE UNIVERSITY

**Introduction** The neuromuscular system must respond with strategies to re-establish the balance or to prevent the loss of stability. One of these strategies is to improve the antagonist cocontraction, which causes a higher joint stiffness. In this context, the objective of this study was to analyze the cocontraction of Rectus Femoris/Biceps Femoris (RF/BF) and the cocontraction of Tibialis Anterior/Gastrocnemius Lateralis (TA/GL) during perturbations to four directions: anterior, posterior, right and left sides. **Methods** Thirteen healthy women, mean age  $21.31 \pm 2.39$  years, height  $1.67 \pm 0.06$ m, and weight  $63.58 \pm 11.84$ Kg, recruited from a university setting participated in this study. The subjects were positioned above a balance board and a mechanism was created to induce perturbations. Each situation was repeated three times. The electromyographic activity from the RF, BF, TA and GL was recorded on the right lower limb of the subject. Then the cocontractions of RF/BF and TA/GL were calculated using the method of common area (Winter, 2005; Candotti et. al, 2009). The cocontraction was analyzed after the perturbation, in a window of 200ms. After that, the means of the cocontraction in the three attempts were compared using the two-way ANOVA test. The significant level was set at  $p < 0.05$ . **Results** The mean values ( $\pm$ SD) of the cocontraction to RF/BF and TA/GL during the four direction perturbations were, respectively:  $84.59 (\pm 7.01)$ ,  $33.97 (\pm 16.21)$  to anterior;  $84.85 (\pm 4.73)$ ,  $73.19 (\pm 11.29)$  to posterior;  $83.45 (\pm 5.92)$ ,  $67.34 (\pm 7.08)$  to right; and  $87.99 (\pm 5.77)$ ,  $86.59 (\pm 5.77)$  to left. These results show that the RF/BF cocontraction is higher than the TA/GL cocontraction ( $p = 0.01$ ), regardless the direction of the perturbation. **Discussion** This higher cocontraction of the RF/BF suggests that the perturbation caused a great displacement of the center of mass. Therefore, the compensatory cocontraction TA/GL was not sufficient to re-establish the balance. However, the increase of muscular co-contraction enhances joint stiffness, which could decrease the effectiveness of this response to fast perturbations like a tripping (Ishida et al., 2008). **References** Ishida A, Masuda T, Inaoka H, Fukuoka Y. #### HIGHER INCIDENCE OF FATIGUE-INDUCED ASYMMETRICAL BETWEEN-LIMB STRATEGIES IN CHRONIC ANKLE INSTABILITY : A SINGLE-SUBJECT ANALYSIS

MCGRATH, D., PATTERSON, M., CAULFIELD, B.

UNIVERSITY COLLEGE DUBLIN

**Higher incidence of fatigue-induced asymmetrical between-limb strategies in Chronic Ankle Instability (CAI): A Single-Subject Analysis** McGrath, D.I, Patterson, M.I, Caulfield, B.I 1:UCD (Ireland) **Introduction** The effect of a functional fatigue protocol (FFP) on the magnitude of end-point variability in spatio-temporal parameters during running was examined in both limbs of a group with unilateral CAI and a control group. It was hypothesised that the injured limb would demonstrate a stereotypical increase in variability due to fatigue. This was not borne out in group analyses however, where no effect for side (injured/uninjured) was observed in any parameter. A single-study analysis was then carried out to investigate the various strategies employed by each subject. **Methods** The magnitude of variability (measured by standard deviation (SD)) of stride time, stance time, swing time and stride length during running was calculated in two groups (CAI,  $n=15$ , control,  $n=17$ ) over 10 strides at the beginning of a FFP and at the end of the FFP in both limbs. Individual graphs were plotted and visually examined for all subjects where the SD was plotted at both time points, for both limbs. **Results** A number of strategies were observed: increased variability in both limbs, decreased variability in both limbs, or unchanged variability in both limbs. These were termed symmetrical strategies. Asymmetrical strategies were defined as increased levels of variability due to fatigue in one limb, while variability decreased in the other limb, or vice versa, or unchanged levels of variability in one limb while the other limb either decreased or increased. The results showed that for all spatio-temporal parameters, the CAI group exhibited more asymmetrical variability strategies (irrespective of the direction of differences) than the control group. **Discussion** The injured limb of the CAI group did not exhibit a consistent increase or decrease in levels of variability due to fatigue. It is possible that the higher incidence of heterogeneous variability behaviours observed between limbs in the CAI group is suggestive of centrally mediated control mechanisms in operation in CAI. The "uncontrolled manifold" hypothesis proposed by Scholz and Schoner (1999) states that elements involved in the performance of a task are restricted to a particular range of operation such that the desired task is successfully achieved. Provided elements stay within the restricted range, they remain uncontrolled. If we were to assume that the appropriate goal function for locomotion in subjects with CAI – particularly in the presence of fatigue – is to protect the injured ankle from further injury while allowing deviations to persist in either limb once this goal is not threatened, it is highly likely that both limbs would exhibit differing patterns of movement variability. **References** Scholz, J.P., Schroner, G. (1999) *Experimental Brain Research* 126(3):289-306

#### DATA MINING IN ANALYSIS OF FORCE PLATE SIGNALS

FAN, Y., LI, Z.

GUANGZHOU INSTITUTE OF PHYSICAL EDUCATION

**Data mining in analysis of force plate signals** Fan, Y.I.\*, Li, Z.Z, 3 1 Center for Scientific Research, Guangzhou Institute of Physical Education, Guangzhou 510500, P. R. China 2 School of Physical Education and Sports Science, South China Normal University, Guangzhou 510631, P. R. China 3 College of Foreign Studies, Jinan University, Guangzhou 510632, P. R. China \* E-mail: tlyf@gipe.edu.cn **Introduction** The force plate plays an important role in the human motion analysis (Zivanovic et al. 2005, Fan et al. 2011). But there has been an absence of a widely accepted method to process data acquired from the force plate (Donelan et al., 2002, Zivanovic 2005). In this study, a method of condition equation to process such data is brought forward by a case study of force plate signals. **Methods** The experiment is conducted by using Kistler Force Plates (Kistler 9281CA) and analysis software program of SIMI Motion 7. The measurement is taken at the frequency of 1000Hz. Before each measurement, the equipment is positioned by the gradienter and is returned to zero-position. According to the characteristics of human motion when walking, gait kinematic and kinetic data processing method is proposed based upon the Hamilton's Principle. **Results** The force plate signals processed by the constraint equations (i.e. condition equations) reveal satisfactory results to

explore and analyze the characteristics of center of mass in human walking. In addition, the standardization of data prepares for a further mining of them. Discussion Based upon the least-action principle in gait (Fan, et al., 2009), our research explores the validity to process the signals acquired from force plate at steady speeds (Kokshenev et al. 2004) by establishing a constraint equation. Though the employment of such condition equations yields satisfactory results, it also shows its limit in analyzing data from the non-steady-speed gait. This is an agenda for future research. ## EFFECTS OF LOADING ON MAXIMUM VERTICAL JUMPS: IVE EFFECTS OF WEIGHT AND INERTIA

LEONTIJEVIC, B., PAZIN, N., BOZIC, P., KUKOLJ, M., UGARKOVIC, D., JARIC, S.

*FACULTY OF SPORT AND PHYSICAL EDUCATION*

**EFFECTS OF LOADING ON MAXIMUM VERTICAL JUMPS: SELECTIVE EFFECTS OF WEIGHT AND INERTIA** Leontijevic, B.1, Pazin, N.1, Bozic, P.1,2, Kukolj, M.1, Ugarkovic, D.1, Jaric, S.3 1: The Research Center, Faculty of Sport and Physical Education, University of Belgrade, Belgrade, Serbia 2: Serbian Institute of Sport, Belgrade, Serbia 3: Department of Kinesiology and Applied Physiology, University of Delaware, Newark, US Introduction A load that originates from added mass inevitably adds to both the body weight and body inertia, while some other loading methods could mimic either additional weight or inertia. The main aim of this study was to explore the selective effects of the added weight and inertia on the both the pattern and output of the maximum vertical jump. Methods Fifteen male college students were tested on maximal countermovement jumps (CMJ) performed with the arm swing. External loading (0-40% of body weight) was applied by using either stretched rubber bands pulling downward, or loaded vest, or both where the bands pulled upward, that mimicked an increase in the subjects' weight (W), weight plus inertia (W+I), or solely inertia (I), respectively. Results An increase in added W and W+I was associated with an increased GRF, while the jumps performed with increased I revealed somewhat prolonged concentric phase. Subjects lowered their center of mass more when loaded with additional W and I then with W+I, while the overall magnitude of the applied loads did not affect the body lowering. Both the force recorded at the instant of transition from the eccentric to concentric jump phase and the peak force increased with the load magnitude, but most prominently with W+I. The peak velocity (that inevitably leads to reduced jumping performance) decreased with the load magnitude, but the most with W+I and the least with W. Both the peak and mean power output decreased with the load magnitude and the effect was the most and least prominent for I and W, respectively. Discussion This is the first study that examines the effects of selective manipulation of different loading components during vertical jumping. The observed changes in the kinematic and kinetic patterns have some similarities with previous studies that investigate vertical jumps (Markovic and Jaric, 2007) under of various loadings. Taken together, the result of this study revealed that W+I cause the larger decline in Vmax, but it effect could be predominantly attributed to the effect of I, rather than to the increased W. The similar adaptation of the recorded vertical forces was obtained by Chung et al. (2000). If extended to other movement tasks, this line of research could not only contribute to better understanding of the effects of external loading on our maximum performance, but also serve for refining athletic training and rehabilitation procedures. ## GROUND REACTION FORCE VARIABLES IN HANDBALL JUMP SHOTS

HANLEY, B., JONES, S.

*LEEDS METROPOLITAN UNIVERSITY*

**Introduction** The jump shot is one of the most important elements in team handball (Pori et al., 2005). The shooter takes off from behind the goal area line, six metres from goal, and must release the ball before landing. Shooters running towards goal must therefore brake before the goal area line and jump vertically above the reach of any defenders while maintaining some forward momentum so that the shot is taken as close to the goal as possible. The aim of this study was to measure and analyse key ground reaction force (GRF) variables involved in the jump shot. **Methods** Ten experienced handball players (stature: 1.79 m ( $\pm$  0.05); mass: 73.9 kg ( $\pm$  7.3)) participated in this study. Each player ran for three steps, dribbled the ball, and took another three steps ending with a jump shot into a standard handball goal. Shots were taken 6 m from the goal and one defender stood with arms raised in front of the 6 m line. For the jump shot, the players took off from a Kistler force plate. The force plate's dimensions were 900 mm X 600 mm and it recorded at 1000 Hz. Each player took three jump shots and the average results for each GRF parameter were calculated. Pearson's r was used to find associations; a confidence level of 5% was set. **Results** There were two main phases during the jump shot. The first was the initial landing phase from the last step during which horizontal velocity decreased by  $-1.53$  m/s ( $\pm$  .51). This was associated with a large horizontal braking force of  $-1.34$  BW ( $\pm$  0.64) ( $p = .009$ ). The entire braking phase lasted 92.4% ( $\pm$  3.6) of contact time with only a very small period of horizontal acceleration following this. The players also experienced a mean vertical impact force of 2.43 BW ( $\pm$  .69) during the landing phase. After this braking phase, a vertical push-off phase occurred prior to shooting. The vertical push-off force of 2.83 BW ( $\pm$  .38) occurred during the last 50% of contact (the mean contact time was 0.260 s ( $\pm$  .028)). The mean flight time was 0.47 s ( $\pm$  .10) during which the vertical displacement of the centre of mass was 0.28 m ( $\pm$  .10). Flight time was correlated with vertical push-off force ( $p = .008$ ). **Discussion** The objective of the jump shot in handball is to get into an airborne position that allows for the most accurate, powerful shot to be taken. In this study, the player's decrease in horizontal velocity during contact of 1.5 m/s was enough to both prevent crossing the goal line and keep moving forward during the flight phase. This brought them closer to the goal increasing their chances of scoring. Large forces occurred during both the landing and take-off phases. Handball players are advised to develop leg strength to withstand the impact forces occurring during the jump shot (vertical and shear) and also to develop push-off forces to increase jump height. **References** Pori P, Bon M, Šibila M. (2005). *Kinesiology*, 37(1), 40-49.

## THE RELIABILITY OF PLANTAR PRESSURE ASSESSMENT IN CHILDREN AGED 7 TO 11 YEARS

COUSINS, S.1, MORRISON, S.2, DRECHSLER, W.2

1: CDU (DARWIN, AUSTRALIA), 2: UEL (LONDON, ENGLAND)

**Introduction** Plantar pressure assessment is commonly used in the clinical evaluation of the foot and provides useful information on the loading characteristics during gait. However plantar pressure measurement systems must be tested to assess their repeatability in order to help standardise and document methodologies. The reliability of plantar pressure measurements has been established in adult popu-

lation (Gurney et al. 2008; Zammit et al. 2010) however subsequent work on children is lacking. It is acknowledged that children's gait is associated with increased variability and therefore it is necessary to establish the feasibility of repeatable plantar pressure measurements in this population as the value of this clinical assessment is undetermined. The aim of this study was to determine the reliability of plantar pressure measurements in children aged 7 to 11 years. Methods 45 participants were recruited from local primary schools in East London. Participants were asked to walk at a self-selected speed on a pre-defined walkway with the MatScan® (TekScan, USA) placed in the centre. The following variables were extracted for further analysis: peak pressure, peak force and pressure-time and force-time integrals. Data for 3 trials were used to determine the reliability. Reliability of the data was explored using Intra Class Correlation Coefficients (3,1) and variability with Coefficients of Variation. Results Within the sample the lateral heel, medial heel, midfoot, 1st metatarsal and 2nd-5th metatarsals demonstrated good reliability (0.69-0.95) and reduced variability (10.22-27.15%) for all the measured variables. In all cases the lesser toe region demonstrated poor reliability (0.17-0.50) and increased variability (27.15-56.08%) within trials. Discussion These results demonstrate that the collection of reliable plantar pressure data is possible in children for all segments of the foot except the toes and can also provide a baseline of normative data that may be used to evaluate loading characteristics of the foot in specific disease populations. The lower reliability and increased variability at the toes has also been reported in adult studies and may be as a result of the plantar pressure sensors having difficulty isolating small areas such as the toes accurately (Gurney et al. 2008; Urry and Wearing 2001). It must also be acknowledged that the results presented can only apply to the sample under investigation and to the instrumentation described. Further work is required to explore the reliability of plantar pressure data in children of varying ages and where deformity is present. References Gurney J, Kersting, U, Rosenbaum, D. (2008). ## BIOMECHANICS AND PODIATRIC ANALYSIS OF FOOT FOOTBALL PLAYERS

LEIRAS, J., SOUSA, F., VILAS-BOAS, J.P.

*PORTO BIOMECHANICS LABORATORY, FACULTY OF SPORTS, UNIVERSITY OF PORTO*

Since the majority of soccer injuries are directly related to morphology and function of lower limb, it becomes essential to characterize the foot of soccer players in order to establish correct strategies to prevent and treat injuries and, to respond to their specific needs, such as choosing correct footwear. The purpose of this study was to morphologically and functionally characterize the footballer's foot in a static situation and while moving, establish a comparison between the dominant and non-dominant leg and positions occupied by the football players. Thirty males from the Football Portuguese League, age 27.1 yr (SD 4.3), height of 178.9 cm (SD 5.7), and body mass 78.0 (SD 7.6), participated voluntarily in this study. For the podiatric study, a Table-bed, a Podoscope, a Goniometer, a Perthes ruler, a Pelvimeter, a Tape-measure, and a Pedigraph were used. For the dynamometric study, a Bertec force plate (1000 Hz) and a Pedar System (50 Hz) with synchronized acquisition was used. Three successful trials were required for each foot. For the data analysis, a descriptive statistic was used and a data base was then created. The homogeneity was studied with the Levene test and the distribution normality with the Shapiro-Wilk test. The One-Way Anova test was also used to verify the existence of significant differences, and the t student was later applied to compare the average of the left and right foot. The adopted level of significance was  $\alpha=0.05$ . Results showed a high incidence of digital and unusual changes, a predominance of hollow foot, heel varus, squared foot morphology and index plus minus, with high incidence of plantar support asymmetry. A smooth light gait was registered with some asymmetries between the left and the right feet. The plantar pressure showed, in general, significant higher results in the left foot. The most common digital deformities were the claw toes and hallux abducts valgus, which is consistent with other studies. The high prevalence of dysmetries and asymmetries causes different capacities to dissipate load. The prevalence of heel varus and cavus foot may be associated with highly demanding tasks in football (Viladot, 2000). Force values were higher in unilateral support to those reported in the literature, suggesting a lower attenuation of weight induced by balancing the contra-lateral limb. Horizontal component of force reflect a high symmetry of footballer's gait. The increased rate of the insoles on the external rearfoot and midfoot reflects a supination heel strike and suggests a tendency for cavus foot or cavus varus foot. The highest pressure was located in the external forefoot, followed by internal forefoot (Cavanagh, 1991). This may be related to metatarsal verticalization of the cavus foot, which induces a decrease in the support surface. The existence of high incidence of asymmetries in several parameters, suggests some functional specificity of the lower limb in soccer players, imposed by the specificity of the tasks performed.

## ATHLETE-SPECIFIC ANALYSES OF THE EFFECT OF SHOE BENDING STIFFNESS ON FOOT FUNCTION DURING SPRINT RUNNING

SMITH, G.

*LIVERPOOL JOHN MOORES UNIVERSITY*

ATHLETE-SPECIFIC ANALYSES OF THE EFFECT OF SHOE BENDING STIFFNESS ON FOOT FUNCTION DURING SPRINT RUNNING Smith, G.1, 2, Lake, M.2, Lees, A.2 1: University of Chester (Chester, UK), 2: LJMU (Liverpool, UK) Introduction The Metatarsophalangeal (MPJ) joint has been shown to be potentially wasteful in maximising athletic performance, absorbing energy and producing little during push off (Stefanyshyn and Nigg, 1997). Increasing the longitudinal bending stiffness of sprint shoes has been suggested to improve sprinting performance (Stefanyshyn and Fusco, 2004). The aim of this study was to determine the effect of sprint spike bending stiffness on sprinting performance, MPJ kinematics and kinetics and pressure distribution for a single subject. Methods Over four separate testing sessions, one female sprinter performed maximal sprints (6 in baseline shoe and 6 in test shoe in each session) on an indoor runway, contacting a force platform (Kistler, Switzerland, sampling at 1000 Hz) and a pressure mat (RSScan, sampling at 250 Hz, 6 mm track surface cover) at approximately 35 m. Kinematic data was also captured at 1000 Hz using 6 opto-electronic cameras (Qualisys Inc, Sweden). Four stiffness conditions were used: a baseline Asics sprint spike (stiffness  $191 \pm 10$  N/mm) and three Puma sprint spikes with stiffness's of  $276 \pm 30$ ,  $388 \pm 29$ ,  $486 \pm 20$  N/mm. Results Mean sprint velocities were highest in the two stiffest conditions ( $8.20$  m/s  $\pm 0.18$  m/s) and lowest in the baseline condition ( $8.07$  m/s  $\pm 0.18$  m/s), although not significant. Overall the stiffer conditions resulted in decreased MPJ angular range of motion, increased MPJ moment and MPJ energy production at takeoff, but also increased MPJ energy loss during stance. Peak pressures on the toes increased in the stiff conditions and peak metatarsal heads loading occurred earlier in the stiffer conditions. Discussion Agreeing with previous findings (Smith and Lake, 2009), during sprinting loading was mostly confined to the medial forefoot and the push off was performed about the transverse axis of the Metatarsophalangeal joint. The loading transition from the lateral to the medial portion of the forefoot seemed to occur faster in the stiffer conditions, possibly indicating a focussed influence of stiffer sole materials. It is possible that stiffer shoe conditions may improve the efficiency of the push off during sprinting, as this subject demonstrated improved sprinting performance in the stiffer conditions (although not significant). The results from this study support the notion of tuning of an athlete's shoe stiffness to their individual characteristics in order to maximise performance. References Smith, G., Lake, M. (2009).

## PLANTAR-PRESSURE DEMONSTRATES THE CHANGE IN FOOT FUNCTION DURING BEND RUNNING

UNDERDOWN, T.B, ROBINSON, M.A., LAKE, M.J.

LIVERPOOL JOHN MOORES UNIVERSITY

**Rationale** During bend sprinting, athletes have to cope with centripetal forces which are detrimental to sprint performance (Bezodis et al. 2007). The metatarsophalangeal joints contribute to forward propulsion, whilst also coping with the curvature of the bend. It is reported that the foot has a two speed construction (Bojsen-Møller, 1978), as it adopts either a transverse axis (MT1-MT2) during straight running or an oblique axis (MT2-MT5) used when walking uphill or during increased loading. The aim of this study was to determine which of these axes are used during curved sprinting. **Methodology** Twelve participants ran at maximal and sub-maximal running speeds along a straight path, a path curved to simulate a standard outdoor running track and a path curved to simulate an indoor running track. Ground reaction forces and barefoot pressure measurements from the inside foot (left) were recorded at 500 Hz. Peak pressures and loading rates of the first and fifth metatarsal heads (MT1 and MT5) and the time of forefoot transition from lateral to medial were obtained. Data were analyzed using a Two-way repeated measures ANOVA over three different curvatures and two different speeds. **Results** During fast running the tightest curvature significantly increased the loading rate under the MT5 head. The loading rate for MT1 increased significantly with speed but also increased significantly as the curve radius lessened. Peak pressures of MT5 were very similar for slow running, but during fast running it increased significantly. The peak pressure under MT1 increased significantly during fast running and was significantly greater during straight running. Forefoot transition occurred significantly later in the tightest bend for both running speeds. **Discussion/ conclusion** During straight sprinting, the transverse axis of the forefoot is dominant, this was evident with increased peak pressure and loading rate under MT1. Bojsen-Møller (1978) reported that the transverse axis is an efficient mechanism to provide propulsion by causing the arch structure to become rigid, this is caused by the plantar aponeurosis becoming tense pulling both ends of the longitudinal arch together. We found that at maximal speed and as radius increases, the forefoot pressure shifts from medial to lateral side. This means that the oblique axis of the forefoot was used predominantly during bend running. This was also supported by the forefoot transition data which moved from lateral to medial as the bend became tighter. In conclusion, the oblique axis is used to stabilise and support the body at slower speeds, whilst forwards propulsion is compromised. **References** Bezodis, I, Salo, T & Kerwin, G. (2007). ## COMPARISON OF GRAND REACTION FORCE CHARACTERISTICS OF NORDIC WALKING INSTRUCTORS AND ELDERLY PERSONS DURING NORDIC WALKING AND WALKING.

SATO, K.1.2, SAIKI, S.1, NAGATOMI, R.2

1:TOHOKU FUKUSHI UNIVERSITY(JAPAN), 2:TOHOKU UNIVERSITY(JAPAN)

**Introduction** Walking is one of the most popular health-oriented activities in Japan. However, even walking, one of the safest exercises may cause joint problems in the elderly people. Nordic Walking (NW) may be favorable to the elderly, because the use of two poles during walking was believed to reduce the load to lower extremities. The results of the recent studies, however, evaluating the load to lower extremities are inconsistent. We hypothesized longer experience in NW may not lead to the reduction of lower extremities load during NW in the elderly people. Therefore, we evaluated the ground reaction force (GRF) profiles of elderly NW experts and compared them to those of young NW instructors **Methods** 8 young NW instructors (seven men, one women: mean age 33.88±6.06 years old) and 12 elderly NW experts (eight men, four women: mean age 67.58±4.78 years old) were recruited for this study and gave their full informed consent to participate in this study which was approved by the Tohoku Fukushi University Research Ethics Committee. The elderly NW experts regularly walked using poles more than 1 hour per day for more than twice a week for more than 3 years. They had no history of knee and ankle joint pain and disorders. GRF was measured using serially placed GRF platforms (Kistler, Switzerland) on which the subjects walked 3 times using poles (NW) and 3 times without walking. The order of the walking speed was 4 km/h±0.5 and 6 km/h±0.5. All motions were recorded using a three-dimensional motion analysis system (Cortex, USA). Motion and force plate signals were synchronized on the Cortex software. GRF was normalized to the body weight. Differences in GRF were analyzed using a two-way analysis of variance (ANOVA) with a confidence level set at 5%. Specific contrasts were identified with a Tukey post hoc analysis. **Results** Vertical GRF of instructors was higher in NW as compared to walking at 4km/h ( $p<0.0002$ ). There was no difference, however, in the elderly people between NW and walking at 4km/h. Vertical GRF during NW was larger than during walking in both instructors and elderly experts when walking at 6km/h ( $p<0.02$ ). Vertical GRF was smaller in the elderly, when walking without poles at 6km/h. **Discussion** GRF does not seem to be reduced in NW as compared to walking in both elderly NW experts and NW instructors. This seemed mainly due to the efficient use of poles to produce driving force so that at each contact of heels larger force was required to brake even in the elderly persons with enough NW experience. This study was supported by Program of Funding Basic Res. Ctr. In Private Univ. (MEXT) to the Kansei Fukushi Res. Inst., Tohoku Fukushi Univ. ## ANALYSIS OF TEST BATTERIES' RESULTS OF YOUTH ICE HOCKEY PLAYERS

GÁBOR, G.

SEMMELEWEIS UNIVERSITY

**Analysis of test batteries' results of youth ice hockey players** Géczi G., Velenczei A., Bognár J. Semmelweis University, Faculty of Physical Education and Sport Sciences (TF) **Introduction** Ice hockey requires high level of the physical skills to perform in elite sport (Géczi et al, 2008). The athletes' physical level and state have a very high importance in the coaches' all around job. Valid motor test batteries are very useful tools to measure the affect of the workout routine in each season. Hungarian ice hockey players are measured by the coaches of

the Hungarian Ice Hockey Federation from 2005 order to recognize every athlete's physical level and also to select the players to the national teams. The purpose of this research was to present the level of development in two age-groups in a four-year course and to verify our hypothesis about the younger age groups' better results. Methods During the one-day long event 102 players (N1990-1991 = 50; N1992-1993 = 52) did the test on-ice (36 m skating forward and backward, slalom, 6\*9m shuttle skating and transition drill) and off-ice (60 m forward run, standing long jump, 6\*9 m shuttle run, 400 m and 1500 m run). Data was obtained once in each season for four years. Data was analyzed by Repeated Measures and MANOVA using the SPSS 17.0 for Windows. Results Results show that in the first three years performances in both groups were increasing, but in the last year only a few every test had better results than before. Also the younger age group could not justify significantly better result than the older age group. Discussion We can recognize that the older age group should work harder to achieve development and to reach the elite level. The main result of this investigation was to identify the MUST value by every motor test and this MUST value is relevant information for the club coaches as well. Also important effect of our investigation detecting all deciding factors which are important for the youth players' development. In one hand we recommend to the coaches testing the players during the competition season to have up to date information about their physical fitness level. On the other hand the tests are really important for the players also, they can recognize their weaknesses and can develop them. References Géczi G., Bogrnár J., Tóth L., Sipos K. and Fügedi B. (2008). International Journal of Sport Science and Coaching Science, 2, 277-285.

### TACTICAL TRAINING IN SOCCER WITH 3D- OR 2D-TECHNOLOGY

FROHNERT, A., FRIESE, C., THRA, D., SCHNAASE, C., ODYSSEOS, P., FERRAUTI, A., PLATEN, P.

*RUHR-UNIVERSITY BOCHUM*

Introduction Tactical training in sports is usually supported by two-dimensional (2D) video information. In recent years three dimensional (3D) technology has been made widely available, but to date only few studies have been conducted about it's potential benefits in the area of tactical training. Thus, our aim was to examine if the assignment of the 3D-technology improves the tactical understanding of soccer-specific scenarios. Methods Two randomized experimental groups of sport students participated in the study: one 3D- (n=12) and one 2D-group (n=12). All subjects were healthy and had no 3D-experience related to sports. Prior to the experiments, 3 typical football game-scenarios with player's positions spread over the whole soccer field were filmed in 2D- or 3D technology from different player's positions using plastic figures. Furthermore, a 2-minute film presenting a typical player's formation from the perspective of the goalkeeper was prepared using a 145° turning camera. The main study included following tests: "Recognize the unmarked teammate": Both groups watched all 3 videos in either 2D- or 3D technology. The task was to find the player, who was not tightly marked by an opponent while watching the scenario. Results were evaluated via a multiple choice questionnaire. "Marking a typical player's formation": Both groups watched the 2-minute film. Following this, each subject was asked to mark the position of the ten players of his or her team on a millimeter paper. The distance of each player towards his or her correct position was determined. Results Correct answers to scenario 1: 3D: 10 and 2D: 9; Chi-square significance test:  $p > 0.05$ . Correct answers to scenario 2: 3D: 6 and 2D: 9; Chi-square significance test:  $p > 0.05$ . Correct answers to scenario 3: 3D: 12 and 2D: 7; Chi-square significance test:  $p < 0.05$ . For the definition of the player's position in the 2nd test we calculated the following total deviations: 3D:  $106 \pm 29$  mm and 2D:  $102 \pm 38$  mm;  $p > 0.05$  (t-test). Conclusions We found a significant difference between the 2D- and 3D-group in one out of three scenarios. Interestingly, in this task every subject of the 3D-group gave the right answer. A possible explanation for this result is the better spatial differentiation of the 3D-technique compared to the 2D-technology in this special situation. 3D-recordings of typical player's positions might improve tactical understanding of playing situations in the future and might therefore contribute to tactical training effects.

### PERFORMANCE MODEL IN FULL CONTACT – STICK FIGHTING

DISTASO, M., INVELITO, G., VILLANI, R.

*UIPASC*

PERFORMANCE MODEL IN FULL CONTACT – STICK FIGHTING Distaso M. 1; Marcoccia R.1; Villani R.1 1:Italian Union Trainers of Combat Sports (UIPASC) Introduction Full contact-stick fighting is a combat sport with weapons, where speed and accuracy of shots to the opponent, are key features for the athletes who practice this discipline. The aim of our research was to analyze what was the performance model for athletes of Stick Fighting. Materials and Methods For an indication of functional characteristics that an athlete must have, we ran several tests on 20 male athletes (years 18/30; height 1,67/1,85 cm; weight 67/90 kg) divided into two groups: 10 professional athletes formed the experimental group and 10 amateurs formed the control group. We examined the maximum number of shots taken in 30 seconds, the speed endurance and we also made a match analysis of the meetings between professionals and amateurs. The maximum number of shots in 30 seconds was calculated by the SOS test (Speed of Stick), a system composed of photocells and ergometer that allows us to accurately count how many shots they get pulled to the punching bag and their frequency. Speed endurance was studied by the analysis of lactate blood. The match analysis was performed by video of the meetings, in order to study the time of attack / defense and study / recovery in the match, also, what were the areas of the body more targeted. Results The results showed un significant difference in the two groups (17%) of the number of shots in 30 seconds (average: professionals 145.5; amateurs 120.2), and also by analyzing the frequency of shots, is known as the professionals we have a split time between shots, shorter and regular until the end. Then we analyzed the lactate blood in the two groups into three distinct phases: baseline, at the end of the match and after three minutes from the end of combat. The results show no significant differences between groups (professionals 6,40 - 11.77 - 8,58; amateurs 3.64 to 12.26, 9.58). The match analysis shows that the area of the body most targeted is the head (64%), followed by upper limbs (16%), corpus (12%) and finally from the lower limbs (8%). Regarding the study of time attack / defense during the match, the data show that it is greater than the professionals (55%), compared with the amateurs (42%), therefore the recovery time / study are more in the second group (58%), compared to the first (45%). Discussion From our results, we can say that the characteristics of an athlete's full-contact stick fighting, is the speed and frequency techniques. In fact, it does not matter the amount of force exerted on the shot stick, but rather the speed of the athlete in making repeated sequences. ## EVALUATION OF TECHNICAL, TACTICAL AND CONDITIONAL COMPETITIVE LOADS IN PROFESSIONAL MMA MIXED MARTIAL ARTS FIGHTERS

RIBERA-NEBOT, D., LLORET-ARREDONDO, R.

*INSTITUTE OF HIGH PERFORMANCE CENTER (ST. CUGAT - BARCELONA), BARCELONA UNIVERSITY*

**Introduction** Recording maximum reliable information on changes in an athlete during the training process and competition - control and evaluation, respectively (Seirul-lo, 1998) – is the main principle of the design of training monitoring (Viru, 2004). The aim of this study was to integrate the evaluation of technical, tactical and conditional competitive loads in one of the professional MMA fights of the Bellator 25 Fighting Championship 2010 held in Chicago. **Methods** In every minute and in every of the three 5-minute rounds of the fight the following parameters were evaluated for each fighter: a) tactical load (based on the difficulty of making decisions - assessed 1 to 10 by expertise judgment), b) technical-conditioning load (based on the quality, scored 1 to 10 by expertise judgment, and the number of effective actions, scored 1 point for every 10 point of quality –overall assessed 1 to 10), c) sum of qualities of effective actions, d) auto-evaluation by the fighter and coaches of technical-tactical execution qualities, strategies, fatigue states and psychological effectiveness. For each of the three rounds and for the total fight the tactical load (mean of each minute and round), technical load (mean of each minute and round), the conditional load (sum of the technical-conditioning load of each minute and each round). **Results** The sum of qualities of effective actions for RLL and CK fighters in rounds 1, 2, 3 and total fight, respectively, are 69/227, 45/84, 94/235 and 208/546. The tactical, technical and conditional loads for RLL fighter in rounds 1, 2, 3 and total fight, respectively, are 6.4, 4.2, 8.2 and 6.27 (tactical load), 5.4, 2.1, 6.3 and 4.6 (technical load), and 27, 10.7, 31.3 and 69 (conditional load). **Discussion** The integration of the evaluation of tactical, technical and conditioning competitive loads in professional MMA fighters is effective to help the coach in training guide and making necessary changes in training design. In order to improve the effectiveness in competition, the most relevant analysis is the auto-evaluation of the fighter and coaches. This methodology to evaluate competition is applied to many other martial arts fighters. **References** Seirul-lo Vargas F. (1998). Control and evaluation of training. ## THE EFFECT OF SHORT-LASTING, ONE-TIME 3D VERSUS 2D VISUALIZATION ON MENTAL REPRESENTATION OF COMPLEX BADMINTON SKILLS

ODYSSEOS, P., FROHNERT, A., FRIESE, C., SCHNAASE, C., THRA, D., PLATEN, P., FERRAUTI, A.

*RUHR-UNIVERSITY BOCHUM*

**Introduction** New methods aimed at helping athletes develop, stabilize and optimize their skills are of utmost importance in sport. Recently, 3D-technology products (TVs, Camcorders) have been made available for consumers. However, the usage of this technology in sports has not been widely examined until today. Thus, our aim was to examine in a pilot study, if the assignment of the 3D-technology improves the mental representation of complex sport skills in badminton novices. **Methods** Two randomized experimental groups of sport students participated in the study: a 3D (n=12) and a 2D group (n=12). All subjects were healthy, had no 3D-experience related to sports and were badminton novices (no team players and non-educated in badminton clear technique). All subjects took part in a three session test: (1.) Students were filmed with a high speed camera (40 fps) by feigning a badminton specified movement ("clear"). (2.) Following this, they watched a video of a perfect "clear" for three times in either 3D or 2D technique. (3.) Then they were presented with seventeen printout pictures of sequences of this movement from different perspectives. The task was to put the pictures in the right chronological order. (4.) Finally, all subjects were filmed again by repeating the "clear" movement. Effects on mental representation were measured by means of quantitative and qualitative measurements. Quantitative measures consisted of controlling the order of position and sequence of the pictures during session 3 by means of a code-word based point system. In a qualitative attempt we compared the quality of the movements filmed in session 1 and 4 according to defined technique criteria (0-1-2-3-phase-modell from Poste & Hasse 2002). **Results** No significant differences were found in mental representation during test session 3 between the 3D (147±8 points) and the 2D group (145±8 points). Analyzing the quality of movement, we found an improvement in both groups from pre to post recording without any significant intervention effect. **Conclusion** Our tests did not find any significant impact of a short-lasting, one-time 3D presentation of a complex badminton movement pattern on mental representation, and no effect on short-time motor learning. This might be due to the not very well developed technical standard of the 3D Camera used (converging point at 1.50 m, no recording of whole body movements). Future studies are necessary with higher technical standards and with longer-lasting visualization sessions. **Literature** Poste, D. & Hasse, H. (2002). ## THE PHYSIOLOGICAL DEMANDS OF COMPETITIVE ONE-DAY EVENTING IN NOVICE FEMALE RIDERS

JOHNSON, J.L.1, PRICE, M.J.2, PETERS, D.M.1,3

*1:UW (WORCESTER, UK), 2: CU (COVENTRY, UK), 3: UIA (KRISTIANSAND, NORWAY)*

**Introduction** One-Day Eventing (ODE) is an equestrian discipline that is comprised of three phases: Dressage (DR), Show Jumping (SJ) and Cross Country (XC). Developing sports specific conditioning requires an understanding of the demands experienced by athletes during competition. At present little is known about the competition demands of ODE as previous research has either focussed on non-competitive athletes in simulation scenarios (Roberts et al., 2009) or has presented the athletes as equestrians per se rather than ODE athletes (Westerling, 1983; Devienne and Guezennec, 2000). The aim therefore was to evaluate the physiological demands of competitive ODE in female novice riders. **Methods** Heart rate (HR, Polar RS800CX Multi, Polar Electro Europe), blood lactate (BLa), and handgrip strength (GS) data were collected from 27 novice female event riders (age 34±10.4 yrs; ht 169.3±6.2 cm; mass 67.4±9.6kg) during competitive events. HR was classified based on percent time spent in five heart rate zones (<35%, 35-54%, 55-69%, 70-89% and 90-100% HRmax, calculated as the highest of either 220-age or the highest HR achieved). BLa was measured at the start of the day (baseline) and 6 minutes post completion of each phase. GS was measured at the start of the day (baseline) and immediately post each phase. **Results** Riders spent a greater percentage of phase time in the high exertion HR zone (90-100% HRmax) in the XC (75%) and SJ (43%) phases compared to the DR phase (28%; p<0.01). Mean BLa increased throughout the event (DR 2.2±1mmol; SJ 3.5±2.2mmol; XC 4.7±1.8mmol, p<0.01). Post XC phase mean GS (26.8±6.2kg) was lower than baseline GS (31.2±4.2kg, p<0.05) in the dominant hand evidence of asymmetry between the dominant and non-dominant hand throughout the events (p<0.01). **Discussion** The high levels of cardiovascular exertion experienced during and the high mean and peak blood lactate levels observed following the SJ and XC phases indicate a need for both aerobic and 'lactate tolerance / threshold' training in these athletes in order to provide cardiovascular and muscle fatigue resis-

tance through improved hydrogen ion buffering and facilitation of lactate removal following high intensity jumping efforts. Strength training may also be beneficial in order to improve hand dominance asymmetry in order to enhance symmetry when controlling the horse and to reduce the potential negative performance impact of muscular fatigue in the upper body. ## THE IMPACT OF RESISTANCE DRY-LAND TRAINING ON PERFORMANCE AND BODY COMPOSITION OF ELITE SWIMMERS

NIKOLOPOULOS, A.1, MOURTAKOS, S.P.2, NAFPAKITITOU, D.1, SOULTANAKIS, H.1

HAROKOPIO UNIVERSITY, UNIVERSITY OF ATHENS

Nikolopoulos, A.1, Mourtakos, S.P.2, Nafpaktitou, D.1, Soultanakis, H.1 1:Aquatics Division, Dep't of Physical Education and Sport Sciences, University of Athens; 2: Laboratory of Nutrition and Clinical Dietetics, Dep't of Nutrition and Dietetics, Harokopio University of Athens, Greece. Introduction Resistance training increases muscular strength and aerobic power, although its contribution in swimming performance has been questioned (Tanaka et al.,1993). Swimming coaches often have to select dry-land weight training programs based on limited research focusing on this area (Girord et al., 2007). The purpose of this study was to determine the effect of two weight training methods of dry-land training, on muscle mass, bone density, strength and sprint performance in elite swimmers. Methods Seventeen elite swimmers with a mean age of  $14.9 \pm 1.14$  years were randomly assigned to either a high resistance-low repetition (HR), or a low resistance-high repetition (LR) weight training program. Bone mineral density (BMD), body mineral content (BMC) and areal bone mineral density (aBMD), total body calcium (TBC), muscle mass and total body fat (TFat%) were determined before and after 6-weeks of training by dual energy X-ray absorptiometry (DXA). Strength of the dominant hand (by a Takei Grip-A-5001, strength dynamometer) and swim time trials on 25, 50 and 100 m were also determined pre and post weight training. A two-way analysis of variance for repeated measures on both factors and a Tukey post-hoc test were used to locate differences between means at a  $p < 0.05$  level of significance. Results The results showed that BMD (pre  $1.01 \pm 0.08$ ; post  $1.12 \pm 0.08$ ), BMC (pre  $2672.7 \pm 527$ ; post  $2736.6 \pm 561$ ), TFat% (pre  $14.9 \pm 5.3$ ; post  $13.3 \pm 5.4$ ) and TBC (pre  $1015 \pm 200$ ; post  $1039.6 \pm 213.3$ ) significantly improved under both types of training but without a training type effect ( $P < 0.05$ ). Strength of the swimmers' dominant hand was increased similarly under both types of training and best times at 25 and 50m but not at 100m of their competitive stroke improved to the same extend in both groups ( $P < 0.05$ ). No changes in muscle mass were observed. Discussion Although the duration of training was relatively short to elicit great gains, speed, strength and certain bone characteristics improved similarly under both weight training programs. The lack of gains in muscle mass with the concomitant improvement in certain strength characteristics and sprinting ability could be attributed to the improved neural recruitment that is initially reported with weight training (Narici M.V. et al, 1989). ## PACING STRATEGIES ASSOCIATED WITH SUPERIOR DUATHLON PERFORMANCE

RENFREE, A., SCRIVEN, M.

UNIVERSITY OF WORCESTER

Introduction Pacing strategies involving a slow start and fast finish have been associated with superior performances in endurance running and cycling events (St Clair Gibson et al 2006). However, little research has examined the optimal pacing strategy during multi-sport events requiring completion of several sequential stages. The aim of this study was to analyse differences in run and cycle performance between the fastest and slowest of two competitive duathlons. Methods Performance data was analysed for 31 participants (29 male, 2 female) who completed two competitive duathlon events (run 3.2 km, cycle 16 km, run 3.2 km) on the same course. Chip timing was used to record both total and individual stage times. Transition times were removed. Total times were divided into fastest (FAST) and slowest (SLOW) individual performances, and T-tests for repeated measures were used to assess differences on each individual stage. Results Of the 31 participants, 18 (58%) achieved their fastest overall performance in race 1 ( $2981 \pm 237$ s) and 13 (42%) achieved their fastest in race 2 ( $2990 \pm 239$ s). Comparison of race 1 with race 2 also revealed no significant differences in performance or relative percentage of total time spent on any individual stage. Comparison of FAST and SLOW reveals no significant differences in performance on run 1 (FAST  $719 \pm 69$ s, SLOW  $724 \pm 62$ s) or run 2 (FAST  $724 \pm 62$ s, SLOW  $758 \pm 62$ s). However, performance was significantly faster ( $P < 0.01$ ) on the cycle stage during FAST (FAST  $1463 \pm 101$ s, SLOW  $1546 \pm 149$ s). Discussion The results suggest performance on the cycle stage of a competitive duathlon is largely responsible for variations in individual performance. In the present study 58% of participants achieved their fastest overall performance in race 1 and 42% in race 2, suggesting differences between fast and slow performances were not simply the result of familiarisation or environmental conditions. The mechanisms for these observations are unclear. If overall pacing was based on a telioanticipatory strategy (Ulmer 1996), then a faster first run would be anticipated during the fastest overall race as the pacing regulatory centre in the brain would have allowed a higher muscular work rate based on a peripheral physiological status more conducive to the coming exercise bout. Alternatively, if work rate in run 1 was too high during slowest overall races due to inappropriate performance goals, then a comparatively greater performance decrement would be expected during run 2. Further research is warranted in order to identify the reasons underpinning the apparent independence of run and cycle performance during a competitive duathlon. ## FACTORS INFLUENCING PROPELLING EFFICIENCY IN COMPETITIVE SWIMMING

HUANG, Z., KUROBE, K., OZAWA, G., NAGIRA, A., TANAKA, T., TAGUCHI, N., TAKEKURA, H., OGITA, F.

NATIONAL INSTITUTE OF FITNESS AND SPORTS

Introduction The propelling efficiency (ep) is defined as the ratio of the power used to overcome drag to the total power output, and has been suggested as an important determining factor of swimming performance (Toussaint 1988, Huang 2010). While several studies determined propelling efficiency using swimmers of different performance level, little is currently known which factors influencing swimming performance are related to ep. Therefore, this study aimed to examine the relationship between ep and various factors, such as drag, swimming economy, stroke parameters, and propulsive surface area. Methods The subjects were 10 well-trained male swimmers (age:  $20 \pm 1$  yrs) including a finalist in Japan Swim Championship. Drag-swimming speed relationship and ep were determined by the use

of the measurement of active drag system, according to the methods described by Toussaint et al.. Drag-swimming speed relationship was then used to estimate the drag at given swimming velocities. Oxygen uptake as swimming economy was measured during swimming at the water flow rate of  $1.25\text{m}\cdot\text{s}^{-1}$  in swimming flume. At the same time, the video picture during swimming was recorded, and it was used to calculate the stroke rate (SR) and length (SL). Those measurements were performed by arm stroke only, and their legs were supported and fixed together by a small buoy. Furthermore, the projected area of hand and forearm was measured as propulsive surface area (PSA). Results The mean value of ep was  $67\pm 5\%$  (range: 60 to 73%). When the relationship between ep and each measured value was examined, individual ep was significantly correlated to individual SL and PSA ( $P<0.05$ ), but not to swimming economy, SR, and estimated drag. Furthermore, a significant positive correlation was observed between PSA and SL ( $P<0.05$ ). Discussion/Conclusion Since propulsive force during swimming is given as the product of the mass of water and the velocity change, a swimmer with larger PSA who can push off against a larger mass of water should generate an equal propulsive force with a smaller velocity change, which should induce a longer SL, too. Furthermore, since stroke with a smaller velocity change decreases the power spent on moving water backward, i.e. a loss of kinetic energy to water during swimming, it should increase ep. Consequently, ep would be more closely related to SPA and SL, rather than swimming economy or drag. References 1. Toussaint, H.M., et al. (1988) Propelling efficiency of front-crawl swimming. *J Appl Physiol*, 65: 2506-2512. 2. Huang, Z., et al. ## NORMATIVE DATA FOR LABORATORY ANAEROBIC PERFORMANCE IN ICE HOCKEY PLAYERS AGED 15 TO 35 YEARS

HELLER, J., VODICKA, P.

*FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY,*

**NORMATIVE DATA FOR LABORATORY ANAEROBIC PERFORMANCE IN ICE HOCKEY PLAYERS AGED 15 TO 35 YEARS** Heller, J., Vodicka, P. Faculty of Physical Education and Sport, Charles University, Prague, Czech Republic Introduction From the physiological assessments, anaerobic exercise testing is of a primary importance in ice hockey players. Regardless that the Wingate anaerobic test (WAnT) is world wide frequently used in ice hockey players (Cox et al. 1995), there are no available normative values for peak power (PP) and anaerobic capacity (AnC) as regards age and position of the players (Vescovi et al. 2006). Therefore, the aim of this study was to reanalyse the data obtained in 7495 tests done in Czech ice hockey players to create age- and positional-related norms for PP and AnC in ice hockey players. Methods The data were collected from 1999 to 2008 seasons. Altogether 7495 ice hockey players (forwards:  $n=3054$ , defensemen:  $n=255$ , goalkeepers:  $n=586$ ) aged 15 to 35 years performed a 30-s WAnT on a cycle ergometer Monark E824 using a breaking force of 6  $\text{W}\cdot\text{kg}^{-1}$  that equals 0.106  $\text{kg}\cdot\text{kg}^{-1}$  (Vandewalle et al., 1985). The main results were 5-s PP [ $\text{W}\cdot\text{kg}^{-1}$ ] and total work or anaerobic capacity AnC [ $\text{J}\cdot\text{kg}^{-1}$ ]. The dependence of PP and/or AnC on age was calculated using a polynomial function of the third order. Peak values were calculated using derivation of the function. Results In forwards,  $\text{PP}/\text{kg} = 0.0007x^3 - 0.0668x^2 + 1.9251x - 2.6599$  ( $R^2 = 0.9155$ ,  $x = \text{age}$  [yrs]), with peak values 15.0  $\text{W}\cdot\text{kg}^{-1}$  at 22.7 years of age, and  $\text{AnC}/\text{kg} = 0.0143x^3 - 1.2333x^2 + 33.124x + 66.295$  ( $R^2 = 0.8665$ ,  $x = \text{age}$ , yrs), with peak values 350  $\text{J}\cdot\text{kg}^{-1}$  at 21.3 years of age. Defensemen attained  $\text{PP}/\text{kg} = 0.0011x^3 - 0.096x^2 + 2.5584x - 7.1553$  ( $R^2 = 0.9691$ ), with peak values 14.9  $\text{W}\cdot\text{kg}^{-1}$  at 22.0 years of age, and  $\text{AnC}/\text{kg} = 0.0166x^3 - 1.3741x^2 + 35.795x + 45.088$  ( $R^2 = 0.9068$ ), with peak values 344  $\text{J}\cdot\text{kg}^{-1}$  at 21.0 years of age. In goalkeepers,  $\text{PP}/\text{kg} = 0.0007x^3 - 0.0642x^2 + 1.8124x - 1.8468$  ( $R^2 = 0.9028$ ), with peak values 14.4  $\text{W}\cdot\text{kg}^{-1}$  at 22.0 years of age, and  $\text{AnC}/\text{kg} = 0.0048x^3 - 0.5158x^2 + 15.255x + 190.69$  ( $R^2 = 0.8905$ ), with peak values 328  $\text{J}\cdot\text{kg}^{-1}$  at 20.7 years of age. Discussion In general, PP and AnC rise with age and the values seem to peak at the end of the third decade (Inbar, O. et al. 1996). In specifically trained population, however, the effect of training seems to be more important than the effect of age. Small but evident position-related differences in PP and AnC are in agreement with the data published by Vescovi et al. (2006). The normative values of PP and AnC could be used by ice hockey coaches, and trainers to evaluate anaerobic performance with respect to the chronological age and playing position of the ice hockey player. ## RELIABILITY OF THE BIOHARNESS MONITORING SYSTEM

JOHNSTONE, J.A.1, FORD, P.A.2, HUGHES, G.1, WATSON, T.1, GARRETT, A.T.1

*1UNIVERSITY OF HERTFORDSHIRE 2BRITISH OLYMPIC ASSOCIATION*

**Introduction:** The Bioharness monitoring system may provide physiological information on sporting performance by recording multiple data streams simultaneously during activity. Understanding the reproducibility of data is fundamental to having confidence in the monitoring equipment being used. This study assessed the reliability of the Bioharness monitoring system. **Methods:** 12 healthy males (age  $20.5\pm 2$  yrs, body mass  $70.4\pm 9.4\text{kg}$ , height  $1.77\pm 0.07\text{m}$ ) participated. Reliability of Heart rate (HR), Breathing Frequency (BF) and Accelerometry (ACC) and Infra-red skin temperature (ST) was tested via a discontinuous incremental (0-12km.h<sup>-1</sup>) treadmill protocol completed within a thermo-neutral ( $\approx 24^\circ\text{C}$ ) environment. A within subject design, assessing inter and intra ( $n=4$  devices) reliability, was completed using the same treadmill protocol. Posture (P) was assessed by securing devices to a tilt table which were moved through 160° at 100 intervals, which was repeated. **Results:** Between subject data ( $n=12$ ) report low Coefficient of Variation (CV) and strong Intra Class Correlation (ICC) for HR (CV 4.8;  $r=0.98$ ,  $p<0.01$ ), ACC (CV 6.5;  $r=0.99$ ,  $p<0.01$ ) and P (CV 7.6;  $r=0.99$ ,  $p<0.01$ ). In contrast ST (CV 3.7;  $r=0.61$ ,  $p<0.01$ ) and BF (CV 17.7;  $r=0.81$ ,  $p<0.01$ ) present more variable data. Weaker reproducibility was reported when data was analysed at each respective velocity with BF (CV 15.0 – 21.9;  $r<0.51$ ), HR (CV <6.2;  $r>0.83$ ) and ACC (CV <9.3;  $r=0.66$  to 0.99). Moreover, complete data sets for HR ( $n=6$ ) and BF ( $n=7$ ) reduced as treadmill velocity increased  $>10\text{km}\cdot\text{h}^{-1}$ . Intra device data set ( $n=4$ ) saw strong ICC ( $r>0.97$ ,  $p<0.01$ ) and low CV values ( $<10.1$ ) for HR, ACC and P. ST maintained strong results (CV<2;  $r>0.90$ ,  $p<0.01$ ) bar one device (CV=2.7;  $r=0.48$ ). BF produced low to moderate ICC values ( $r=0.41$  to 0.72) and CV (<13.7). Inter device data resulted in strong ICC values ( $r>0.89$ ,  $P<0.01$ ) and low CV (<9.3) for HR, ACC, ST, P. BF ICC were weak ( $r=0.33$  to 0.59) and CV range was 12.3 to 17.4. **Discussion:** Data suggest that the Bioharness is a reliable monitoring device within ambulatory laboratory testing. Breathing frequency demonstrated the largest variance in both testing designs which may be linked to the technical single strap set-up for this variable. Increased variance of breathing frequency and heart rate data with higher velocity could be also be attributed to EMG or movement artefacts. Inter/intra data analysis suggests better reproducibility. Moreover, the latter testing design accomplished full sets of data at all velocities unlike the between subject test. The subject's upper body physical profile, issue of fitting and securing the device during activity could be a consideration to improve the reproducibility of data. ### PP-PM40 Sports Nutrition: Supplements 3

#### EFFECTS OF INTERVAL TRAINING & CREATIN SUPPLEMENTATION ON ANAEROBIC FACTORS AND SPRINT PERFORMANCE

HEMMATI, J.

AZAD UNIVERSITY

Eslami, S1 Hemmati, J.2 1: PNU (Delfan/Iran), 2: IAU (Islamic Azad University, Khoramabad Branch, Iran) Introduction Suitable nutrient is based physical performance. Because it provide fuel for organic activities and provide chemical materials for energy producing and using of potential energy in chemical materials (Hoffman JR et.al2005).There fore the aim of this study was to investigate of effects four week interval training with creatin supplementation on peak power, mean power, fatigue index and sprint performance in amatory female swimmers. Methods The subject in supplement group (N=10) ingested 20gr Creatin supplementation per day for 5 day (2x10 per day) (loading phase) and then ingested 5 gr pre day for 23 days (maintenance phase). In placebo group (N=10), the subject ingested the same dose of placebo and in same time. Both groups participated in interval training for four weeks. Wingate test used to evaluation the anaerobic factors (peak power, mean power, fatigue index), and for staminate the sprint performance all subjects performed sprint swimming (25m). These tests performed by all subjects before and after 4 week training. Results Results of one way ANOVA test showed that four week interval training with Creatin supplementation improved anaerobic factors such as peak power ( $F= 4.8$ ,  $P= 0.02$ ), fatigue index ( $F= 4.95$ ,  $P= 0.01$ ), but don't effect on mean power ( $F= 4.1$ ,  $P= 0.02$ )and sprint performance ( $F= 1.52$ ,  $P= 0.23$ ). Discussion Findings in our research showed that using Creatin supplement, increase storage of muscle Creatin that it related to improved peak power and fatigue index. Because it due to increase in available fuel (Hall et al 2007, Anomaciry 2006). in the other hand interval training with short time and acute activities periods and recovery periods between activities periods due to improve performance of phosphate system . Major energy system in interval training is phosphate system but so Gelycoletic system is involved in this training. Thus improving in mean power that it evaluated anaerobic Gelycoletic capacity and sprint performance can be related to interval training. Therefore using Creatin supplement in power athletes that trained more than 1 per day can increase fatigue tolerance and made high capacity of training that is due to better adaptabilities to power training (Barnet et al 2005). #### BLOOD BICARBONATE BUFFERING DURING REPEATED SHORT-TERM INTENSE EXERCISE

YUNOKI, T., YAMANAKA, R., ARIMITSU, T., LIEN, C.S., AFROUNDEH, R., MATSUURA, R., YANO, T.

HOKKAIDO UNIVERSITY

Blood bicarbonate buffering during repeated short-term intense exercise Yunoki, T.1, Yamanaka, R.1, Arimitsu, T.1, Lien, CS.1, Afroundeh, R.1, Matsuura, R.2, Yano, T. 1: Hokkaido University (Sapporo, Japan), 2: Kyushu Kyoritsu University (Kitakyushu, Japan) Introduction During short-term intense exercise (STIE), decreased pH can become a factor limiting exercise performance. During repeated STIE, decrease in pH is attenuated due to decreased lactate production associated with muscle glycogen reduction. In this situation, the primary limiting factor would be decrease in rate of ATP synthesis from the glycolytic system. However, since the glycolytic pathway is inhibited by low-ered pH, defence against pH decline must be important even during repeated STIE. Bicarbonate buffering is neutralization of  $H^+$  by  $HCO_3^-$  and is linked to elimination of  $CO_2$  by hyperventilation (respiratory compensation). Since decreased blood pH is one of the factors that contribute to hyperventilation during exercise, bicarbonate buffer power ( $\beta_{bi}$ ) during STIE may be decreased by repetition of exercise because of attenuation of pH decline. The purpose of this study was to examine  $\beta_{bi}$  during repeated STIE. Methods Eight subjects performed three STIEs (120 s, 100-105% of  $VO_{2max}$ , 60 rpm) using a cycle ergometer. STIEs were separated by 20 min of recovery, 40 min of middle-intensity (= ventilatory threshold) cycling, and a further 40-60 min of recovery. Respiratory variables were measured during each STIE and 20 min of recovery. Blood gas, acid-base status, and lactate concentration ( $[La^-]$ ) were measured in arterialized-capillary blood withdrawn from pre-warmed fingertips before and after each STIE.  $\beta_{bi}$  was calculated from change ( $\Delta$ , difference in the value at rest and at 3 min of recovery) of  $HCO_3^-$  and pH ( $\Delta[HCO_3^-]$ - $\Delta pH$ -1). Results Increase in  $[La^-]$  was significantly lower in the 3rd STIE than in the 1st STIE. Consequently, decrease in pH ( $\Delta pH$ ) was significantly attenuated in the 3rd STIE (from  $7.425 \pm 0.005$  (mean  $\pm$  SE) to  $7.270 \pm 0.009$ ) compared to that in the 1st STIE (from  $7.431 \pm 0.007$  to  $7.231 \pm 0.012$ ). There was no significant difference in  $\beta_{bi}$  between the three STIEs (1st:  $55.2 \pm 3.9$ , 2nd:  $58.0 \pm 2.8$ , 3rd:  $59.3 \pm 2.4$  mmol-l-l). Ventilation (VE) during exercise was significantly higher in the 3rd STIE than in the 1st STIE, and  $PaCO_2$  during exercise tended to be lower in the 3rd STIE than in the 1st STIE. Discussion The significant decreases in  $[La^-]$  increase and pH decline observed in the 3rd STIE suggest that muscle glycogen was reduced by the repetition of STIE. Despite attenuation of pH decline, VE during the 3rd STIE was significantly higher than that in the 1st STIE. Respiratory compensation was thus maintained even during the 3rd STIE and, as a result,  $\beta_{bi}$  could not have been decreased by the repetition of STIE. This implies that in repeated STIE, maintenance or enhancement of respiratory compensation supports the function of the glycolytic system by maintaining  $\beta_{bi}$ .

#### THE EFFECT OF SODIUM BICARBONATE ON EXERCISE RECOVERY AND SUBSEQUENT PERFORMANCE OF MAXIMAL SHORT TERM EFFORT

WARNE, J., FITZPATRICK, P., WARRINGTON, G.

DUBLIN CITY UNIVERSITY

Purpose: To examine the effect of Sodium Bicarbonate ( $NaHCO_3$ ) on exercise recovery and subsequent performance of maximal short term effort and to establish side effects of GI distress that may result from the supplement use. Methods: 9 trained subjects ( $VO_2$   $64.65 \pm 6.81$  ml/kg/min) competing at national level 800m ( $115.50 \pm 4.98$  s) or 1500m ( $237.89 \pm 4.98$  s) were recruited to Dublin City University. Each subject undertook a treadmill familiarisation and  $vVO_2$  maximal incremental test ( $23.96 \pm 0.73$ kph) to determine 110% of max. Subjects then took either a control (maltodextrin) or  $NaHCO_3$  (SB) supplement on two separate days one week apart in a double blind fashion. The test involved two supra-maximal trials three hours apart, with time to exhaustion recorded. Blood gas ( $CHCO_3^-$ -(P,st), pH,  $pCO_2$ ,  $pO_2$ ) and lactate were taken from the ear at 11 times during testing. Heart rate and RPE was measured, and GI distress was measured

with questionnaires and a 0-5 scale. Results: Subjects displayed large individual responses to SB supplementation. Mean subsequent performance was not significant ( $p=0.266$ ) but was higher than the placebo group, and some subjects ( $n=5$ ) improved significantly. Lactate, pH and  $\text{CHCO}_3^-$  (P,St), was significantly higher ( $p=0.033$ ,  $p=0.000$ , and  $p=0.000$  respectively) in the SB group, whilst  $\text{pO}_2$  and  $\text{pCO}_2$  did not show any difference ( $p=0.457$  and  $p=0.057$  respectively). GI distress displayed no significant difference ( $p=0.511$ ) and mean values were low (0.64 being the highest). Recovery times were not improved in the SB group. Conclusion: This study adds to the limited evidence that SB may improve subsequent performance, but does not improve recovery times with regard to pH. Effects seem to be subject dependent, with some displaying no change where others perform significantly better. New methods of SB ingestion yield very little side effects of GI distress.

## EFFECTS OF CAFFEINE ON EXERCISE PERFORMANCE IN SEDENTARY MEN

WALLMAN, K.

THE UNIVERSITY OF WESTERN AUSTRALIA

EFFECTS OF CAFFEINE ON EXERCISE PERFORMANCE IN SEDENTARY MEN George J Laurence, Karen E Wallman, Kym J Guelfi, School of Sport Science, Exercise and Health, The University of Western Australia, Perth, Western Australia Introduction: Caffeine is an easily accessible central nervous system stimulant that has minimal negative side effects and high social acceptability (Fredholm, Battig, Holmen, Nehlig & Zvartau, 1999). While various studies have reported an ergogenic effect of caffeine in an athletic population, there has been minimal investigation into the effects of caffeine on exercise performance in a sedentary population (Engels & Haymes, 1992, Wallman, Goh & Guelfi, 2010). This is an important area of research, as caffeine may benefit this population by lowering the perception of effort and pain during exercise, possibly resulting in an increased amount of work being performed, and more energy being expended during an exercise session. This could lead to increased motivation in establishing a regular pattern of exercise. Therefore the purpose of this study was to examine the effect of caffeine ingestion on total work, mean power, oxygen consumption ( $\text{VO}_2$ ), energy expenditure (kJ), respiratory exchange ratio (RER), ratings of perceived exertion (RPE) and heart rate (HR) during 30 min of self-paced stationary cycling in a sedentary population. Methods: Using a counterbalanced, double-blind, crossover design, twelve healthy, sedentary, male, non-regular caffeine users completed two exercise trials 7 days apart, following ingestion of either caffeine (6 mg/kg body mass) or placebo 1 hour prior to exercise. Exercise trials were performed on a cycle ergometer and consisted of 30 min of stationary cycling in which participants were instructed to complete as much work as possible in the time allowed. Results: The total amount of work completed and power output maintained during the caffeine trial were significantly higher compared to placebo ( $p = 0.001$  and  $p = 0.001$ , respectively). In addition, there was a significant increase in HR,  $\text{VO}_2$  and energy expenditure during exercise after caffeine ingestion ( $p = 0.031$ ,  $p = 0.009$  and  $p = 0.018$ , respectively), however RPE and RER were similar between trials ( $p = 0.877$ ,  $p = 0.760$ , respectively). Conclusion: Acute caffeine ingestion resulted in sedentary men performing more work in a 30 min cycle exercise session, compared to the placebo trial, without any change in substrate utilization or the perceived effort of the exercise. ## EFFECT OF CAFFEINE ON FATIGUE DURING SUBMAXIMAL ISOMETRIC CONTRACTIONS AT DIFFERENT KNEE ANGLES

WILLEMS, M.E.T., MADIGAN, D.J.

UNIVERSITY OF CHICHESTER

Introduction Time to fatigue during intermittent submaximal isometric contractions of knee extensors is muscle-length dependent (Kooistra et al., 2005). The time to fatigue of knee extensors can be increased by caffeine ingestion (e.g. Plaskett and Cafarelli, 2001). It is not clear whether the effect of caffeine on fatigue is muscle-length dependent. We determined the effect of caffeine on fatigue during intermittent isometric contractions of knee extensors at two knee joint positions. Methods Ten male subjects ( $24 \pm 3$  yr,  $177 \pm 5$  cm,  $75 \pm 6$  kg), non-smoking and with low caffeine intake ( $<200$  mg/wk) volunteered. The study had a double-blind, counter-balanced design. Familiarized subjects were administered caffeine (C, 6 mg/kg) added to a non-caloric beverage or placebo (P), 1 hr before performing functional testing. Maximal voluntary isometric torque (MVIT) and intermittent isometric contractions at 50%MVIT (15 s contraction, 5 s rest) of knee extensors were performed at knee angles of  $30^\circ$  (long muscle length) and  $90^\circ$  (short muscle length) (Humac Norm, CSMi) until torque fell below 45%MVIT for more than 2 s providing time to fatigue. Fatigue was quantified by measurement of a MVIT, 20 s after completion of the intermittent protocol. Surface EMG (Bagnoli-8, Delsys) of m.vastus lateralis was recorded and analysed for root mean square (RMS). Data were analysed with 2-way ANOVA and paired t-tests with significance set at  $P < 0.05$ . Results Similar MVIT values were obtained for caffeine and placebo at both knee positions [e.g.  $30^\circ$ :  $151 \pm 29$  Nm (C),  $152 \pm 30$  Nm (P)]. Caffeine showed increased time to fatigue, being equal by 15% ( $30^\circ$ ) and 13% ( $90^\circ$ ) at both knee positions [ $30^\circ$ :  $150 \pm 18$  s (C),  $131 \pm 19$  s (P);  $90^\circ$ :  $101 \pm 11$  s (C);  $90 \pm 14$  s (P)]. Time to fatigue was higher at  $30^\circ$  (long muscle length) for both conditions. Fatigue index was similar for both conditions and knee positions [e.g.  $30^\circ$ :  $19.8 \pm 1.7\%$  (C),  $19.6 \pm 1.9\%$  (P)]. Changes in RMS ( $n=6$ ) were similar for both conditions and knee positions [e.g.  $30^\circ$ :  $154 \pm 14\%$  (C),  $154 \pm 16\%$  (P)]. Discussion Similar increases in time to fatigue following caffeine ingestion with an identical endurance protocol were shown before (Plaskett and Cafarelli (2001). These authors proposed that the caffeine-induced increase in time to fatigue may be due to alterations in muscle sensory processes. In addition, caffeine's enhancing effect may be related to calcium reuptake (Meyers and Cafarelli, 2005). Caffeine enhances time to fatigue during submaximal intermittent isometric contractions. However, potential mechanism(s) seem not to be muscle length dependent. References Kooistra RD, de Ruiter CJ, de Haan A. (2005). *J Appl Physiol*, 98, 810-816. Meyers BM, Cafarelli E. ## CAFFEINE AFFECTS TIME TO EXHAUSTION AND BLOOD LACTATE CONCENTRATION AT MAXIMAL LACTATE STEADY STATE IN ACTIVE SUBJECTS DURING CYCLING.

CAPUTO, F., TURNES, T., DE AGUIAR, R.A., CRUZ, R.S.O., FARACO, H.C., GUGLIELMO, L.G.A.

SANTA CATARINA STATE UNIVERSITY

Caffeine affects time to exhaustion and blood lactate concentration at maximal lactate steady state in active subjects during cycling. Caputo, F.<sup>1</sup>, Turnes, T.<sup>1</sup>, de Aguiar, R.A.<sup>1</sup>, Cruz, R.S.O.<sup>1</sup>, Faraco, H.C.<sup>1</sup>, Guglielmo, L.G.A.<sup>2</sup> 1 – UDESC (Florianópolis, Brazil); 2 – UFSC (Florianópolis, Brazil) Introduction The factors that can affect the exercise tolerance ( $\text{Tlim}$ ) at the velocity associated with maximal lactate steady state ( $\text{vMLSS}$ ) are still unclear (Baron et al., 2008; Fontana et al., 2009). Recently, Fontana et al. (2009) showed that  $\text{Tlim}$  at  $\text{vMLSS}$  was not different between cycling and running despite of differences in blood lactate concentration ( $[\text{La}]$ ), heart rate (HR), oxygen uptake ( $\text{VO}_2$ ) and

ventilation (VE) between exercise modes. Caffeine ingestion has presented increase in both Tlim and blood metabolites such as lactate, glucose and glycerol (Graham and Spriet, 1995). Thus, our hypothesis is that caffeine intake could also increase the Tlim at vMLSS regardless of its effects on [La], since Tlim does not seem to be affected by changes in [La]. Therefore, the aim of this study was to analyse the effect of caffeine ingestion on Tlim during exercise at vMLSS. Methods MLSS was determined in nine male active subjects ( $51.4 \pm 5.1$  ml.kg<sup>-1</sup>.min<sup>-1</sup>;  $24.6 \pm 3.9$  years;  $175.7 \pm 7.9$  cm,  $78.3 \pm 12.5$  kg) by 2-4 constant-load tests (30min). vMLSS was defined as the highest velocity that can be maintained with an increase in [La] lower than 1.0 mMol.L<sup>-1</sup> during the final 20 minutes. In two different occasions, all subjects were asked to perform a test until exhaustion at the vMLSS with either caffeine (6 mg.kg<sup>-1</sup>) or placebo (dextrose). Blood lactate concentration was measured every 10 min. A two-way ANOVA with repeated measures was used for statistical analysis. Results Tlim was significantly higher after Caffeine ingestion (CAF) compared to placebo (PLA). The [La] was significantly higher in both 30th min and immediately after the end of exercise during CAF compared to PLA, however it was found no differences on [La] for 10th min between CAF and PLA. During CAF trial, [La] at 30th min and immediately after the end of exercise were not different, but higher compared to 10th min. During PLA trial, [La] was higher immediately after the end of exercise compared to 10th min, but similar between 10th min and 30th min. Conclusion The caffeine ingestion caused a significant ergogenic effect (17%) on Tlim performed at vMLSS, regardless of the changes on [La]. However, besides increasing the [La] relative to placebo, the CAF condition has presented an increase in [La] higher than 1.0 mMol.L<sup>-1</sup> ( $1.77 \pm 0.6$  mMol.L<sup>-1</sup>) between the 10th and 30th min suggesting that caffeine ingestion, at least a dose of 6 mg.kg<sup>-1</sup>, can affect the MLSS determination and its corresponding velocity. ### DETRAINING PROMOTES AN INCREASE IN FAT VOLUME, BUT DOES NOT AFFECT GLUCOSE TOLERANCE AND INSULIN SENSITIVITY IN RATS SUPPLEMENTED WITH LEUCINE

MATOS-NETO, E.M.1, TRINDADE, M.C.C.1, TORRES-LEAL, F.L.1, PANTALEÃO, L.C.1, FONSECA-ALANIZ, M.H.2, ROGERO, M.M.1, TIRAPEGUI, J.1

1: USP (SÃO PAULO, BRAZIL); 2: INCOR (SÃO PAULO, BRAZIL); 3: UNIVERSITY OF SÃO PAULO

Introduction The changes promoted by physical training in fat mass, glucose tolerance and insulin sensitivity, as well as in the activity of enzymes involved in energy metabolism can be rapidly reversed with the initiation of detraining. Thus, the total interruption of training can lead to metabolic disturbances consistent with a pre-obesity condition. Therefore, the aim of this study was to evaluate the effects of detraining on fat volume, glucose metabolism and enzyme activity in rats supplemented with leucine. Methods The study was conducted with 23 male adult Wistar rats subjected to treadmill training for 8 weeks. Subsequently, the animals were divided into three groups: (1) trained (T: n=8) and (2) detrained (D: n=8), maintained on a diet AIN93-M; and (3) detrained + 5% leucine supplementation (DL: n=7). These three groups were kept in this experimental protocol over a period of six weeks and were subjected to an oral glucose tolerance test (OGTT) and an intraperitoneal insulin tolerance test (ipITT). After sacrifice, samples of epididymal white adipose tissue and soleus muscle were excised for analysis. Data were analyzed using one-way ANOVA followed by post-hoc Tukey test ( $P < 0.05$ ). Results Both groups D ( $20.20 \pm 5.94$ ) and DL ( $18.81 \pm 5.52$ ) showed fat cell hypertrophy when compared to trained animals ( $10.47 \pm 2.45$ ). The area under the curve for OGTT showed no significant difference between groups D ( $12850 \pm 692,6$ ), DL ( $13440 \pm 323,4$ ) and T ( $12470 \pm 255,8$ ). The rate of glucose disappearance during insulin tolerance test (Kitt) was similar in all groups (D:  $2.10 \pm 0.44\% \cdot \text{min}^{-1}$ ; DL:  $2.39 \pm 0.45\% \cdot \text{min}^{-1}$ ; T:  $2.22 \pm 0.44\% \cdot \text{min}^{-1}$ ). The enzymatic activity of citrate synthase was similar between groups D ( $5.18 \pm 0.43$ ) and DL ( $5.01 \pm 0.26$ ), but differed from group T ( $7.52 \pm 0.65$ ). Discussion We found that detraining promoted fat cell hypertrophy, which corroborates previous studies showing increased fat mass (Yasari et al, 2007); lower citrate synthase activity in detrained animals, with leucine supplementation not capable to reverse such conditions. On the other hand, six weeks of detraining did not affect glucose metabolism in the experimental groups, differing from a previous study performed in humans (Chen et al, 2006) which demonstrated increased insulin plasma levels after OGTT. #### RAT MODELS SELECTIVELY BRED FOR LOW AND HIGH RESPONSE TO TRAINING

KOCH, L.G.1, BYE, A.2, STØLEN, T.2, KEMI, O.J.3, BRITTON, S.L.1, WISLOFF, U.2

1:UNIVERSITY OF MICHIGAN (ANN ARBOR, MI, USA); 2:NTNU (TRONDHEIM, NORWAY) 3:UNIVERSITY OF GLASGOW (GLASGOW, UK)

Introduction On average, populations derive physiological benefit through exercise training. Yet, there is wide heterogeneity for response to exercise, whereby some individuals experience little or no gain in variables such as VO<sub>2</sub>max (i.e. non-responders). Given the potential for exercise as prescription for cardiovascular disease risk, we were motivated to develop animal models of low and high response to training by two-way (divergent) artificial selection in rat. Methods Starting with a genetically diverse population, 10 generations of selection (n= 1816) has produced heterogeneous lines of Low Response Trainer (LRT) and High Response Trainer (HRT) rats that differ markedly for gain in running performance after 8 weeks of classic treadmill training. We used 6 weeks of high-intensity interval treadmill training to evaluate for exercise stimulated changes in VO<sub>2</sub>peak and cardiac function. Isolated left ventricular cardiomyocytes from sedentary (SED) and exercise trained (TR) LRT and HRT rats (n=5 per group) were measured for morphology, contractility, and Ca<sup>2+</sup> handling. A whole-genome microarray experiment was designed to compare SED and TR expression patterns from LRT and HRT cardiac left ventricles. Results HRT and LRT rats were similar at baseline for VO<sub>2</sub>peak but after training, HRT VO<sub>2</sub>peak increased from 65 to 90 ml/kg/min whereas LRT VO<sub>2</sub>peak was not altered. Left ventricular weights were lower (-8%), cardiomyocytes shorter (-6%) and wider (32%) in LRT-SED compared to HRT-SED. Post-training, these differences became larger in HRT hearts whereas LRT did not change. Fractional shortening and intracellular Ca<sup>2+</sup> cycling were not different between untrained LRT-SED and HRT-SED hearts. Exercise training improved contractility and intracellular Ca<sup>2+</sup> handling in HRT-TR, but not LRT-TR. Similarly, T-Tubule density, an assessment of active remodeling response, did not change in LRT but increased 12% with training in HRT rats. The microarray analysis revealed p53 tumor suppressor-dependent, IGF and TGF-beta signaling pathways as the main divergence between SED HRT and LRT hearts. mRNA levels of the 3 genes with highest expression differential, osteoglycin (Ogn), early growth response 2 (Egr2), and galanin (Gal) for LRT vs HRT in SED condition were validated with qPCR as significantly more abundant in LRT-SED than HRT-SED, LRT-TR and HRT-TR. Discussion By artificial selection, we developed a

contrasting animal model system useful for deeper exploration of exercise adaptation response at several levels of biological organization. We find that inherited cardiac flexibility for growth and remodeling are important for expansion of maximal O<sub>2</sub> transport capacity.

## MONITORING THE EFFECTS OF TRAINING LOAD ON BIOCHEMICAL PROFILE IN INDIAN MALE CYCLISTS

MAJUMDAR, P., SRIVIDHYA, S.

*SPORTS AUTHORITY OF INDIA*

**MONITORING THE EFFECTS OF TRAINING LOAD ON BIOCHEMICAL PROFILE IN INDIAN MALE CYCLISTS.** Pralay Majumdar, S. Srividhya Introduction Biochemical tests are widely used to assess the health, fitness of the intensively training athlete, to improve the performance of players. Several studies have shown the physiological approach to training in the sport of cycling (Boulay, 1995) and our study is concerned about the biochemical changes during the training cycle. Methods A total of 12 male cyclists volunteered to participate in this study. The training program is divided into four phases during phase I, phase II, phase III and phase IV, the volume of training is based on duration of hours and the km traveled by the cyclist (I – 560, II – 680, III – 720 & IV – 560 km). The intensity was measured on the percentage of heart rate, wherein E1= Up to 60% HR, E1b= 60-69% HR, E2= 69-80% HR (Threshold), E2S= Working at 80% HR (Threshold, S=Strength), E3= 81-90% HR, E4= 90-100% HR. The blood samples are collected in each phase to find out the impact of training load on Indian male cyclist. Results Iron, TIBC, Lactate dehydrogenase and cortisol level increases till III phase and decrease in the IV phase of training. Ferritin, creatine phospho kinase and testosterone level decreases in II, increases in IV and again decreases in the IV phase. Hemoglobin level increases whereas testosterone/cortisol ratio level decreases subsequently in the periodized cycle. Discussion The present study was designed to find out the impact of training on cyclist's biochemical profile. The values of biochemical profile are within the normal range except enzymes and cortisol level. Hematological profile of cyclists fluctuates depends on the volume/frequency/intensity of training. The demand of iron increases as volume/intensity of training increases, so there was increase in TIBC level to use the maximum amount of iron available. The depletion of iron store is more in II phase which is due to the increment of 21% of training volume whereas in III phase the increment is only 6%. The hemoglobin level of the cyclists increases subsequently in the training cycle whereas the iron level decreases in the fourth phase due to alteration in training and revealed that the hemoglobin level is high during the lowest volume/frequency of training. The highest intensity, volume and frequency of E2S training in III phase increases the CPK, LDH and cortisol level the most (Majumdar et al., 2010) and decreases the testosterone level the most. The testosterone/cortisol ratio decreases subsequently due to more training load in subsequent cycle. Hence, the above mentioned biochemical markers are to be monitored in all the phases to prevent anemia and over training. References 1.Boulay, M.R. (1995). ## AMINO ACID CHANGES IN TYPE I AND II FIBRES OF HUMAN SKELETAL MUSCLE AFTER MAXIMAL CONCENTRIC AND ECCENTRIC EXERCISE

BORGENVIK, M.1, ESSÉN-GUSTAVSSON, B.2, BLOMSTRAND, E.3

*1 SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES, 2 SWEDISH UNIVERSITY OF AGRICULTURAL SCIENCES, 3 KAROLINSKA INSTITUTET*

**AMINO ACID CHANGES IN TYPE I AND II FIBRES OF HUMAN SKELETAL MUSCLE AFTER MAXIMAL CONCENTRIC AND ECCENTRIC EXERCISE** Birgitta Essén-Gustavsson<sup>1</sup> and Eva Blomstrand<sup>2</sup> <sup>1</sup>Department of Clinical Sciences, Swedish University of Agricultural Sciences, Uppsala, Sweden <sup>2</sup>Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden Introduction Sustained endurance exercise leads to a pronounced reduction in the concentration of glutamate in muscle along with an elevation of tyrosine in both type I and type II fibres, with no alterations with respect to taurine and glutamine (Essén-Gustavsson and Blomstrand 2002). During resistance exercise glutamate is lowered in both fibre types, especially in type II fibres and alanine is elevated in both fibre types (Blomstrand and Essén-Gustavsson, 2009). These observations indicate that amino acid metabolism plays an important role in both types of fibres during exercise. The aim of this study was to investigate how amino acid concentrations were affected in type I and type II muscle fibres by maximal concentric and eccentric exercise. Material and Methods Four healthy young men performed 4x6 maximal isokinetic (30 degrees/sec) contractions with one leg, both concentric and eccentric with one hours rest period in between. Muscle biopsies (vastus lateralis) were taken before and after both exercise bouts. Freeze-dried muscle tissue was used to separate single fibres and fragments of these were identified as type I or type II after staining for myosin ATPase. Pools (50-500 µg) of either type I or type II fibres were weighed and extracted in perchloric acid. After centrifugation concentrations of free amino acids in the supernatant were analysed using HPLC-technique. Results After both the concentric and eccentric exercise bouts the glutamate levels decreased (30-40%) in both type I and II fibres and the levels of alanine increased (40-60%). Glutamine levels were unchanged in both fibre types, whereas branched chain amino acids decreased (20-30%) in type I fibres after both exercise bouts. The levels of taurine were higher in type I than type II fibres and were not influenced by the exercise. Discussion Although data are available from only four subjects, the results indicate that certain amino acids, such as glutamate and alanine in both fibre types and branched chain amino acids in type I fibres, plays an important role in amino acid metabolism during both concentric and eccentric exercise. Furthermore, the changes seen in amino acids support that both type I and type II fibres are recruited during maximal concentric and eccentric exercise. ## EFFECTS OF ENDURANCE TRAINING ON SKELETAL MUSCLE MEF2-HDAC5 INTERACTIONS

ZHANG, Y.

*BEIJING SPORT UNIVERSITY*

**Introduction** As a co-repressor of myocyte enhancer factor 2 (MEF2) transcription factor, histone deacetylase 5 (HDAC5) is abundant in skeletal muscle of mammals and can repress MEF2-mediated transcription when MEF2 associated with HDAC5. In vitro AMPK could phosphorylate HDAC5 and induce its nuclear export, thereby removing HDAC5 transcriptional repressive function to MEF2. However, in vivo there have been no experiments revealing the relationship among AMPK, HDAC5 and MEF2. Therefore, the aim of this study was to explore the role of AMPKα2 in regulating HDAC5 and MEF2 interaction after a four week period of endurance training. **Methods** Two month old C57BL/6J wild-type (WT) mice (n=20), AMPKα2 over-expression (OE) transgenic mice (n=20) and AMPKα2 whole-body knock-out (KO) mice (n=20) were randomly subdivided into control groups and exercise groups. After four weeks of treadmill running (12m/min, 1h/day), the MEF2-associated HDAC5 activity in the nucleus of quadriceps femoris muscle was measured by co-immunoprecipitation. Total and nucleus HDAC5 protein expressions were measured by western blot. **Results** After four weeks of endurance training: (1) the

MEF2-associated HDAC5 activities in skeletal muscles of OE, KO and WT mice were all significantly lower than their control groups, but there were no significant differences among their exercise groups; (2) nucleus HDAC5 protein expressions in skeletal muscles of OE, KO and WT mice were also significantly lower than their control groups, and they were significantly lower in the exercise group of OE mice than in the exercise group of WT mice; (3) total HDAC5 protein expressions in skeletal muscles of OE, KO and WT mice had no significant changes when compared to their control groups and among their exercise groups. Discussion Exercise may disrupt MEF2/HDAC5 complexes and increase the accessibility of MEF2 transcription factors to their binding domains on DNA to increase MEF2/DNA interactions (McGee and Hargreaves, 2004; Beato and Eisfeld, 1997). Consistent with this theory, we observed that HDAC5 association with MEF-2 decreased 35% after 28 days of exercise training. Also observed was a 27% decrease in nuclear HDAC5 protein, whereas there was no change in total HDAC5 protein, suggesting that HDAC5 was exported from the nucleus. Additionally, the increase in AMPK activity associated with AICAR treatment decreased the abundance of HDAC5 found at the MEF2 binding region on the GLUT4 promoter (McGee et al., 2008). However, in the present study, OE or KO of the AMPK $\alpha$ 2 isoform did not have any effect on the content of nuclear HDAC5 association with MEF-2 after 28 days exercise training, although 35% lower nuclear HDAC5 protein content was found in  $\alpha$ 2-OE training muscles. Therefore, we reasoned that the observed decrease in nuclear HDAC5 association with MEF-2 was likely the result of other factors. Reference McGee SL, Hargreaves, M. (2004). *Diabetes*, 53, 1208–1214. ## HYPOXIA MODULATES MUSCLE SIGNALING IN RESPONSE TO SPRINT EXERCISE

MORALES-ÁLAMO, D., PONCE GONZÁLEZ, J.G., FUENTES, T., SÁNCHEZ, R., GUADALUPE-GRAU, A., GUERRA, B.L., CALBET, J.A.

LAS PALMAS UNIVERSITY

Sprint exercise elicits signaling in skeletal muscle through AMPK, presumably resulting in ACC phosphorylation. AMPK is phosphorylated and activated when the AMP/ATP ratio increases and may be when the redox state of the cell is changed. Purpose. To determine if CamKII is implicated in the sprint exercise-induced AMPK phosphorylation, and to ascertain if CamKII phosphorylation is modulated by free radicals. To this purpose we determined AMPK phosphorylation in response to sprint exercise in normoxia (N, FIO<sub>2</sub>=0.21; barometric pressure 735–745 mmHg) and hypoxia (H, FIO<sub>2</sub>=0.10; barometric pressure 735–745 mmHg) to have two conditions with different levels of oxidative stress. Methods: Ten healthy males (age: 25±5 yrs; VO<sub>2</sub>max: 51±6 ml.kg<sup>-1</sup>.min<sup>-1</sup>; means ± SD) performed on separate days and random order two 30s-isokinetic Wingate tests at 100 rpm under N and H. Immediately before the start, at the end of the test, and at 30 and 120 min into the recovery period, muscles biopsies were taken and CamKII, AMPK $\alpha$  and ACC $\beta$  phosphorylation determined by Western blot. Results: Peak power output, peak blood lactate and fatigue index were similar in N and H. Mean power output and mean VO<sub>2</sub> were, respectively, 6% and 37% lower in H than in N. Thirty min after the normoxic sprint, CamKII phosphorylation was increased 1.5 fold compared to resting (P<0.05) whilst there was no significant changes in CamKII phosphorylation after the hypoxic test. Compared to pre-exercise levels, AMPK phosphorylation was increased by 21% 30 minutes after the sprint (P<0.05). ACC $\beta$  phosphorylation, a downstream kinase for AMPK and CamKII was increased 3-fold immediately after the normoxic sprint and ~4-fold 30 min later (both P<0.05). In contrast, no significant changes in ACC $\beta$  phosphorylation were observed in response to the hypoxic sprint. In hypoxia, but not in normoxia, the 30 kDa skeletal muscle oxidized proteins increased immediately after the sprint (1.4-fold, P<0.05) and remained elevated during the next two hours (~1.5-fold, P<0.05). Conclusion: This study shows that muscle oxygenation modulates the signaling response to sprint exercise in human skeletal muscle by a mechanism that may involve free radicals. Our findings are compatible with CamKII as having a role in sprint exercise-induced phosphorylation of AMPK. Neither AMPK nor CamKII phosphorylations appear to be mandatory for the immediate postexercise ACC $\beta$  phosphorylation. ## EFFECT OF DIFFERENT RESISTANCE TRAINING PROTOCOLS ON THE WNT SIGNALING PATHWAY

LEAL, M.L.1, LAMAS, L.2, UGRINOWITSCH, C.2, TRICOLI, V.2, MORISCOT, A.S.1, AOKI, M.S.3

<sup>1</sup>INSTITUTE OF BIOMEDICAL SCIENCES, UNIVERSITY OF SAO PAULO; <sup>2</sup>SCHOOL OF PHYSICAL EDUCATION AND SPORT, UNIVERSITY OF SAO PAULO; <sup>3</sup>SCHOOL OF ARTS, SCIENCES AND HUMANITIES, UNIVERSITY OF SAO PAULO

**Introduction** The wingless-type MMTV integration site family (WNT) has recently been shown to be involved in adaptations to mechanical overload. For instance, this pathway was activated during skeletal muscle hypertrophy induced by an ablation protocol which overloaded the plantaris muscle in mice (Armstrong and Esser 2005). Armstrong and Esser (2005) observed that key components of the WNT pathway were up-regulated in overloaded plantaris muscles, i.e. the ligand receptor Frizzled 1, DVL1,  $\beta$ -catenin, LEF1 and the target gene Cyclin D1. Although some data are available on WNT modulation in animal models, it is still unclear whether WNT pathway components are regulated following different resistance training regimens in humans. Therefore, the aim of the present study was to investigate the effect of different resistance training regimens (ST or PT for 8 weeks) on the gene and protein expression of the canonical WNT signaling pathway components in physically active men. **Methods** Twenty five subjects (27.4±4.6 yrs) were randomly assigned to strength training (ST) (n=10), power training (PT) (n=10), and control (C) (n=5) groups. The ST and the PT groups performed high and low intensity squats, respectively, 3 times per week, for 8 weeks. Muscle biopsies from the vastus lateralis muscle were collected before and after the training period. **Results and Discussion** Relative strength and power increased similarly in both ST and PT groups (P<0.001). Fiber cross-sectional area also increased similarly in both ST and PT groups.  $\beta$ -catenin protein expression levels was assessed by Western blot. Certain genes were up-regulated in the ST group (WNT1: 6.4-fold, P<0.0001; SFRP1: 3.3-fold, P<0.0001 and LEF1: 7.3-fold, P<0.0001) and also in the PT group (WNT1: 24.9-fold, P<0.0001; SFRP1: 2.7-fold, P<0.0001; LEF1: 34.1-fold, P<0.0001 and Cyclin D1: 7.7-fold, P<0.001). In addition, the expression of key WNT pathway genes was substantially more responsive to PT than to ST (WNT1: P<0.0001; LEF1: P<0.0001 and Cyclin D1: P<0.001). Finally, the total  $\beta$ -catenin protein content increased only in the PT group (P<0.05). The results of the present study indicate that a PT regimen triggers greater responses in key elements of the WNT pathway. **References** Armstrong, D.D., Esser, K.A. (2005). Wnt/ $\beta$ -catenin signaling activates growth-control genes during overload-induced skeletal muscle hypertrophy. *Am J Physiol* 289 (4):C853–859.

### INTERACTION OF MYOGLOBIN WITH MITOCHONDRIA IN SKELETAL MUSCLES

MASUDA, K.1, YAMADA, T.1, FURUICHI, Y.1, TAKAKURA, H.1, HASHIMOTO, T.2, HANAI, Y.3, JUE, T.4

**INTRODUCTION** The mechanism of myoglobin (Mb)-mediated oxygen transport remains unclear. Recent evidences suggested that in the myocardium, the transverse diffusion of Mb is too slow to supply oxygen effectively to meet the immediate mitochondrial oxygen demand at the onset of muscle contraction (Lin et al., 2007); however, Mb supplies oxygen in response to mitochondrial activation (Takakura et al., 2010). This implies that Mb might exist close to or on mitochondria. The objectives of this study were to investigate the co-localization of Mb and mitochondria and confirm a possible interaction of Mb with mitochondrial respiratory chain proteins. **METHODS** Hindlimb muscles (m. soleus, m. plantaris, and m. gastrocnemius) and myocardia from male Wistar rats were used in the present study. Cellular sub-fractions were separated by serial centrifugation, and western blotting assessed the presence of Mb in whole cell (except nuclear), cytosol, and mitochondrial fractions. In transverse sections of muscles, the co-localization was examined by double immunohistochemical staining of Mb with mitochondrial marker proteins. Co-immunoprecipitation was performed to confirm a protein-protein interaction of Mb with COX-IV. **RESULTS** In all skeletal muscles, western blotting confirmed the presence of Mb protein in the mitochondrial fraction. The Mb content in the mitochondrial fraction was significantly higher in oxidative slow muscles (m. soleus, red portion of m. gastrocnemius) than in glycolytic fast muscles (other muscles). Immunohistochemical analysis also indicated an obvious co-localization of Mb with mitochondria. The area of co-localization in oxidative low muscles was greater than that in glycolytic fast muscles. In the protein-protein interaction assay, COX-IV was found to co-immunoprecipitate with Mb. **DISCUSSION** The present study revealed that Mb localizes on mitochondria. We provide evidence of strong association of Mb with COX-IV. This suggests the presence of a complex that enables immediate and effective submitochondrial oxygen transport. Mb has important roles in oxygen storage and translational diffusion, but it is not considered to contribute to mitochondrial respiration positively (Jürgens et al., 2000). Our findings should provide new paradigm of intracellular oxygen transport and mitochondrial respiration. **REFERENCES** Jürgens KD, Papadopoulos S, Peter T, Gros G. ### CHANGES OF AUTOPHAGIC REGULATIONS IN RESPONSE TO VOLUNTARY EXERCISE TRAINING IN RAT CARDIAC MUSCLE

YOSHIHARA, T.1, NAITO, H.1, KAKIGI, R.1, ICHINOSEKI-SEKINE, N.1, SUGIURA, T.2, KATAMOTO, S.1

1: JUNTENDO UNIVERSITY, 2: YAMAGUCHI UNIVERSITY.

**Introduction** Autophagy is a bulk degradation system in lysosome, and plays an important role in maintenance of cellular homeostasis. Under conditions of starvation, autophagy is drastically induced in various cells (Mizushima et al., 2004). Autophagy is also upregulated by reactive oxygen species, exercise, and ischemic preconditioning in cardiac muscle (Gottlieb et al., 2009). However, it remains unclear whether the levels of autophagic makers LC3-I/II would be changed by voluntary exercise training. Therefore this study examined the effects of voluntary wheel run training on the atophagic regulation in rat cardiac muscle. **Methods:** Twenty-four female Fisher344 rats (9 wk-old; 136.3±3.7 g) were used in this study. Rats were randomly divided into three groups; pre training (Pre, n=6), control (CON, n=8) or voluntary wheel run training (TR, n=7) groups. Training rats were housed individually in cages equipped with running wheels and allowed to run at their own pace for 4 weeks. After the training period, the cardiac muscle was removed. The expression of LC3-I/II, PPARγ coactivator -1α (PGC-1α) and Mn-superoxide dismutase (Mn-SOD) protein in the muscle was determined by Western blotting. **Results:** A mean running distance was 7.4±0.6 km/day. After 4 weeks training period, there were no significant differences in the expression levels of PGC-1α and Mn-SOD. Although the levels of LC3-II was unchanged, that of LC3-I was significantly increased in TR group compared with CON (p<0.05). **Discussion** In present study, LC3-I protein expression was significantly increased in Training group. This shows that wheel run training induced the upregulation of a basal form of LC3 protein expression; it may contribute to enhancement the ability to induce autophagy. These data suggest that LC3-I protein upregulates by voluntary exercise training. In conclusion, although short-term voluntary wheel run training upregulates the LC3-I expression, run training doesn't activate autophagy and mitochondrial biogenesis at the resting condition. **References** Gottlieb, RA., Finley, KD., Mentzer, RM Jr. (2009). *Basic Res Cardiol.*, 104(2), 169-180. ### NEUROCHEMICAL EFFECTS OF PHYSICAL EXERCISE IN THE BRAIN OF RATS WITH PARKINSON'S DISEASE

PINHO, R.A., TUON, T., TROMM, C., BOM, K., ROSA, G.L., LUCIANO, T.F., SOUZA, D.R., SILVA, L.A., DE SOUZA, C.T.

UNIVERSIDADE DO EXTREMO SUL CATARINENSE

**Introduction** Beneficial effects of exercise on Parkinson's disease (DP) has been suggested (Bloomer et al., 2008; Elokda et al., 2010), but the mechanisms responsible for these effects are poorly understood. Thus, the aim of this study was to evaluate the effect of training physical on the neurochemical and oxidative stress markers in the striatum of rats with DP. **Methods** Twenty-four 2-month-old male Wistar rats were divided into untrained+sham-operated (USO), untrained+DP (UDP), trained+Sham-operated (TSO), trained+DP (TDP), n=6. The animals were submitted to training on the treadmill (8-week, 4 days/week on alternate days, 50 min/day, 13-17 m/min). Twenty-four hours after training, DP was induced by lesion unilateral on the left hemisphere with an injection of 6-OHDA (8 µg in 1 µl in 0.2% ascorbic acid). Seven days after the lesion the animals underwent rotational test (rotameter) and euthanasia by decapitation ensued. The striatum was homogenized in specific buffer for Western Blot and immunoblotting with anti-tyrosine hydroxylase (TH), anti-brain-derived neurotrophic factor (BDNF), anti-superoxide dismutase (SOD), anti-catalase (CAT), anti-glutathione peroxidase (GPX), and specific buffer for oxidative damage in lipid (TBARS) and protein (carbonyl content). **Results** The UDP and TDP groups showed a clear rotational asymmetry when compared to sham groups and TDP group showed less asymmetry in relation to UDP group, apart from a significant reduction in the expression of TH, BDNF, SOD, CAT, GPX as well as an increase in TBARS and carbonyl content. The expression of TH was not significantly altered by exercise, but the TDP group increased the expression of BDNF, SOD, GPX and decreased the oxidative damage in lipids and protein. **Discussion** Similar post-lesioning results were found in other studies (Smith and Cass, 2007; Khan et al, 2010), suggesting that the model utilized was effective and the involvement of oxidative stress in the lesion induced by 6-OHDA. The effects of exercise on DP indicate the possibility that exercise, to a certain extent, modulates neurochemical status in the striatum of rats, possibly by improving the antioxidant defense system. In addition, the drop in oxidative stress restores the redox state and may result in the maintenance of NMDA channel function (Lu et al., 2001; Bustos et al., 2009) increasing levels of BDNF. **References** Bloomer RJ et al. (2008). *Med Sci Sports Exerc.* 40:1385-1389. Elokda A et al. (2010). *J Neurol.* 257:1648-1653. Smith MP and Cass WA (2007). *Neurosci Lett.*

### PROTEOMIC ANALYSIS OF HEART OF OBESE AND NON-OBESE MICE. UNDERSTANDING THE ACUTE EFFECTS OF EXERCISE ON OBESITY

ROCHA, L.A.O.1,2, PETRIZ, B.A.1, CUNHA, V.N.1, VILLETCH, G.R.C.3, MEHTA, A.3, SILVA, O.N.1, SIMÕES, H.G.1, FRANCO, O.L.1,4

1UNIVERSIDADE CATÓLICA DE BRASÍLIA, 2 UNIVERSIDADE DE BRASÍLIA, 3 EMBRAPA RECURSOS GENÉTICOS E BIOTECNOLOGIA, 4 UNIVERSIDADE FEDERAL DE JUÍZ DE FORA

Exercise has been proven to prevent and attenuate several metabolic and cardiovascular disorders. Metabolic dysfunction such as obesity is commonly related to cardiovascular diseases, frequently resulting in heart failure and death. In order to elucidate how exercise may influence acutely these pathologic dysfunctions in heart tissues from obese individuals, twelve-week-old C57BL6/J obese (ob/ob) and non-obese (ob/OB) mice were submitted to a single bout of swimming and had their hearts analyzed by proteomic techniques. Mice were divided into three groups: control without exercise (ob/ob, n=3; ob/OB, n=3); a moderate intensity consisting of 20 min of swimming around 90% of Maximal Lactate Steady State (ob/ob, n=3; ob/OB, n=3); and a severe intensity exercise with increasing overload until exhaustion (ob/ob, n=3; ob/OB, n=3). Obesity modulations were analyzed by comparing ob/ob and ob/OB control groups. Differential 2-DE analysis revealed that single session of exercise was able to acutely up-regulate: myoglobin, aspartate aminotransferase and zinc finger protein (Zfp) and down-regulate: nucleoside diphosphate kinase B and mitochondrial aconitase. Alpha-actin and Zfp were up regulated by the effect of obesity on heart proteome. These data demonstrate the immediate response of metabolic and stress-related proteins after exercise so as contractile protein by obesity modulation on heart proteome.

### WEEKLY TRAINING HOURS AND CATECHOLAMINE LEVELS DURING VITA MAXIMAL TEST

PROTZNER, A., TRÄJER, E., UDVARDY, A., KOMKA, Z., BOSNYÁK, E., SZENDREI, B., SZÖKE, V.B., TÓTH, M.

SEMMELEWIS UNIVERSITY FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES

**Introduction** Catecholamines like adrenalin and noradrenalin play an essential role in glucose metabolism in response to exercise. Adrenalin is a powerful regulator of a number of metabolic and physiological functions, and noradrenalin reflects the actions of the sympathetic nervous system. Exercise performed on intensity above anaerobic threshold leads to a marked increase in catecholamine levels. **Methods** A total of 99 elite athletes (24 male and 75 female) participated in this study. They were separated into two groups based on the weekly training hours. Team-sports: handball, soccer, waterpolo (18,83 hours/week) and individual sports: kayaking/canoeing, triathlon(31,5 hours/week). After a medical examination and anthropometric measurements, the subjects completed a vita maximal treadmill protocol while VO<sub>2</sub>rel (ml/min/kg) was measured. Subsequently, 10mL of venous blood was extracted at rest (r) and after the test was over (max). Adrenalin (A) and noradrenalin (NA) were measured in venous plasma (pg/ml). Statistical analysis was made by Statistica for Windows 9.0 software, linear correlation, Student t-test were used to learn about connections. **Results** The mean age of athletes was 23,53 ± 5,29 years. Correlation analysis confirmed significant relation between Ar and Amax in the whole sample (p<0,05) while no significance was found between NAr and NAmx. Significant correlations were found between VO<sub>2</sub>rel and NAr (p<0,05) among the examined athletes. We compared the two groups based on the training hours and there was significant difference between them in Amax, NAr and NAmx (p<0,05). Significant difference was found also in VO<sub>2</sub>rel values (individuals: 60,62; team players:49,29; p<0,05). The differences between adrenalin values (Amax-Ar) were significantly higher in the group, where the training hours were lower (p<0,05). The same pattern can be observed in case of noradrenalin values (NAmax-NAr, p<0,05). **Discussion** In this pilot study we observed higher differences at the catecholamine values (calculated: max-r) in case of the team sport players. The Vo<sub>2</sub>rel was remarkably higher at the athletes with higher training hours. Our future aim is to increase the number of the subjects, and examine the relationship between catecholamines from more aspects. **References** Zouhal H, Gratas-Delamarche A, Rannou F, Granier P, Bentue-Ferrer D, Delamarche P. (Clinical trial gov number: NCT01116856) **Introduction** Lactate moves across the sarcolemma mainly through the monocarboxylated transporters (MCT) 1. Recently it has been reported that men carrying the MCT1 A1470T polymorphism (rs1049434) showed a higher capillary lactate accumulation slope than non-carriers during circuit weight training (CWT) 2. The aim of the present work is to study whether the A1470T polymorphism effect is present also in women and if it is influenced by gender. **Methods** 15 men (mean±standard deviation; 22,53±2,59 yrs; 76,66±6,45 kg; 177,21±3,77 cm) and 14 women (20,14±2,77 yrs; 60,38±5,43 kg; 164,46±5,06 cm) performed a CWT of 8 machine exercises at 70% of 15RM. Venous blood lactate during the session was analyzed using the YSI 1500 SPORT Lactate Analyzer. The MCT1 A1470T polymorphism was determined by direct sequencing. Two ways ANOVA with repeated measures was used to determine differences between genetic groups in each gender. The significant level was set at  $\alpha \leq 0.05$ . **Results** Interaction between genetic group and measurement was found in men (p=0.004) but not in women (p=0.361). Bonferroni post hoc showed higher venous lactate values for AA compared to TT in men (p=0.008). **Discussion** Our results show different blood lactate accumulation depending on the

A1470T polymorphism in men, confirming the influence of this genetic variant on lactate metabolism reported previously 2. However, with the same circuit we did not find effects of the polymorphism in the lactate curves in women, maybe because of their lower lactate concentrations when compared with men. If, as presumed, the lactate transporter MCT1 has a lactate threshold, the polymorphic MCT1 could have different effects in men than women. Moreover, when compared with previous studies, the polymorphism has different effect in capillary (arterialized blood) than in venous lactate levels<sup>2</sup>. These differences could be explained because a bidirectional function of MCT1<sup>3</sup>. In conclusion, our results confirm an influence of A1470T polymorphism on lactate metabolism in men, but not in women, and a potential different effect in the arterial and venous lactate levels. However, further research is required to better define the MCT1 function and the polymorphism role during high intensity exercises. References 1. Juel, C. *Eur J Appl Physiol* (2001); 86: 12-6. 2. ## THE IMPACT OF ACE GENOTYPE ON SERUM ACE ACTIVITY AND POWER PERFORMANCE IN THE KOREA POPULATION

KIM, C.H.1, KIM, H.J.2, PARK, J.H.2, JUNG, S.H.3, NAM, H.S.4

1: EULJI UNIVERSITY SCHOOL OF MEDICINE (DAEJEON, KOREA), 2: KOREAN NATIONAL SPORT UNIVERSITY (SEOUL, KOREA), 3: ANDONG NATIONAL UNIVERSITY (ANDONG-SI, KOREA), 4: KANGDONG SACRED HEART HOSPITAL (SEOUL, KOR

**Introduction** The deletion (D) rather than insertion (I) of a 287 bp fragment in the human ACE polymorphism is associated with higher circulating ACE activity and with power performance amongst Caucasians. However, there was no association between ACE genotype and ACE activity or human performance in some African populations, indicating the ethnic differences of the ACE genetic influence on the phenotypes (Payne et al., 2006; Scott et al., 2005). There is little information of the association of the ACE polymorphism with the phenotypes in the Asian population. Therefore, this study investigated this issue in the geographically and ethnically well-defined (Jin et al., 2003) Asian-Korean population. **Methods** A total of 940 Korean subjects were recruited, composing of 55 international level power-oriented athletes (High-performance), 100 power-oriented elite athletes (mid-performance) and 765 healthy adults (Control). Blood samples for the whole blood and serum were obtained and assayed for circulating ACE activity and the ACE I/D genotype. The distribution of ACE polymorphism throughout the groups was analyzed. Results In the Korean population, ACE I/D genotypes significantly associated with circulating ACE activity, showing I allele had low ACE activity and D allele did high (II vs. ID vs. DD =  $31.6 \pm 9.0$  vs.  $40.5 \pm 10.0$  vs.  $48.3$  nmol/ml/min;  $p < 0.01$ ). The ACE I/D polymorphism explained 22.8% of variation in circulating ACE activity levels ( $p < 0.01$ ). In genetic association to human power performance, there was a gradual decrease of frequencies of the DD genotype with advancing levels of power performance (Control vs. Mid-performance vs. High-performance = 17.2% vs. 100% vs. 5.5%,  $p < 0.01$ ). Therefore, power-oriented athletes at the top level had a markedly diminished frequency of the DD genotype. **Discussion** The findings of this study show the Asian-Korean population has the genetic association of ACE polymorphism with circulating ACE activity and human power performance. The DD genotype had the highest ACE activity and II genotype did the lowest, showing the results comparable to the Caucasian population (Rigat et al., 1990). However, it was not the DD genotype but the II genotype that showed higher power-oriented performance. Therefore, there was the ethnic difference in association of the ACE I/D genotype with power performance (Myerson et al., 1999). Further study will be needed for finding gene-to-gene interactions, gene-environment interactions, and mechanisms of ACE polymorphism on muscle functions. References Jin H-H, Kwak K-D, Hammer YN. ## ACE, ACTN3 AND PTK2 GENOTYPE ASSOCIATIONS WITH HUMAN SKELETAL MUSCLE PHENOTYPES AND THE RESPONSES TO RESISTANCE TRAINING

ERSKINE, R.M., JONES, D.A., WILLIAMS, A.G., STEWART, C.E., DEGENS, H.

MANCHESTER METROPOLITAN UNIVERSITY

**ACE, ACTN3 AND PTK2 GENOTYPE ASSOCIATIONS WITH HUMAN SKELETAL MUSCLE PHENOTYPES AND THE RESPONSES TO RESISTANCE TRAINING** Erskine R.M.1, Jones D.A.2, Williams A.G.1, Stewart C.E.2, Degens H.2 1 Institute for Performance Research; 2 Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University, UK. **Introduction** It is equivocal whether the human angiotensin converting enzyme (ACE) I/D and alpha actinin-3 (ACTN3) R577X polymorphisms are associated with skeletal muscle strength, power and size, and the variable responses to resistance training. Furthermore, it is not known whether polymorphisms of the protein tyrosine kinase-2 (PTK2) gene, which encodes focal adhesion kinase (involved in cell interactions with the extracellular matrix), are related to these phenotypes. **Methods** Quadriceps femoris (QF) maximum muscle force, volume, physiological cross-sectional area (PCSA), specific tension (force per PCSA) and maximum power were determined in vivo before and after 9 weeks of leg-extension resistance training in 51 untrained young men. All participants were genotyped for the ACE I/D, ACTN3 R/X, PTK2 rs7460 A/T and rs7843014 A/C polymorphisms. DNA was extracted from 200 µL whole blood using spin columns and genotyping was performed via real-time PCR using a Chromo4 machine and a pre-designed Taqman genotyping assay. Results Larger post-training increases in the single repetition maximum (1-RM) were observed in ACE I/I ( $+103 \pm 26\%$ ) than in I/D ( $+65 \pm 27\%$ ) and D/D ( $+61 \pm 31\%$ ) genotype ( $P < 0.05$ ). Similarly, maximum power increased more in ACE I/I ( $+16 \pm 6\%$ ) than in I/D ( $+3 \pm 12\%$ ) and D/D ( $+4 \pm 11\%$ ) genotype ( $P < 0.05$ ). The ACTN3 R-allele was associated with greater baseline 1-RM ( $P < 0.05$ ), muscle volume ( $P < 0.05$ ) and power ( $P < 0.05$ ) but not with the responses to training. Baseline QF specific tension was higher in PTK2 rs7843014 A/A ( $P < 0.05$ ) and rs7460 T/T ( $P < 0.05$ ) homozygotes than in their respective rs7843014 C- and rs7460 A-allele counterparts, while power increased more in PTK2 rs7843014 C/C genotype ( $+13 \pm 8\%$ ) more than A/A ( $+1 \pm 12\%$ ) or A/C ( $+1 \pm 12\%$ ) following training ( $P < 0.05$ ). **Conclusions** The inter-individual variability in the response to strength training was associated with both the ACE I/D polymorphism (regarding changes in dynamic strength and power) and the PTK2 rs7843014 polymorphism (concerning the change in power). Differences in muscle strength, volume and power between untrained people were associated with the ACTN3 R/X polymorphism. Associations between muscle specific tension and polymorphisms of the PTK2 gene suggest that inter-individual differences in intrinsic muscle force might be related to variability in the lateral transmission of force. Future experiments should investigate potential associations between PTK2 genotype and skeletal muscle focal adhesion kinase concentration and activation, as well as the role of costameres in lateral force transmission.

### THE ACTN3 R577X NONSENSE ALLELE IS UNDER-REPRESENTED IN ELITE-LEVEL JAPANESE ENDURANCE RUNNERS

FUKU, N.1, SAITO, D.2, MIKAMI, E.2, KAWAHARA, T.3, TANAKA, H.4, HIGUCHI, M.2, TANAKA, M.1

1: TOKYO METROPOLITAN INSTITUTE OF GERONTOLOGY (TOKYO, JAPAN), 2: WASEDA UNIVERSITY (SAITAMA JAPAN), 3: JAPAN INSTITUTE OF SPORTS SCIENCES (TOKYO, JAPAN), 4: FUKUOKA UNIVERSITY (FUKUOKA, JAPAN)

**Introduction** Although previous reports have shown a lower proportion of the ACTN3 XX genotype (R577X nonsense polymorphism) in sprint/power athletes compared with controls, possibly attributed to the importance of skeletal muscle function associated with alpha-actinin-3 deficiency (Yang et al., 2003), the findings on association between endurance athlete status and R577X genotype are equivocal. The purpose of the present study was undertaken to examine the association of ACTN3 R577X genotype with elite Japanese endurance athlete status. **Methods** Subjects comprised 79 elite Japanese endurance runners (E) who participated in competition at national level and 96 Japanese controls (C). We divided endurance runners into two groups, i.e., 42 national level runners (E-N) and 37 international level runners (E-I) who had represented Japan in international competition. R577X genotype (rs1815739) was analyzed by direct sequencing. Frequency differences of polymorphisms between athletes and controls were examined by Chi-square tests. **Result** The R allele frequency tended to be higher in E group than in C group (0.557 vs. 0.458, OR: 1.49, 95% CI: 0.97-5.81,  $P=0.066$ ). When we divided endurance runners into two groups, the R allele frequency in E-I group was significantly higher than that in C group (0.595 vs. 0.458, OR: 1.73, 95% CI: 1.01-2.99,  $P=0.046$ ); whereas there were no significant differences between E-N and C groups. Then, the three genetic models were tested. The additive genetic model (RR>RX>XX) can be fitted to explain the differences between E-I and C (RR vs. XX, OR: 3.47, 95% CI: 1.04-11.56,  $P=0.038$ ), but not the dominant (RR vs. RX+XX) and the recessive (RR+RX vs. XX) genetic models. **Discussion** Although many previous studies suggest that R allele of the R577X in the ACTN3 gene was associated with sprint/power athlete status, this allele may also be one of determinants of competitive ability in endurance athletes. Our result agrees with those obtained by Ahmetov et al (2010). High-intensity intermittent training, which is also called "interval training", is now well known to improve endurance athletic performance (Lindsay et al, 1996). To improve endurance performance, very hard interval training is normally incorporated at least once a week in Japan, aimed at maximizing racing endurance performance and oxygen uptake capacity. It has been reported that subjects with RR genotype have a protective effect of muscle damage after eccentric training compared to subjects with XX genotype (Vincent et al., 2010). Thus, there is a possibility that people with R allele of ACTN3 R577X can adapt to high-intensity exercise training. **References** Yang N, MacArthur DG, Gulbin JP, et al., (2003). *Am J Hum Genet.* 73 (3), 627-631. ### THE ACE GENE INSERTION/DELETION POLYMORPHISM IN THE 2010 WORLD CHAMPION GROUP OF RHYTHMIC GYMNASTICS

CALCAGNO, G.1, SAPERE, N.1, PIAZZA, M.2, CORDÌ, M.C.1, D'ARTIBALE, E.1, INTRIERI, M.1, DI CAGNO, A.1

1:UNIVERSITY OF MOLISE, CAMPOBASSO, ITALY; 2:UNIVERSITY OF FLORENCE, FLORENCE ITALY

**Introduction** Genetic variants of some genes are related to athletic performance. The ACE gene codes for angiotensin converting enzyme (ACE), that is an integral part of Renin-angiotensin system (SRAA). It controls blood volume, blood pressure, electrolyte balance, cardiac and vascular function. Several polymorphic loci in the ACE gene have been identified but the most studied is Alu insertion (I allele) in intron 16. The insertion of a fragment of 287 bp is associated with lower ACE levels in serum and in tissues and may be associated with elite endurance performance. The Alu deletion (D allele variant) is associated with higher concentrations of serum ACE activity and this could lead to sprint and power performance. **Purpose:** The aim of this study was to examine if the ACE allelic variants have different frequencies between a group of elite rhythmic gymnasts and two different control groups matched for age and sex: one constitute by middle level gymnasts and the other one by sedentary university students. To date, very little is known about the frequencies of the ACE genotype in rhythmic gymnasts, and no data are available for the world champions in this sport. **Methods** The study included: a) 20 Italian National Rhythmic Gymnasts, six among them triumphed in the last World Rhythmic Gymnastics Championship (Moscow 2010); b) 23 rhythmic gymnasts middle level and c) 21 healthy nonathletic students from the University of Molise. The ACE genotype was evaluated by two independent polymerase chain reaction with two different primer pair. **Results** For these analysis a dominant model for allele D was assumed (DD vs ID/II). No significant differences were found for genotype ( $p=0.234$ ) or for allele ( $p=0.035$ ) frequencies within the two control groups, so we considered them as a unique reference population. Instead, the D allele of the ACE gene was more frequent in elite athletes respect to the control (Chi square=5.44  $p<0.01$ ); the data was confirmed also when compared to the middle level group alone ( $X^2 = 6.70$   $p<0.001$ ). **Conclusion** By the analysis of our data we observed that there is a significant association of ACE D allele in rhythmic gymnastics, sport in which anaerobic metabolism is more used.

### A POLYMERASE CHAIN REACTION-BASED METHODOLOGY TO DETECT GENE DOPING

CARTER, A.1, FLUECK, M.1,2,3

**Affiliations:** 1: Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University, Manchester, United Kingdom, 2: Centre for Cardiovascular Sciences, University of Birmingham Medical School, Birmingham, United Kingdom, 3: Department of Cardiovascular Surgery, Insel-Hospital, Berne, Switzerland **Introduction:** Gene doping is a novel threat to the World of Sports which arose as a spin-off with the invention of genetic vectors for the therapy of human diseases. Skeletal muscle is a prime target of current gene therapy and we asked whether we can develop a test system to produce and detect gene doping. **Methods:** We overexpressed the chicken homologue for the regulator of muscle growth, focal adhesion kinase (FAK) in rat soleus and gastrocnemius muscle by electro gene transfer. This was achieved by injecting 150 microgram of a constitutively active plasmid (pCMV-FAK) in the belly portion of the muscle followed by electric pulsing (Durieux et al 2009). Downstream effects on hypertrophy signalling were monitored by assessing the expression of ribosomal kinase p70S6K and cross sectional area of muscle fibres vs. empty plasmid transfected contralateral muscle. Plasmid DNA was detected in soleus muscle and serum of transfected animals with polymerase chain reaction (PCR) using oligonucleotide primers which distinguish between the exogenous (chicken) and endogenous (rat) FAK isoform. **Results:** Muscle transfection with pCMV-FAK produced FAK overexpression in 12% of soleus muscle fibres. 7 days after electro gene transfer the protein levels of p70S6K (2.1-fold) and mean cross section of muscle fibres were increased (+52%) in transfected soleus muscle but not in transfected m. gastrocnemius ( $p=0.6$ ). PCR amplified the introduced plasmid sequence in DNA from transfected soleus muscle up to 7 days after transfection. Using the same setup we were unable to detect the exogenous DNA in blood of collected 7 days after transfection but not in serum

except close to the site of plasmid deposition, 1 hour after injection. Titration experiments demonstrated the specificity of the PCR assay for the exogenous FAK isoform and indicated that the threshold of detection situated at 4 femtogram DNA. Discussion: The findings show that the deposition of genetic medicine can be identified at the site of injection up to seven day after transection but not in serum. The findings suggest that under the current legislation the detection of gene doping in the immoral athlete is currently impossible with PCR technology as this requires collecting serum or muscling sample in temporal-spatial proximity of the doping intervention. ### THE COL6A1 GENE AND PERFORMANCE IN THE SOUTH AFRICAN IRONMAN TRIATHLON

O'CONNELL, K.1, POSTHUMUS, M.1,3, COLLINS, M.2,1,3

1: MRC/UCT RESEARCH UNIT FOR ESSM, UCT, SOUTH AFRICA 2: SOUTH AFRICAN MRC, TYGERBERG, SOUTH AFRICA 3: IOC RESEARCH CENTRE, NEWLANDS, SOUTH AFRICA

**Introduction** Mutations in the type VI collagen  $\alpha 1$  chain gene (COL6A1) cause myopathy and muscle weakness (Bertini and Pepe, 2002). In addition col6a1 knockout mice were shown to have impaired running performance and reduced muscle strength (Bonaldo et al., 1998). The COL6A1 IVS32-29 T/C polymorphism within intron 32 of the COL6A1 gene has been associated with several complex phenotypes (Kong et al., 2007; Tsukahara et al., 2005). The aim of this study was therefore to determine if the COL6A1 IVS32-29 T/C polymorphism is associated with performance in the South African Ironman triathlon. **Methods** Participants (661) were recruited at the registration of four South African Ironman triathlons. Finishing times for the swim-, bike-, and run-component, as well as the overall race were provided by the race organisers. All participants were genotyped for the COL6A1 IVS32-29 T/C polymorphism. **Results** Participants with the COL6A1 IVS32-29 TT genotype were significantly faster than those with a CC or TC genotype in the bike-component ( $p=0.014$ ) and overall race ( $p=0.030$ ). When participants were grouped into tertiles (fast, middle and slow finishers) for the bike-component, the TT genotype showed a significant linear trend ( $p=0.008$ ). The TT genotype frequency was highest in the fast group (TT, 35.7%), followed by the middle (TT, 29.0%) and slow groups (TT, 23.8%). No significant genotype frequency differences were observed for the swim-component or run-component of the South African Ironman triathlon. **Conclusion** This study identified, for the first time, the COL6A1 gene as a potential performance marker for endurance cycling. These effects may be mediated through changes to the composition of type VI collagen containing connective tissues, such as muscle and tendon. **References** Bertini E, Pepe G. ### INFLUENCE OF THE BRAIN DERIVED NEUROTROPHIC FACTOR GENE IN HEART RATE RECOVERY IMMEDIATELY AFTER EXERCISE

SANCHEZ, J.1, BRUGADA, R.2, GUERRA, M.1, CAMPUZANO, O.2, CABEDO, J.1, ALCALDE, M.2, IGLESIAS, A.2

1:FPCEE BLANQUERNA (RAMON LLULL UNIVERSITY) 2:CARDIOVASCULAR GENETICS (UNIVERSITY OF GIRONA/UDG)

**Introduction** A common single nucleotide polymorphism in the human brain derived neurotrophic factor (BDNF) gene (Val66met) may have a modulatory effect on the cardiac sympathovagal balance (Yang A., Chen, Tsai, Hong, Kuo, & Yang, 2010). Recovery of the heart rate immediately after exercise is a function of vagal reactivation. During exercise the increase of the sympathetic activity and the decrease of the vagal activity produce an increase of the cardiac heart rate. The parasympathetic activation, seems that causes the deceleration of the heart (Levy, 1971; Javorka, Zila, & Balhárek, 2002). **Methods** The sample was 67 healthy university Spanish students (age, 18-35 years), 17 females and 50 males, All of them were Caucasian for  $\geq 3$  generations. The genotype frequency was val/val ( $n=41$ ), val/met ( $n=22$ ) and met/met ( $n=4$ ). Hardy-Weimberg equilibrium  $\chi^2$  test ( $p = 0.65$ ). They performed a treadmill test with an inclination 3%, and speed increment (beginning at 6 km/h and increasing 2km/h every 2 minutes) until exhaustion, maximal heart rate was obtained as well as heart rate recovery immediately after the exercise during the first minute. Treadmill Lifefitness (USA), MP100 System Hardware. AcqKnowledge Software 3.9-Windows XP. Biopac Systems (USA) and Polar T31 (Finland) were used. Descriptives with Mean and Standard deviation were calculated using SPSS 18 package. **Results** Heart rate peak was 185.2 bpm. The results suggest that subjects with genotype met/met have a better heart rate recovery during the first minute (25.2 bpm.), Meanwhile subjects with val/val genotype showed 24.4 bpm. and last the val/met genotype (22.3 b.p.m.). **Discussion** It seems to be that the genotype met/met presents a main efficiency in the parasympathetic regulation, contrary to what expresses the study of Yang et al.(2010). Other studies associate the allele met of the polymorphism BDNF Val66Met with the increased BDNF serum concentrations. The decreased BDNF concentration in healthy people is more important in Val/Val subjects than in Val/Met. (Lang, Hellweg, Sander, & Gallinat, 2009). Our research was only a descriptive study and needs more research to determine the influence of the (BDNF) gene (Val66met) in the heart rate recovery. **References** Javorka, M., Zila, I., & Balhárek, T. a. ### ACE I/D GENE POLYMORPHISM, BLOOD PRESSURE, C-REACTIVE PROTEIN AND PHYSICAL TESTS IN ZULU SOUTH AFRICAN CRICKETERS

DJAROVA, T.1, RAMAKOABA, A.1, MUNGANDANI, S.2, BASSON, A.1, GRACE, J.2, CLOETE, J.3, WATSON, G.4

UNIVERSITY OF ZULULAND 1, 2, 3: UKZN 4

**Introduction** Angiotensin converting enzyme (ACE) polymorphism is the most extensively studied genetic variation related to physical performance, cardiovascular and muscle function and trainability in athletes (Wang et al., 2008). The aim of the study was to explore the ACE I/D polymorphism, blood pressure, C-reactive protein (CRP) and association with physical tests in Zulu cricketers. **Methods** Cricketers ( $n=14$ ) and students ( $n=17$ ) as controls were genotyped (blood spots) for ACE gene by PCR amplification (Alvarez et al., 2000). Systolic and diastolic blood pressure (SBP and DBP) and grip strength (kg), knee extension and flexion (Nm/kg) were measured, systolic tension time (STT) and metabolic rate (MR) were calculated. After ANOVA the association was probed using  $\chi^2$  maximum likelihood test and Fisher's exact test. **Results** ACE genotyping for the whole group displayed a complete absence of II genotype, 67.7% DD and 32.3% ID genotypes. The frequency of D allele was 83.8% and I allele 16.2%. In cricketers DD and ID genotypes were 50% each compared to controls-83% DD

and 17% ID. No differences in grip strength, knee extension and flexion between the groups were observed, but for the whole cohort 86% D allele frequency was associated with higher ( $> 43.3$  kg) grip strength ( $p < 0.037$ ). In cricketers CRP ( $< 3.0$  mmol/l) was associated with 79% D allele frequency. SBP and DBP were significantly lower by 3.2 mmHg and 4.25 mmHg, whereas increased values of STT by 5.5%, MR by 10.3% were found. Discussion Strength parameters contributed to cricketers performance. D allele has been associated with power output (Ruiz et al., 2010) and I allele with endurance (Collins et al., 2004). The limitation is the small number of participants. Null II homozygosity was established for the first time in Zulu athletes. Low frequency of II genotype was reported in African Americans, Kenyans, Jamaicans athletes (Scott et al., 2010) and Xhosa South Africans (Payne et al., 2007). Conclusions ACE I/D genotyping has shown a null II genotype and high D allele frequency associated with strength grip in the whole cohort. In cricketers no overrepresentation of DD or ID genotypes was noted and beneficial changes in blood pressure and metabolic rate were observed. ### PP-PM43 Training and Testing: Maximal Exercise 1

#### GRADED EXERCISE TESTING: RELATIONSHIP BETWEEN MAXIMAL RESPIRATORY EXCHANGE RATIO AND TEST DURATION IN RUNNERS

SENTIJA, D., VUCETIC, V.

*FACULTY OF KINESIOLOGY, UNIVERSITY OF ZAGREB*

**INTRODUCTION** The respiratory exchange ratio registered at maximal exercise in graded exercise tests (RERmax) is used as a criterion for test interpretation, and confirmation that maximal oxygen uptake has been obtained. Several arbitrary 'cut-off' values (i.e. 1.00, 1.10, 1.15) are used for acceptance or rejection of exercise tests. The steeper is the ramp slope (the work-rate increase per unit of time), the shorter is the duration of the incremental test, yielding greater rates of CO<sub>2</sub> output and higher RERmax values. However, the relationship between RERmax and test duration has not been clearly defined. The aim of this study was to determine the relationship between RERmax and duration of all-out incremental treadmill tests, in runners competing in different running events. **METHODS** The sample consisted of 48 male runners: 25 sprinters, and 23 middle/long distance runners. All subjects performed three incremental treadmill tests to the limit of tolerance in random order, with increases in running speed: a) 1 km/h each ½ minute (T0.5), b) 1 km/h each minute (T1), and c) 2 km/h every four minutes (T2). In all trials, the starting running speed was 8 km/h, with a constant inclination of 1.5%. Gas exchange data were recorded breath-by-breath and analyzed (Quark b2, Cosmed). Regression analysis of pooled data was used to model the relationship between RERmax and the duration of the tests. Two-way ANOVA was used to determine differences in the measured variables between the tests and the groups. **RESULTS** The average test durations were  $7.6 \pm 1.0$  min (T0.5),  $13.0 \pm 2.1$  min (T1) and  $22.8 \pm 4.1$  min. The mean VO<sub>2</sub>max values did not differ between protocols ( $p > 0.10$ ). With increasing duration of the test, a progressive decrease of maximal respiratory exchange ratio was found. The RERmax mean values were as follows:  $1.23 \pm 0.10$  (T0.5),  $1.18 \pm 0.08$  (T1) and  $1.12 \pm 0.07$  (T2), and the differences between tests were statistically highly significant ( $p < 0.001$ ). The regression analysis of pooled data showed an inverse linear relationship between RERmax and test duration ( $\text{RERmax} = 1.272 - 0.0064 \text{min}$ ). For the same absolute test duration, a trend towards higher RERmax values in sprinters than in aerobically trained runners was present. **CONCLUSIONS** In incremental treadmill tests of 5 to 30 minutes duration, performed to the limit of tolerance, runners of various predominantly anaerobic (100m-400m) and predominantly aerobic (800m-marathon) specific events show an inverse linear relationship between test duration and the respiratory exchange ratio at maximal exercise. For practical implications, the RERmax value used as a VO<sub>2</sub>max criterion in the interpretation of graded exercise testing should be protocol dependent.

#### COMPARING EQUATIONS THAT PREDICT PEAK VO<sub>2</sub> USING THE 20-M MULTISTAGE-SHUTTLE RUN-TEST IN 6-10-YEAR-OLD CHILDREN

VENCES BRITO, A.

*SPORTS SCIENCES SCHOOL OF RIO MAIOR - POLYTECHNIC INSTITUTE*

Comparing equations that predict peak VO<sub>2</sub> using the 20-m multistage-shuttle run-test in 6-10-year-old children António Vences Brito<sup>1,2</sup>; Tiago Santos<sup>1</sup>, Nádja Magalhães<sup>1,2</sup>, Nelson Valente<sup>1,3</sup>, João P. Brito<sup>1,2</sup> 1 Sports Sciences Research Laboratory Sports Science Institute of Rio Maior, Rio Maior, Portugal) 2 Centre of Research in Sports, Health and Human Development (CIDESD, Vila Real, Portugal) 3 Universidade da Extremadura, Espanha **Introduction** This study aimed to compare the validity of reported equations as predictors of VO<sub>2</sub> peak in 6-10 year-old children **Methods** Subjects, 128 children, aged 6 to 10 years old (67 were boys, age  $7.97 \pm 1.11$  years, weight  $31.47 \pm 8.99$  kg, height  $130.81 \pm 9.16$  cm, BMI  $18.04 \pm 2.84$ ; and 61 girls, age  $7.67 \pm 0.94$  years, weight  $29.26 \pm 6.22$  kg, height  $128.93 \pm 7.50$  cm, BMI,  $17.46 \pm 2.55$ ) performed the multistage-shuttle-run-test (MSRT) and VO<sub>2</sub> peak was measured in field using a portable gas analyzer (Cosmed K4b2, Cosmed, Rome, Italy). The equations that estimated VO<sub>2</sub> peak from the MSRT performance were chosen according to the age range of this study. As follows, the FITNESSGRAM reports and the equations of Leger et al. (1988) and Oliveira (1998) were used to estimate the VO<sub>2</sub> peak and compared with the directly measured value. **Results** The estimated VO<sub>2</sub> peak by the equations of Leger et al. (1988) and Oliveira (1998), respectively, underestimate the measured values of measured VO<sub>2</sub> peak ( $49.05 \pm 2.53$  ml/kg/min). In females the equation of Leger et al. (1988) overestimates the measured VO<sub>2</sub> peak. In the analysis by age and gender, in females of 7 to 8 years, the VO<sub>2</sub> peak estimated by the equation of Leger et al. (1988), overestimate the measured VO<sub>2</sub> peak. When applied the Pearson correlation coefficient, it was verified that Oliveira's equation (1998) had higher values of correlation ( $r = 0.51$ ,  $r = 0.46$  and  $r = 0.58$ ) for males, females and for the overall sample, respectively. However by applying the concordance coefficient was found that the equation of Leger et al. (1988) was the one that proved more consistent/concordant with the measured VO<sub>2</sub> peak ( $r_c = 0.21$ ,  $r_c = 0.27$  and  $r_c = 0.27$ ) for males, females and for the overall sample, respectively. **Conclusion** The shuttle test is presented as a valid instrument for assessing the VO<sub>2</sub> peak of school-age children. Although the Oliveira (1998) equation has been determined based on a sample of Portuguese children, but for the sample of the present study it is ended that the prediction equation of Leger et al. (1988) proved to be the most suitable to predict the VO<sub>2</sub> peak of children. **References:** Leger, L., Mercier, D.; Gadoury, C. and Lambert, J. (1988). ### CONSTRAINTS OF USE PORTABLE GAS ANALYZER IN THE CARDIO-RESPIRATORY EVALUATION OF CHILDREN AGED 6-10 YEARS WHILE PERFORMING THE 20 M MULTISTAGE SHUTTLE RUN TEST

VENCESBRITO, A., SANTOS, T., MAGALHÃES, N., NELSON, V., FERNANDES, R., BRITO, J.

*SPORTS SCIENCES SCHOOL OF RIO MAIOR - POLYTECHNIC INSTITUTE OF SANATAREM*

**Introduction** The aim of this study was to assess if the use of a portable respiratory gas analyzer is a constraint on performance in the 20 m multistage shuttle run test (20mMST). **Methods** 128 Portuguese children, 67 boys (age, 7.97 ± 1.11 years; weight, 31.47 ± 8.99 kg; height, 130.81 ± 9.16 cm; IMC, 18.04 ± 2.84) and 61 female (age, 7.67 ± 0.94; years; weight, 29.26 ± 6.22 kg; height, 128.93 ± 7.50 cm; IMC, 17.46 ± 2.55) performed the 20mMST in two different moments, each separated by 1 week in a randomly sequence, with (M1) and without (M2) the portable gas analyzer (K4b2, Cosmed, Rome, Italy). In M1, the peak oxygen consumption (VO<sub>2peak</sub>) was measured and the number of laps registered, while in M2, the maximum oxygen consumption (VO<sub>2max</sub>) was estimated with the Leger et al. (1988) equation and the number of laps also registered. **Results** The weight of the portable gas analyzer is 1000 grams, which represent approximately 3.3% of the children's medium body weight (30.41 ± 7.84 kg). When we analyzed all the children, there were no significant differences in the estimated VO<sub>2max</sub> between the two test trials. When compared by gender, there were significant differences in the female children between the mean values of VO<sub>2max</sub> estimated in M1 and M2 of -0.65 ± 1.46 ml/kg/min (p=0.005). When compared by the BMI category, there were significant differences in the categories, "normal weight" and "obesity" with mean difference values of 1.1 ± 8.08 and 1.5 ± 4.34 ml/kg/min, respectively (p=0.005). **Conclusion** Generally, the portable gas analyzer Cosmed K4b2 does not influence the 20mMST performance, although in female children, may cause some discomfort that possibly will lead to a decreased performance in the same test.

### THE INFLUENCE OF MUSIC ON MAXIMAL OXYGEN UPTAKE IN RUNNERS

KELLER, B., STEFANELLO, J.M.F., SILVA, A.M.B., COELHO, R.C.

*FEDERAL UNIVERSITY OF PARANÁ*

**Introduction:** The music was broadcast from the beginning and it is felt today by all. It would be impossible to live without it, because everything has rhythm, as the heart. In sport, music has been used to enhance performance and relax the contestants, but empirically. **Purpose:** To investigate if different musical styles significantly alter the maximal oxygen uptake (VO<sub>2max</sub>) from runners in the maximal exercise test. **Methods:** Participants (n=14) performed four exercise tests with a break of at least 48 hours between each other, we used three musical styles (rock, classical and a favorite one chosen by the runner) and a test without music to serve as a control group. The maximum oxygen consumption was measured indirectly and the protocol used for the maximal exercise test was the Bruce one. The statistical analysis was descriptive, Friedman and Qui-square using the statistical package SPSS 18.0, in a level of p<0.05. **Results and Conclusion:** There was a significant difference in maximum oxygen uptake by the use of music, \*2F = 17.74, p = 0.000, whereas the highest values were found in their favorite music, mean = 87.48 l/kg.min (SD = 4.50). New researchers should be done with different subjects to confirm the results.

### ATHLETES HAVING HIGH AEROBIC CAPACITY SHOW HIGHER AEROBIC CONTRIBUTION IN THE WINGATE ANAEROBIC TEST

KENICHI, M., KARIYAMA, Y., OGATA, M.

*UNIVERSITY OF TSUKUBA*

**Introduction** The wingate anaerobic test (WAnT) is widely used to evaluate anaerobic power and capacity (Bar-Or, 1987). A typical person uses the aerobic metabolic pathway to release 40% of the total energy required during WAnT (Medbø and Tabata, 1993); however, no study has tested the influence of aerobic energy supply on output power. Therefore, we aimed to investigate the individual effects of aerobic and anaerobic energy supply systems on the physical characteristics in WAnT. **Methods** Twenty-three male track and field college athletes (8 sprinters, 9 long-distance runners, and 6 decathletes) participated in this study. They performed WAnT on a cycle ergometer, and the peak power, mean power, and fatigue index were determined. The applied resistance was 7.5% of body weight, and the duration was 60 seconds. Aerobic capacity (maximal oxygen uptake [VO<sub>2max</sub>]) was determined by an incremental test, and anaerobic capacity (maximal accumulated oxygen deficit [MAOD]) was determined by a supramaximal constant load test (Medbø et al., 1988). The oxygen uptake during each test was recorded by a breath-by-breath method. The participants were divided into high VO<sub>2max</sub> group (High; n = 11) and low VO<sub>2max</sub> group (Low; n = 12). **Results** Although the VO<sub>2max</sub> was significantly higher in the High group, the MAOD was not significantly different between the 2 groups. The aerobic contribution was significantly higher in the High group than in the Low group (51.5 ± 8.8% vs. 42.1 ± 6.9%). In contrast, the anaerobic contribution was significantly higher in the Low group than in the High group (57.9 ± 6.9% vs. 48.5 ± 8.8%). The oxygen uptake during WAnT (WT-VO<sub>2</sub>) was significantly higher in the High group, and the accumulated oxygen deficit during WAnT (WT-AOD) was significantly higher in the Low group. The MAOD and WT-AOD showed a significant correlation (High: r = 0.85, p < 0.01; Low: r = 0.76, p < 0.01) in both the groups. WT-AOD was attained at 101.7 ± 12.3% MAOD in the Low group, and this value was significantly higher than that in the High group. **Discussion** Our findings show that the energy supply influences the physical characteristics during WAnT. Thus, athletes having a high aerobic capacity preferential use an aerobic metabolic pathway, whereas athletes with lesser aerobic capacity use an anaerobic metabolic pathway to satisfy the required oxygen demand during exercise. Therefore, even in WAnT, which is a short and maximal effort exercise, the individual's aerobic and anaerobic capacities should be considered when assessing WAnT performance. **References** Bar-Or. ## ASSESSING AEROBIC CAPACITY AND PERFORMANCE USING PHYSIOLOGICAL AND BIOMECHANICAL PARAMETERS DURING AN INCREMENTAL SWIMMING TEST

OLIVEIRA, M., CAPUTO, F., DENADAI, B., GRECO, C.

SANTA CATARINA STATE UNIVERSITY

**ASSESSING AEROBIC CAPACITY AND PERFORMANCE USING PHYSIOLOGICAL AND BIOMECHANICAL PARAMETERS DURING AN INCREMENTAL SWIMMING TEST** Oliveira MFM.1,2, Caputo F.2, Lucas RDL.3, Denadai BS.1, Greco CC.1 1: UNESP (Rio Claro, Brazil), 2: UDESC (Florianópolis, Brazil), 3: UFSC (Florianópolis, Brazil) **Introduction** In human swimming metabolic changes detected by blood lactate concentration ([La]) are related to the changes observed in the stroke parameters (Wakayoshi et al. 1995; Keskinen and Komi 1993; Dekerle et al. 2005). Therefore, the purposes of this study were to identify the speed corresponding to anaerobic threshold using the D-max method for both blood lactate and biomechanical stroke parameters determined in an incremental swimming test and to compare this information with the speed corresponding to the maximal lactate steady state (SMLSS). **Methods** Five male long-distance swimmers and eight triathletes ( $n = 13$ ;  $23.8 \pm 9.5$  years;  $1.76 \pm 0.1$  m; and  $71.3 \pm 9.8$  kg) performed the following protocols: (1) 7 x 200-m incremental test to determine the speed corresponding to the D-max point (Cheng et al. 1992) on the blood lactate (SLa), stroke rate (SSR), stroke length (SSL), and stroke index (SSI) responses; (2) two to four 30-min sub-maximal tests to determine the SMLSS. **Results** SLa ( $1.18 \pm 0.08$  m\*s<sup>-1</sup>), SSI ( $1.18 \pm 0.08$ ), SSR ( $1.17 \pm 0.1$ ) and SSL ( $1.16 \pm 0.09$ ) were not significantly different from each other or from SMLSS ( $1.13 \pm 0.08$ ). There were high correlations between SLa, SSI, SSR, SSL and SMLSS ( $r = 0.91, 0.89, 0.85$ , and  $0.80$ , respectively). The typical error of estimate for SLa (3.2%), SSI (3.7%), SSR (4.1%), and SSL (4.7%) suggest good validity of these variables to predict SMLSS. **Discussion** It is possible to obtain a physiological index of aerobic capacity and performance using simple biomechanical measurements during an incremental test without performing blood lactate analyses. However, despite low TEE values, the physiological and biomechanical index may not represent [La] equilibrium over time. Therefore, we recommend that SMLSS be determined directly whenever precision is required. **References** Cheng B, Kuipers H, Snyder AC, Keizer HA, Jeukendrup A, Hesselink M. ## VALIDITY OF A SUBMAXIMAL CYCLING TEST TO EVALUATE AEROBIC FITNESS IN ELITE ICE HOCKEY PLAYERS

ROMANN, M., SONDEREGGER, K., TSCHOPP, M.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN

**Introduction** Several studies have shown the importance of aerobic capacity in improving ice hockey performance (Stone & Kilding, 2009). Hence, various tests have been proposed to evaluate aerobic fitness in team sports. Often, maximal tests are not well accepted by players or coaches because they require maximal effort of the athletes and can be strongly influenced by motivation. Thus, the aim of this study was to determine whether a submaximal bicycle ergometer test is valid for predicting lactate threshold as an indicator of aerobic fitness in elite ice hockey players. **Methods** Forty-nine male Swiss ice hockey players ( $18.6 \pm 0.5$  y;  $81.7 \pm 9.2$  kg) of the under 20 (U-20) national team were evaluated. Each subject performed a maximal incremental test (MIT) and a submaximal test (SMT) on a bicycle ergometer. The initial workload of the MIT was 130 W, with an increment of 30 W every 3 min until exhaustion. In the MIT relative power at lactate threshold (PLT) and relative maximal power (Pmax) were determined. The SMT test consisted of a single rectangular workload for 6 min with a power of 2.9 W/kg body weight. Maximal lactate value (LAm<sub>ax</sub>), difference between lactate concentration at rest and after the test (LADelta), mean heart rate during the last minute (HR) and rate of perceived exertion (RPE) were used for analysis. **Results** The MIT showed a mean PLT of  $3.1 \pm 0.4$  Watt/kg and a mean Pmax of  $3.9 \pm 0.4$  Watt/kg. In the SMT mean LAm<sub>ax</sub> of  $5.2 \pm 1.7$  mmol/l, mean LADelta of  $3.3 \pm 1.2$  mmol/l, mean HR of  $164 \pm 21$  beats/min and mean RPE of  $13.8 \pm 1.6$  were measured. Significant correlations (Pearson,  $p < 0.001$ ) were found for PLT as dependent variable with LAm<sub>ax</sub> ( $r = -0.79$ ), LADelta ( $r = -0.84$ ), HR ( $r = -0.62$ ) and RPE ( $r = -0.53$ ) as independent variables in the SMT. The highest correlation was between PLT and LADelta with an SEE = 0.20 Watt/kg. Using these parameters, we calculated the following linear regression equation:  $f(x) = 3.91 - 0.25x$ . **Discussion** Confirming previous research, we found significant correlations between parameters in the MIT and a rectangular SMT (Impellizzeri et al., 2004). These results suggest that this SMT could be used to estimate intra-individual progress and team-progress in aerobic fitness without using a MIT. Although MITs are the most accurate way to evaluate aerobic fitness individually, this SMT provides valid results and do not require the maximal effort of the athletes. Additionally this SMT can be performed during the season and is not influenced by motivation. **References** Impellizzeri, F., Mognoni, P., Sassi, A., & Rampinini, E. (2004). Validity of a submaximal running test to evaluate aerobic fitness changes in soccer players. *Journal of Sports Sciences*, 22, 547. Stone, N., & Kilding, A. (2009). ## STUDY ON THE FORMULAS FOR ESTIMATION OF CARDIO- PHYSIOLOGICAL STATE DURING EXERCISE TEST IN BIKE SIMULATOR

KIM, S., PARK, S., CHOI, C., CHUNG, K., PARK, G.

KOREA INSTITUTE OF INDUSTRIAL TECHNOLOGY

The purpose of this study is to develop the formulas for estimation of cardio-respiratory fitness during exercise test in bike simulator. To define the exercise intensity and work load, maximal heart rate (HR<sub>max</sub>) was used for exercise prescription. In addition, it is important to control exercise intensity and energy expenditure during exercise, because high intensity training hurts health and low intensity cannot be achieved the effect of exercise on health. Thirty-seven volunteers (17 men: age,  $21.1 \pm 2.5$  yr; weight,  $66.9 \pm 10.3$  kg; height,  $173.2 \pm 7.7$  and 20 women: age,  $20.9 \pm 1.3$  yr; weight,  $54.5 \pm 5.8$  kg; height,  $161.1 \pm 5.4$  (mean  $\pm$  SD)) were participated in this experiment. They executed maximal exercise test using ramp protocol and four interval training programs. They also executed sub-maximal test using YMCA protocol. We extracted the average heart rates between 10 seconds before and end of each step in YMCA protocol. Exercise load of the four interval training programs was controlled by manually to adjust participant's target heart rate during the interval training. MONARK bike was used for testing and obtained via a portable metabolic measurement system COSMED Quark b2 (Italy). Regression analysis was used to estimate factors such as HR<sub>max</sub>, exercise load and energy expenditure. Therefore, independent variables are heart rate, age, weight, height, target range etc. We developed two formulas to estimate HR<sub>max</sub> of the men and women, and an algorithm to feedback exercise load and energy expenditure for the four interval training programs to consider cardio-physiological state in real time. Estimated values were compared with measured to verify the accuracy of the results, and the results obtained were statistically significant ( $p < .05$ ). From the result, using YMCA protocol in bike simulator could be measured cardio-respiratory fitness, and collecting heart rate could be used to control the exercise load and estimate energy expenditure in real time basis.

**ADJUSTING HEART RATE RESERVE METHOD FOR INDIVIDUALIZED AEROBIC TRAINING PRESCRIPTION**

RIANI COSTA, L.A., POLANCZYK, S.D., MURAD NETO, A.

DIAGNÓSTICOS DA AMÉRICA SA

The selection of adequate heart rate zones for aerobic training prescription is the key factor to efficient and safety design individualized exercise protocols. Cardiopulmonary stress testing is the gold standard for clinical evaluation and exercise prescription based on ventilatory thresholds, but some equations can accurately define these individual training zones. The heart rate reserve method (HRR) has proven to be very useful in many different clinical and exercise settings, but only recently, in their last guidelines, the American College of Sports Medicine recommended different intensities of exercise prescription based on HRR for each level of aerobic fitness to ensure the efficacy of training program (ACSM's Guidelines for Exercise Testing & Prescription. 8th Edition. Lippincott, Williams & Wilkins Inc, Philadelphia, USA - 2010). However, these recommendations are based on limited investigations and may not represent the specific populations of different countries. Therefore, the aim of this study was to identify the percentage of HRR recommended for aerobic prescription in Brazilian population and to compare the specific training zones between high and low fitness subjects. Methods Sixty eight healthy Brazilian subjects between 25 and 35 years old (49 men and 19 women) performed a maximal cardiopulmonary exercise test (ramping treadmill) to define the aerobic fitness level and to find the specific heart rate at the ventilatory thresholds. The subjects were then divided into 2 groups: low fitness (LF, n= 29,  $VO_{2peak} < 85\%$  predicted) and high fitness (HF, n= 39,  $VO_{2peak} > 85\%$  predicted). We analyzed heart rate (HR, bpm) and oxygen consumption ( $VO_2$ , ml/kg.min) in the anaerobic threshold (AT), the respiratory compensation point (RCP) and in the peak of exercise. Statistical analyses were performed using Student's T test ( $p < 0.05$ ) to compare the two groups. The results are presented as mean  $\pm$  standard deviation. Results In the AT, the recommended HRR prescription was significantly lower for LF than HF group ( $51 \pm 12\%$  vs  $61 \pm 10\%$ , respectively -  $p = 0.002$ ), and the same occurred in the RCP ( $84 \pm 7\%$  vs  $88 \pm 5\%$ , respectively -  $p = 0.014$ ). Discussion These results demonstrate that healthy young Brazilian subjects should be stratified by fitness level, prescribing higher intensities for individualized aerobic training in better conditioned individuals. The adequate training zones for Brazilian population should be more specific than ACSM's recommendations. Thus, it is possible to suggest that the prescription between 51-84% of HRR for LF and 61-88% of HRR for HF subjects could be more efficient to elicit aerobic training adaptations.

**APPLICATION OF A MULTIPLE LINEAR REGRESSION MODEL FOR THE PREDICTION OF PHYSICAL TEST PERFORMANCE**

REIS, R.A., PÁSCOA, M., PAPALÉO, F., COSTA, K.G., MACEDO, D., BRENZIKOFER, R.

UNICAMP

APPLICATION OF A MULTIPLE LINEAR REGRESSION MODEL FOR THE PREDICTION OF PHYSICAL TEST PERFORMANCE Reis, R.A.1, Páscoa, M.1, Papaléo, F.1, Costa, K.G.1, Macedo, D.1, Brenzikofer, R.1 1: LABEX-IB, UNICAMP (Campinas, Brazil) Introduction Predicting future physical test performance of a group submitted to a training period is a complex challenge. The Brazilian Military Preparatory School implements systematic daily training to the students for one year. A minimum performance level is required at the end of the year, which allows the students to continue their career in the army. In this work, we propose a methodology able to reveal in advance subjects at risk of scoring below the level required on the final 3000-meter running test, using a Multiple Linear Regression model. Methods In total, 1030 subjects aged  $19 \pm 2$  years participated in the study, 504 of which were from the 2009 school year and 526 were from 2010. All volunteers were evaluated on 3000-meter running test, horizontal counter movement jump, repeated sprint ability test and body composition. These tests occurred three times during the year: February, June and October. New variables were calculated by their square and the difference between the results of June and February. We performed Multiple Linear Regression based on Stepwise method for the variable selection. The prediction model for the October 3000-meter running times was established using data from February and June 2009. We applied the model to the 2010 data to verify its accuracy. Subjects with times above 13.5 minutes are considered reproved in the final 3000-meter running test. Students were considered at risk of failure with predicted times above 13.5 minutes minus one standard error of estimate (SEE). Results The predicted time in the October 3000-meter running test ( $T_{3000oct}$ ) was given in terms of four variables: time in the February 3000-meter running test ( $T_{3000feb}$ ), the difference between June and February 3000-meter running test ( $D_{if3000}$ ), squared counter movement jump result (SCMJ) and the difference between June and February in counter movement jump ( $D_{ifCMJ}$ ). Thus, we found the following equation starting with the 2009 data:  $T_{3000oct}(min) = 0.865 * T_{3000feb}(min) + 0.793 * D_{if3000}(min) - 0.169 * SCMJ(m) - 0.539 * D_{ifCMJ}(m) + 1.967$   $R^2 = 0.73$ ,  $SEE = 0.43(min)$  Applying the data from February and June 2010, the model predicted a list of 74 subjects with times above 13.07 minutes (13.5-SEE). In the real test, performed in October 2010, out of the 526 subjects evaluated, 24 exceeded the threshold of 13.5 minutes, and 22 of them were on the list created in June. Discussion With the model developed in this study, we revealed in June 91.7% of the students at risk of failure in October. This way you can extend the time for intervention on those less able subjects, minimizing the risk of failure in the October final test. The use of a multiple linear regression model has proved to be useful, accurate and easy to apply.

**GENERAL FUNCTIONAL FITNESS INDEX IS ASSOCIATED WITH LOWER RISK FACTOR OF CARDIOVASCULAR DISEASE**

ZAGO, A.S., JACOMINI, A.M., SILVEIRA, L.R., PRIMINI, C.M., VIOLA, D., TRAPE, A.A.

UNIVERSITY OF SAO PAULO

Introduction: Physical exercise (PE) has been considered an important factor against cardiovascular disease. However, there are many controversies about the effects of PE due to the wide variety of exercises and how it can be performed (Brinkley et al 2009). Therefore, fitness level seems to be more appropriate to establish this relationship. Thus, the aim of this study was to analyze the relationship between fitness level and the risk factor of cardiovascular disease in adults and elderly people. Methods: The AAHPERD functional fitness test was designed to assess fitness level and it included the following tests: coordination, flexibility, muscular strength, agility and cardiovascular endurance (Rikli et al 1999). The general functional fitness index (GFFI) was calculated using the sum of the percentile score of each test as described by Zago et al. (2003). Participants (50-70 years-old) were divided in three groups: G1 – regular GFFI; G2 – good GFFI; and G3 – very good GFFI. Blood samples (12h overnight fast) were used to evaluate the total-cholesterol (CHOL), LDL-cholesterol (LDL), HDL-cholesterol (HDL), triglycerides (TG) and uric acid (UA) by enzymatic-colorimetric methods. Systolic and diastolic blood pressure (SBP and DBP) was measured after 15 min of seated quiet rest on three separate days. Results: ANOVA one-way showed significant differences between G1 and G3 in CHOL ( $221 \pm 40$  to  $177 \pm 28$  mg/dL), LDL ( $131 \pm 30$  to  $109 \pm 15$  mg/dL), TG ( $175 \pm 67$  to  $94 \pm 38$  mg/dL), UA ( $4.6 \pm 0.7$  to  $3.7 \pm 1$  mg/dL), BMI ( $31 \pm 5$  to  $24 \pm 3$  w/h<sup>2</sup>) and SBP ( $127 \pm 14$  to  $114 \pm 15$  mmHg). No differences were found in HDL ( $41 \pm 7$  to  $49 \pm 7$  mg/dL) and DBP ( $70 \pm 16$  to  $74 \pm 11$ ). Pearson analysis showed a significant correlation between GFFI and CHO ( $r = -0.4$ ;  $p < 0.01$ ), LDL ( $r = -0.5$ ;  $p < 0.01$ ), HDL ( $r = 0.3$ ;  $p < 0.05$ ), TG ( $r = -0.6$ ;  $p < 0.01$ ), UA ( $r = -0.4$ ;  $p < 0.05$ ), BMI ( $r = -0.7$ ;  $p < 0.01$ ) and SBP ( $r = -0.6$ ;  $p < 0.01$ ). Discussion: High level of GFFI (G3 group) results in a reduced risk factor of cardiovascular diseases, regardless of how PE was previously performed. This is in

agreement with Marques et al (2009) supporting the evidence that multicomponent exercise seems to be better than performing only one component such as resistance exercise. These data suggest that higher GFFI may induce favorable changes in risk factors of cardiovascular disease thus providing a better quality of life for the population. ### **SUBJECT SPECIFIC COMPETENCES EXPECTED OF A GRADUATE OF THE MASTERS IN HEALTH REHABILITATION THROUGH PHYSICAL EXERCISE IN BULGARIA**

DASHEVA, D.1, KOLEVA, D.1, FESTEVA, D.2

NATIONAL SPORTS ACADEMY-1; BUCKINGHAMSHIRE NEW UNIVERSITY (UNITED KINGDOM) - 2

**Introduction** The study of subject specific competences for masters' students in program health rehabilitation through physical exercises is a part of the Key competencies study from the Project no. 503202-LLP-1-2009-1-UK-ERASMUS-ECDSP funded by the LLP of the EC. The aim of the Project is to develop a Masters in Health Rehabilitation through Physical Exercise in non-clinical settings based on the "Tuning" project framework. This study will assist the project promoters in establishing the structure of the program and in formulating the learning outcomes in each module. This program will be implemented across four European Universities the European Qualification Framework will be used to benchmark the appropriate skill levels. This will relate different countries' national qualifications systems to a common European reference framework. Individuals and employers will be able to use the EQF to better understand and compare the qualifications levels of different countries and different education and training systems. **Methods** Surveys and desk research were conducted in Bulgaria involving university lecturers, PE teachers, hospitals managers, fitness instructors and practitioners in the field of rehabilitation. Descriptive statistics were completed to determine the frequencies and percentages. **Results** During collecting data from questionnaires for Bulgarian academics we found out the most important competences in their opinion are: Capacity of applying knowledge in practice (40%); Basic knowledge of the field of study (20%); Basic knowledge of the profession (15%). The Bulgarian practitioners indicated as specific competences the following: analyzing and interpreting data; planning, conducting and evaluating; health improvement practices; professional behaviour and ethics; coordination and management and carrying out research project. **Discussion** The use of learning outcomes and competences is necessary in order to make the study programme and its modules student centred and output oriented. This approach requires that the key knowledge and skills that a student needs to achieve during the learning process determine the content of the study programme. Learning outcomes and competences focus on the requirements both of the discipline and of society in terms of preparing for citizenship and employability. HARPE promoters recognize fully the importance of making maximum use of the available expertise of the staff, but this aspect should not dominate a programme. **References** 1.Tuning Educational Structures in Europe (2005). #### **CARDIAC TROPONIN T IN HEALTHY HUMANS FOLLOWING DIFFERENT PROFILES OF EXERCISE**

THOMAS, K.N.1, GRAHAM, M.J.1, FRANCOIS, M.E.1, PARR, E.B.1, LUCAS, S.J.E.1, STAVRIANEAS, S.2, COTTER, J.D.1

1: UNIVERSITY OF OTAGO (DUNEDIN, NEW ZEALAND), 2: WILLAMETTE UNIVERSITY (OREGON, USA)

**Introduction** Troponin T (TnT) is a highly specific marker of cardiac damage, used clinically in identifying myocardial infarction. Recent studies have shown elevated TnT also in normal, healthy subjects following prolonged endurance exercise, such as a marathon. TnT response to different exercise parameters (intensity, duration, mode) is largely unknown. We examined whether: 1) TnT is released in young, healthy subjects following unaccustomed exercise; 2) this differs for endurance (END) versus repeated maximal-intensity interval exercise (RHIE); and 3) differs with arm versus leg exercise. We hypothesised that RHIE with arms or legs would elicit comparable responses to those with END exercise. **Methods** Twelve healthy, sedentary male participants (age: 23±3 y; VO<sub>2</sub> peak: 44±8 mL/kg/min) completed one END exercise session (50 min at 65% VO<sub>2</sub> peak) and one RHIE session each for arms and legs (5 x 30-s sprints with 4.5 min recovery), ~2 wk apart. Venous blood was sampled before exercise and at 0.5, 1, 3, 8 and 22 h after exercise. Cardiac TnT was analysed using a Roche Diagnostics high-sensitivity assay. The assay detects TnT in the range 3 – 10 000 ng/L. A result of <14 ng/L is considered normal, as this represents the 99th centile of a healthy population (Thygesen et al., 2007), whereas ≥14 ng/L is abnormal. **Results** Increased TnT (≥14 ng/L) was evident in 5/12 participants after END exercise (average HR during session 158±17 bpm); four peaking at 3 h and one at 8 h after exercise, in the range 16 – 70 ng/L. In contrast, no participant showed raised TnT after RHIE with either arms or legs. The mean (±95%CI) difference in peak TnT between END and leg RHIE was 11 (±13) ng/L, and between END and arm RHIE: 13 (±13) ng/L. All TnT results were normal by 22 h. **Discussion** These data indicate that TnT may be released in many (but not all) healthy, sedentary individuals following endurance exercise of moderate duration and intensity. The absence of a TnT elevation following repeated 30-s sprint exercise was unexpected, but adds support to the notion that duration of exercise may be more consequential than intensity. **References** 1. #### **THE IMPACT OF THREE REPEATED 60 MIN CYCLING BOUTS IN ONE DAY ON CARDIAC TISSUE VELOCITIES IN TRAINED CYCLISTS**

WILLIAMS, K., AKERMAN, A., WHYTE, G., GAZE, D., GEORGE, K.

UNIVERSITY OF SURREY

**Introduction** Prolonged strenuous exercise has been associated with a decline in cardiac function during a range of exercise modes, durations and intensities. With the emergence of a large number of events requiring repeated bouts of exercise, few studies have assessed the impact of repeated bouts of prolonged exercise in one day and whether this results in an accumulation of dysfunction and exercise induced cardiac fatigue. **Methods** Six trained cyclists completed three, 60 minute bouts of cycling exercise at 90% of ventilatory

threshold, in one day. The exercise bouts were separated by 2 hours of rest. Echocardiographic scans of cardiac function were completed on all cyclists prior to and immediately post each exercise bout. Echocardiograms analysed septal, left ventricular free wall and right ventricular free wall tissue velocities during systole and diastole. Results Changes in ventricular wall tissue velocities were minor and not cumulative. Peak atrial diastolic tissue velocity in the septal wall, left ventricular free wall and right ventricular free wall did not increase significantly ( $p > 0.05$ ) over the course of the repeated bouts of exercise therefore no significant impact upon the ratio of early to late diastolic wall motion was apparent. Peak atrial systolic tissue velocities in the septal, left ventricular free wall and right ventricular free wall also showed no significant increase over the course of the repeated bouts of cycling exercise ( $p > 0.05$ ). Discussion The lack of changes in cardiac function as measured by tissue velocities in the septal wall, left ventricular free wall and right ventricular wall during systole and diastole, during the course of three repeated bouts of 60 minute cycling at ventilatory threshold suggests that this intensity and duration of exercise was not enough to induce alterations and subsequent cardiac dysfunction in trained cyclists.

## COMPARISON OF SEISMOCARDIOGRAPHY TO ECHOCARDIOGRAPHY FOR MEASURING CARDIAC CYCLE EVENTS

MACQUARRIE, D.S., GEBHARDT, V., NEARY, J.P.

UNIVERSITY OF REGINA, REGINA, SK; REGINA QU'APPELLE HEALTH REGION, REGINA, SK

**Introduction** Echocardiography (Echo) is recognized as a standard for measuring cardiac performance but can be technically difficult and expensive. Seismocardiography (SCG) has been studied for over 60 yr but has been impractical until recently because of advances in computer software and micro-processors. SCG records the low frequency vibrations induced by the heartbeat, and provides information on cardiac mechanics and timing of atrial and ventricular contractions, including valve opening and closing. Limited research is available comparing SCG to Echo (Crow et al, 1994; Salerno & Zanetti 1990; Salerno et al. 1991) to determine whether SCG could be used as a screening tool in applied exercise science or clinical research. This aim of this study was to compare SCG with Echo to determine whether SCG provided a valid measure of cardiac performance. We hypothesized that the SCG measurements would not be different from Echo. **Methods** Twenty-four volunteer subjects with no known cardiac disease were recruited (age range = 18-70 yrs; 13 females). The SCG was recorded by placing the SCG device on the sternum of the chest 1cm above the xiphoid process. SCG was collected simultaneously with Echo on identical and consecutive heartbeats ( $n=10$ ). Both Doppler and M-mode Echo measurements were collected. A total of 234 beats were analysed (M Mode, PW mode and SCG). Each event was analyzed and stored for comparison in standard statistical software. The timing events included the Q-wave (ECG) to: atrial systole (AS), mitral valve open/close (MVO, MVC), aortic valve open/close (AVO, AVC), acceleration time ( $P/2T$ ) and early diastolic filling (ED) wave. Isovolumic relaxation time (IVRT) was computed. The same technician performed all Echos with an echocardiologist confirming all images. **Results** There were no statistical differences in timing of the MVC, AS or IVRT between methods. Although there were statistically significant differences ( $P < .001$ ) in the other timing events (MVO, ED,  $P/2T$ , AVO, AVC) the effect sizes ( $< 0.2$ ) and mean differences (MVO=8msec, ED=9.9msec,  $P/2T$ =7.9msec, AVO=7.5msec, AVC=33.1msec) were small, with the exception of AVC ( $P < .001$ ; 0.83). The SEM ranged from 2.1 - 7.0%. **Discussion** Although some significant differences were found between the SCG and Echo for cardiac timing events, the low effect size and small mean differences suggest that the SCG can be used to provide clinically relevant information about cardiac performance in healthy individuals. SCG is an easy-to-use, non-invasive technique to evaluate cardiac function in a minimum time period, and thus can be used as a valid screening methodology. Future applied and clinical research is needed to explore whether SCG can be used in unhealthy populations and during and after exercise training. Crow et al. Am J Noninvas Cardiol, 8:39-46, 1994. ## RELATIONSHIP BETWEEN DIASTOLIC FUNCTION AND HEART RATE IN ATHLETES AND IN NON-ATHLETES

MAJOR, ZS., KNEFFEL, ZS., KOMKA, ZS., TÓTH, M., PAVLIK, G.

SEMELWEIS UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES

**Introduction** Characteristics of the athlete's heart can be divided into three groups: Morphologic: - LV hypertrophy - richer coronary capillary network Functional: - better diastolic function (higher E/A ratio) Regulatory: - lower heart rate (HR) (training bradycardia). One of the most important effects of the sedentary way of life is its effect on the cardiovascular system. While left ventricular (LV) hypertrophy is a marked characteristic of the athlete's heart, in non-athletic subjects it is a predictor of cardiomyopathy and it can lead to sudden death. **Method** The main aim of the present study was to establish differences of the diastolic function and regulation between highly trained athletes (75 women and 140 men) and non-athletic subjects (37 woman and 40 men), as the most important factors to differentiate physiologic from pathologic LV hypertrophy. We analyzed with pulsed Doppler echo and tissue Doppler imaging left ventricular (LV) regional function (velocities, such as E/A, heterogeneity and asynchrony indices) in the longitudinal (apical views, 4 segments) axis. The echocardiogram were performed according to the recommendation of the American Society of Echocardiography. In the second step a 5 minutes long, 12-lead resting ECG was recorded to establish heart rate (HR). Statistical analysis was done by using the Statistica 9.0 for the Statsoft. Significance was determined with t-test, independent, by group and the correlation with Correlation matrices. **Results** Heart rate was significantly lower in athletes, than in sedentary subjects (women: 55,72  $\pm$  9,68 vs. 66,91  $\pm$  10,85  $p < 0,01$ ; men: 54,41  $\pm$  8,91 vs. 64,09  $\pm$  9,83  $p < 0,01$ ). Both in the traditional measurements E/A was higher in the athletes than in the non-athletes (women: 2,06  $\pm$  0,51 vs. 1,68  $\pm$  0,51  $p < 0,01$ ; men: 1,920  $\pm$  0,43 vs. 1,85  $\pm$  0,46  $p < 0,01$ ). The difference in the tissue Doppler measurements between the two groups was not statistically significant ( $p < 0,6$ ). The correlation was significant between the heart rate and the E/A ( $r = 0,46$ ), but it wasn't significant between the heart rate and tissue Doppler measurements ( $r = 0,1$ ). **Discussion** Top-level athletes competitors showed functional and regulatory characteristics of the athlete's heart very markedly. The higher E/A in traditional Doppler measurements is only a consequence of the lower heart rate of athletes.

## INFLUENCE OF BREATH-HOLD AND DYNAMIC EXERCISE ON CARDIAC OUTPUT DURING ACUTE BLOOD VOLUME SHIFTS DUE TO CHANGES IN BODY POSTURE

STEEGMANN, A., DRESCHER, U., HOFFMANN, U.

GERMAN SPORT UNIVERSITY COLOGNE

**Influence of breath-hold and dynamic exercise on cardiac output during acute blood volume shifts due to changes in body posture**  
Authors: Ansgar Steegmanns\*, U. Drescher\*, U. Hoffmann\* \* Institute of Physiology and Anatomy, German Sport University Cologne, Germany **Introduction** The combination of breath-hold in combination with dynamic exercise could be found in various daily life activities. Moreover, this is sometimes overlapped by an increase in venous return due to posture changes, e. g. at the start of competitive swim-

ming. The influence of these combined stimuli on cardiac output is in the focus of this analysis. Methods 16 healthy and normotensive subjects (13 males, 3 females; age:  $27 \pm 4.5$  years; height:  $177 \pm 8$  cm; weight:  $74.5 \pm 11$  kg (mean  $\pm$  SD)) were tested on a tilt-table with an ergometer mounted. The tilt-table was operated manually to change body position from  $75^\circ$  to  $6^\circ$ -head-down-tilt (HDT) within 2 s. 20 s of 200 W with breath-hold and with eupnea (interventions hiP&BH and hiP) were repeated three times in a randomized order combined with tilting to  $6^\circ$  HDT. The interventions were separated by 160 s pedaling at 30 W in  $75^\circ$  body position. The start of each intervention was announced by a countdown. The Task Force Monitor (CNSystems, Austria) was used to measure beat-to-beat heart rate (HR) via electrocardiography and stroke volume (SV) via impedancecardiography. Cardiac output (CO) was computed as  $CO = HR \times SV$ . A trigger was used to align the onset of intervention periods. 1 s data were calculated using cubic spline interpolation. Results With onset of intervention CO shows a steep rise in hiP as well as in hiP&BH. CO of hiP increase till second 13 with a maximum of  $12.28 \text{ L min}^{-1}$  ( $\pm 0.37 \text{ L min}^{-1}$ ) (mean  $\pm$  SE) and decrease slightly till end of intervention period. With begin of hiP&BH CO increase till second 10 with a maximum of  $10.81 \text{ L min}^{-1}$  ( $\pm 0.31 \text{ L min}^{-1}$ ) and decrease slightly till the offset of intervention. With end of intervention CO show a second steep and rapid increase within a few seconds with a new maximum of  $11 \text{ L min}^{-1}$  ( $\pm 0.39 \text{ L min}^{-1}$ ). Discussion These results indicate a loss in exercise capability during high intensity dynamic exercise in combination with breath-hold when changing body posture to  $6^\circ$ -HDT position. Reductions in CO are possibly caused by reductions in heart rate due to a bradycardic response to breath-hold in concert with a diminished increase of venous return due to a loss of the breathing pump. ### CARDIAC AUTONOMIC MODULATION IN SIMULATED JUDO COMPETITION: HEART RATE VARIABILITY AND HEART RATE RECOVERY

CARBALLEIRA, E., IGLESIAS-SOLER, E., MAYO, J., GARCÍA-ARES, N., SEIJAS-GONZÁLEZ, L.M.

A CORUÑA UNIVERSITY (UDC)

CARDIAC AUTONOMIC MODULATION IN SIMULATED JUDO COMPETITION: HEART RATE VARIABILITY AND HEART RATE RECOVERY Carbalreira, E.I, Iglesias-Soler, E.I, Mayo, J.I, García-Ares, N.I, Seijas-González, L.M.1. Department of Physical Education and Sport. University of A Coruña (Spain) Introduction The aims of this study were (1) to assess heart rate recovery (HRR) in the successive judo bouts, and (2) to measure the acute effects of judo competition over cardiac autonomic modulation at rest. Methods Eleven national and international level male judokas participated in the study (mean  $\pm$  SD):  $19.72 \pm 3.06$  years,  $175.54 \pm 5.83$  cm,  $81.21 \pm 12.59$  kg. They performed 4 judo bouts with decrease rest time to simulate the schedule of judo competition. Pre and post fight (1st and 3rd minute) blood lactate (LA, Lactate Scout®) was collected and RR-interval was registered during fight and two minutes after in stand position with Polar S810 (Kempele, Finland). Competition day and next morning athletes remained still for 10 min after awakening to collect HRV (nuLF, nuHF = low and high frequency in normalized units; LF/HF ratio) during supine rest. Results Blood lactate (1 and 3 minute measure) was higher in the first bout (B1:  $11.93$ ; B2:  $10.94$ ; B3:  $9.65$ ; B4:  $9.57$ ) and decreased among the competition. LA clearance rate in bout 1 was higher than bout 3 ( $p = 0.023$ ). Heart rate variability analysis at rest in the morning after competition reached higher values in nuLF and lower values in nuHF ( $p = 0.032$ , both). In the same way it was obtained that values of LF/HF ratio increased in post-competition morning ( $p = 0.043$ ). Short-term HRR index (HRR30 = first 30 seconds of HRR semilogarithmic regression) (Buchheit et al., 2007) showed better recovery in bout 1 and 2 compared to 3 ( $p = 0.038$  and  $p = 0.036$ , respectively). LA clearance rate in bout 3 reached a negative association with LF/HF ratio post-competition ( $r = -0.661$ ;  $p = 0.027$ ). Discussion The results of our study suggest that analysis of HRV at rest may be a useful tool to detect a large-scale effort as a judo competition. Further work is needed to explore the possibilities of this tool for monitoring training in combat sports, where the quantification of training load is difficult. Noninvasive assessment of cardiac parasympathetic function: postexercise heart rate recovery or heart rate variability? *American journal of physiology*. 293(1)

### COMPARISON IN HEART RATE AND OXYGEN UPTAKE ON BICYCLE ERGOMETER AND ARM ERGOMETER IN MAXIMAL EXERCISE

ARAKANE, K.1, TAKAGI, Y.1, SAITO, T.1, NOSE, Y.1, TAKAHARA, T.1, YOSHIOKA, A.2, ONODERA, S.3

1) GRADUATE SCHOOL KAWASAKI UNIVERSITY OF MEDICAL WELFARE. 2) KAGAWA UNIVERSITY. 3) KAWASAKI UNIVERSITY OF MEDICAL WELFARE.

Introduction Find out the effects of maximum oxygen uptake for different locomotory appendages and also bring out the effects of maximum oxygen uptake for locomotory appendages. Methods Six healthy men (age:  $21 \pm 2$  years) volunteered for this study. We got an informed consent from subjects. Subjects performed a bicycle ergometer and an arm ergometer in maximal exercise stress tests. Measurement items were oxygen uptake, heart rate (HR), blood pressure (systolic and diastolic blood pressure), ratings of perceived exertion (RPE) and grip strength. Results It was observed significant correlation between grip strength and HR max ( $p < 0.05$ ). HR max and  $VO_{2\text{Peak}}$  of a bicycle ergometer was significantly higher than those of arm ergometer. Changes in systolic and diastolic blood pressure between allout of a bicycle ergometer exercise and an arm ergometer exercise were no significant difference. However there were significant changes in systolic and diastolic blood pressure between before and after exercise. Discussion Based on the results, activity muscle mass using the bicycle ergometer exercise was bigger than an arm ergometer exercise. Oxygen uptake of arm ergometer was considered that the more upper limbs muscle strength, more. Changes in systolic and diastolic blood pressure between 2exercise in allout were no significant differences. However, there were significant differences in systolic and diastolic blood pressure measurements. It was considered that arm ergometer measurement site near locomotory appendages and blood pressure get higher than the bicycle ergometer. Conclusion It was observed change in HR and oxygen uptake from exercise for different locomotory appendages. References Vokac Z, Bell H, Bautz-holter E, Rodahl K. (1975). *Journal of Applied Physiology*, 39 (1), 54-59 Bigland-Ritchie B, Graichen H, Woods JJ. (1973). *Journal of Applied Physiology*, 35 (5), 739-740

### CHARACTERISTICS OF VARIABILITY OF HEART RHYTHM OF ELITE ATHLETES

SUKHOV, S.

NATIONAL RESEARCH AND PRACTICAL CENTRE OF PHYSICAL CULTURE

Introduction Vegetative nervous system (VNS) has an important role in regulation of adaptation to intensive physical load. One of the most informative methods of study of VNS is spectral analysis of variability of heart rhythm – VHR. Goal of the study was to investigate VHR of elite athletes and young male non-athletes. Methods Resting VHR study according to International Standard (1996) was conducted with

use of hard- and software complex VNS-Spectrum. Twenty-five judoists (experimental group) and fifteen healthy adult male non-athletes (control group) have been examined. Study protocol included a 5-minute registration of ECG and pneumogram, with determination of spectral power in each frequency ranges (High Frequency – HF, Low Frequency – LF and Very Low Frequency – VLF) and total power (TP) of the range. Vagal activity is a main element of the HF component, while the LF indicator describes the status of the sympathetic part of VNS. Results Average heart rate of athletes ( $60.0 \pm 2.1$  per min.) was significantly below the average HR in the control group ( $74.0 \pm 2.9$  per min.) ( $p < 0.05$ ). The control group demonstrated well-expressed waves of heart rate in all three frequency ranges (TP -  $2450 \pm 643$  ms<sup>2</sup>/Hz, VLF -  $851 \pm 164$  ms<sup>2</sup>/Hz, LF -  $702 \pm 199$  ms<sup>2</sup>/Hz and HF -  $896 \pm 355$  ms<sup>2</sup>/Hz), equilibrium of VNS sections defined as a ratio of LF/HF –  $0.78 \pm 0.16$ . No prevalence of VLF wave should be seen in the structure spectral power of VHR of healthy persons. Indicators of VHR spectral analysis were about twice higher in athletes as compared with non-athletes (TP -  $5189 \pm 806$  ms<sup>2</sup>/Hz, VLF -  $1469 \pm 190$  ms<sup>2</sup>/Hz, LF -  $1465 \pm 275$  ms<sup>2</sup>/Hz and HF -  $2254 \pm 458$  ms<sup>2</sup>/Hz). Ratio of low and high frequency powers in athletes (LF/HF –  $0.65 \pm 0.10$ ) evidences to prevalence parasympathetic regulation as compared with the control group. In the VHR structure of spectral power, the experimental group had less VLF waves and more HF waves as compared with the control group. LF waves share in the both groups was the same. Three athletes showed reduction of indicators of VHR spectral power, which evidences to insufficient adaptation to physical load in the given phase of training process. Conclusion Analysis and dynamics of VHR indicators allows more accurately assess the functional condition of athletes, adequacy of physical load for individual, condition of fatigue.

## HEART RATE AND VENTILATION RESPONSES TO ANTICIPATE EXHAUSTION IN SCUBA DIVING

STEINBERG, F.1, DALECKI, M.1, STEEGMANN, A.1, DRÄGER, T.2, LOOSEN, D.1, HOFFMANN, U.1

1: GERMAN SPORT UNIVERSITY COLOGNE, 2: AQUA MED, BREMEN

Introduction New technologies in diving equipment i.e. modern diving computers allow to measure heart rate (HR) and ventilation (VE) simultaneously online during SCUBA diving. The concept of ventilatory threshold can be adapted to field testing and a warning system based on these data can be developed to avoid incidents due to overload in free water diving with SCUBA. Methods 12 subjects (11 male, 1 female; age:  $28.8 \pm 4.6$  years; height:  $177 \pm 5$  cm; weight:  $77.6 \pm 15.3$  kg (mean  $\pm$  SD)) participated in a standardized incremental field test for SCUBA divers (fit2dive-test). The test consists of an incremental protocol that is performed in a pool or confined water space ( $< 5$  m depth). The underwater swim speed is increased stepwise by 0.2 m/s, starting with 0.4 m/s until subjective exhaustion. Swimming velocity is controlled by timing every 10 m. Test termination criteria include: a) exhaustion; b) failure to achieve the set swimming time on two consecutive instances. Subjects diving equipment consisted of a 10 l steel tank, ADV jacket, breathing regulator and the Uwatec® Galileo sol diving computer. This computer measures HR via a usual Polar® system (chest strap) adapted to the underwater environment, pressure changes in the SCUBA tank, depth and temperature. These pressure changes in the tank were used to calculate ventilation per minute with respect to the depth. The HR at disproportional increase of VE (HRin) was determined by linear regression. Results HRin were found in the range between 132 beats per minute (bpm) and 173 bpm with mean HRin = 151.3 bpm (SD = 13.1 bpm). Mean maximum HR (HRmax) was found at 173.8 bpm (SD = 13.8 bpm) with mean HRin at 87.1% (SD = 3.1%) of mean HRmax. The differences in HRin were not only related to individual fitness but also to diving equipment (e.g. fins) and swimming efficiency (e.g. kicking technique). Conclusion These results show that an individual HRin can be determined, probably indicating the onset of significant anaerobic metabolism in the specific conditions in SCUBA diving. Based on these data commercial diving computers can be personalized to provide an early warning in exhausting situations.

## COMPARISON OF HR AND BP RESPONSE DURING GRADUAL INCREASE AND DECREASE OF WORKLOAD EXERCISE BETWEEN EATING AND SKIPPING BREAKFAST

NISHIMURA, K., NOSE, Y., YOSHIOKA, A., YAMAGUCHI, H., ONODERA, S., TAKAMOTO, N.

HIROSHIMA INSTITUTE OF TECHNOLOGY

Purpose: The purpose of the present study was to compare HR and BP response during gradual increase and decrease of workload exercise between eating and skipping breakfast. Method: Volunteering to participate in this study were 8 healthy Japanese males, who gave their informed consent prior to participation. Each subject performed cycling exercise for 32 min, recovered for 10 min in the supine position. They performed the exercise in two portions, a calibration test portion and gradual increase and decrease of workload exercise test portions. The calibration test consisted of three 4min bouts of exercise at 20, 60 and 40% of maximum oxygen uptake. The gradual increase and decrease of workload exercise test consisted of 4min bouts of gradual increase and decrease of workload exercise at between 20 and 60% of maximum oxygen uptake. The experimental conditions were fasting breakfast (C-condition) and eating breakfast (E-condition). C-condition comprised fasting for 12 hours prior to the experiments. E-condition comprised eating breakfast at 3 hours prior to the experiments. Both experimental conditions were performed at the same time in the morning (9-11 a.m.). HR, BP, oral temperature and cardiac ANS activity were measured in both experiments. Maximal and minimal HR values, amplitude and phase lags at workload top and bottom were measured in each gradual increase and decrease of workload exercise cycle. Results and Discussion: At rest, HR, SBP and oral temperature in E-condition were significantly higher than in C-condition. The ln HF, index of cardiac PNS modulation, in E-condition was significantly lower than in C-condition. During calibration exercise testing, HR at 20% and 40% in E-condition was significantly higher than in C-condition. At 60%, however, HR showed no significant difference in either condition. SBP at 20%, 60% and 40% in E-condition was significantly higher than in C-condition. During gradual increase and decrease of workload exercise, HR at top and bottom of workload exercise were no significant differences under both conditions. However, SBP in the E-condition was significantly higher than the C-condition at top and bottom of workload exercise. During recovery in the supine position, SBP in E-condition was significantly higher than in C-condition. These data suggest that eating breakfast might be followed a circadian rhythm. Also, during exercise and recovery BP responses might be conformed to exercise in the afternoon. In conclusion, SBP was increased by eating breakfast during exercise and recovery.

## HEART RATE RECOVERY FOLLOWING SUBMAXIMAL EXERCISE TESTING: ASSOCIATIONS WITH CENTRAL ADIPOSITY IN MIDDLE-AGED ADULTS.

MELLIS, M.G., INGLE, L., CARROLL, S.

LEEDS METROPOLITAN UNIVERSITY, LEEDS, UK. NUFFIELD HEALTH WELLBEING, MANCHESTER, UK.

Introduction Heart rate recovery (HRR) following maximal and submaximal exertion, especially responses within the first minute (HRR60) are a simple, non-invasive measure of vagal reactivation. HRR is known to be more rapid in individuals of high cardiorespiratory fitness

(Imai et al. 1994), but delayed in obese individuals (Brinkworth et al. 2006). The aim of this study was to evaluate sex differences in the association between HRR and waist circumference in a healthy middle-aged cohort. Methods A retrospective analysis of 404 males and 200 females aged  $47.2 \pm 7.3$  and  $46.6 \pm 8.1$  years, respectively, and free of cardiovascular disease was undertaken. Obesity measures included body fat content (BF%) from whole-body bioelectrical impedance analysis and waist circumference (WC). Participants were separated into 3 groups based on recommended cut-off points for WC and BF% into distributional tertiles. Weekly frequency of moderate and vigorous physical activity was determined by questionnaire (Nuffield Health Wellbeing). A submaximal Bruce treadmill test was performed ( $91 \pm 5\%$  and  $89 \pm 3\%$  of age-predicted maximum heart rate (APMHR), males and females respectively). HRR was evaluated at one and two minute time points (HRR60 and HRR120) in a supine position. Correlations between HRR and obesity variables were assessed using Pearson correlation coefficients. Analysis of covariance (ANCOVA) was used to examine mean differences in HRR across tertiles of WC and between the sexes. Results In males and females, significant negative associations were observed between HRR60 and HRR120 with both adiposity measures (all  $P < 0.001$ ). However, WC and HRR120 showed the strongest associations in both sexes, especially in females ( $r = -0.38$  versus  $-0.31$ ; both  $P < 0.001$ ). ANCOVA (adjusting for age and %APMHR) showed HRR120 was significantly reduced in males ( $P = 0.009$ ) and higher tertiles of WC ( $P$  for trend  $= 0.001$ ). Following further covariate adjustment (for treadmill time and frequency of moderate and vigorous physical activity), HRR120 remained significantly reduced in males ( $P < 0.001$ ) and those with higher WC ( $P < 0.001$ ). Treadmill exercise time and vigorous physical activity were independently associated with HRR120 in this model. The differences between the mean HRR120 was only significant between the highest compared to lower tertiles of WC in both sexes (both  $p < 0.01$ ). Discussion Females showed a more rapid HRR and this may represent a cardio-protective effect. HRR120 appears to be most strongly associated with WC measures. These findings are suggestive that central adiposity is more closely linked with dampened HRR amongst middle-aged adults. References Imai K, et al (1994). JACC, 24, 1529-1535. ### CARDIOVASCULAR REMODELING, PHYSICAL ACTIVITY LEVEL AND WALKING TRAINING IN POST-MENOPAUSE.

D'ANGELO, E.1, DI BLASIO, A.1, DI DONATO, F.1, IZZICUPO, P.2, NAPOLITANO, G.2, DI BALDASSARRE, A.2, GALLINA, S.1

G. D'ANNUNZIO UNIVERSITY CHIETI - PESCARA

Introduction Post-menopause is linked to an increase in Cardiovascular risk because of hormonal modifications. Although aerobic exercise has been shown to positively affect heart function and structure, few studies investigated their relationships with spontaneous physical activity. The aim of our study was to assess the role of daily physical activity level (PAL) on the left ventricle structure and the effect of aerobic training in post-menopause. Methods Thirty-eight post-menopausal ( $56.03 \pm 4.03$ ) healthy women without history of physical exercise were recruited after initial screening including medical history, echocardiography and electrical bioimpedance (BIA). To evaluate cardiovascular remodeling we measured the following echocardiographic-doppler parameters: left ventricle relative wall thickness (RWT), midwall fractional shortening (MFS) and elastance (LVE). Daily energy expenditure was measured by SenseWear Pro 3 Armband; basal metabolic rate was estimated by BIA. PAL was calculated by dividing daily energy expenditure by basal metabolic rate. Women walked at moderate intensity 4 days/week for 14 weeks. All the tests were executed also at the end of the training period. Results Cluster analysis on basal values of RWT, MFS and LVE showed the presence of two groups: Group- ( $n=16$ ) and Group+ ( $n=22$ ). Unlike, Group+, Group- had not favorable values regarding to RWT, MFS and LVE. The groups The groups differed significantly in plasma lipids, total cholesterol (TC) and triglycerides (TG) and PAL. Group+ values were better than those of Group-. Logistic regression performed with PAL, TC, TG, smoking habits and hypertensive treatment as independent variables, and sub-group membership as dependent variable, showed that PAL predicted sub-group membership ( $p=0.019$ ). RM-ANOVA showed that aerobic training modified MFS ( $p=0.022$ ) and LVE ( $p<0.001$ ) independently of sub-group membership, while RWT modification has been shown related to its basal values ( $p=0.006$ ). Discussion In post-menopause PAL, without aerobic exercise, has positive influences on both left ventricle function and structure. Walking training positively affects them even if the modification of the latter is related to its basal value.

Introduction The purpose of this study is improving knowledge about the different phases in a speed race (60 y 80 meters) and its relation with the values of force and power. This can be an useful tool to regulate the training loads of the sprinters during the competition period. Methods Twenty two high level sprinters (age  $23.1 \pm 4.4$  yr, body mass  $73.7 \pm 4.6$  kg, height  $177.6 \pm 5.9$  cm; body fat  $9.6 \pm 2.9\%$ ) took part in the study. They executed bouts of 40, 60 and 80 meters in different sessions at the maximal speed with complete recoveries (4 minutes, 6 minutes and 8 minutes for 40, 60 and 80m, respectively), registering the time with photoelectric cells. In each distance, the shuttle time in ten meters was registered. Before and after each sprint, every athlete executed three "Countermovement jump" (CMJ), measured with an infrared platform. Further an evaluation of force and power was made with measures of CMJ, CMJ with loads and Squat Jump (SJ), using for it a force platform, an infrared platform and a linear measurer of force. Results The loss of speed in 60 m and 80m is proportional and significantly higher in the final phase of the race (from 50m to 60m for the 60m distance and from 70 to 80m for the 80m distance), than in the acceleration phase (0 to 50 m and 0 to 70m). The performance decreases during repeated-series in short distances are sharper in the maximum speed phase within the run distance than in the acceleration phase. On the other hand, we do not observe this same tendency for the 40m distance, in which this loss of relative speed occurs only to a lesser extent in the final part (from 30m to 40m). Discussion This distribution has relation with the values of strength and power as the fatigue is greater when the available time to apply force is lower (Hakkinen, 1989), and this is what happens during the maximum speed phase, in which the available time to apply force is lower than in the acceleration phase. Therefore the percentual greatest loss of speed in the maximum speed phase could be by the fact of a lower contact time and the consequence in a greater RFD in this phase in relation to the acceleration phase. Nevertheless, are required more investigations in this line of work for the control of all the factors that play an important role to obtain the performance in

this kind of sprints events. References Hakkinen, K. (1989). Neuromuscular and hormonal adaptations during strength and power training. *J. Sports Med.* 29(1): 9-26.

### BLOOD LACTATE AND ACID-BASE BALANCE DURING TWO DIFFERENT LONG- SPRINT TRAINING REGIMENS

HANON, C.1, BERNARD, O.2, THOMAS, C.1,3

1: INSEP 2: LAPHAP EA 3813, 2 SPORT SCIENCES FACULTY OF POITIERS, 3: UNIVERSITY OF EVRY VAL D'ESSONNE

**Introduction** Most studies on long-sprint have focused on interval training regimens with a ratio of 1:3 to 1:9 between sprints and recovery durations (recovery periods never exceed 4.5 min) and have described a progressive decrease in the intensity of the repeated sprint exercises [1] as well as a decrease in the anaerobic glycolytic contribution to the ATP resynthesis during the training session. Surprisingly, conventional textbooks on training [2] recommend interval sprint training with long recoveries (up to 20 minutes with an exercise/recovery ratio of 1:20) for the enhancement of long sprint performance. This study aimed to analyse two different long sprint training sessions of equal total work load, realized either with short (SR) or long recovery (LR) between sets and to compare the effects of 6 long-sprint training sessions on a 300-m performance. **Methods** Fourteen trained subjects performed three maximal sprints (50, 100 and 300-m). They were paired according to their 300-m performance and were randomly allocated to LR or SR training group. Blood pH, bicarbonate concentration, excess-base and lactate concentration were recorded during the third training session and the 300-m pre- and post-test. **Results** Compared to a similar SR training session, the LR training tends to induce a larger alteration of the acid-base balance: pH:  $7.09 \pm 0.08$  (LR) and  $7.14 \pm 0.05$  (SR), bicarbonate concentration;  $7.8 \pm 1.9$  (LR) and  $9.6 \pm 2.7$  (SR) and excess-base:  $-21.1 \pm 3.8$  (LR),  $-17.7 \pm 2.8$  (SR) ( $P=0.11$ ,  $0.04$  and  $0.12$ , respectively). Post-training, a significant improvement in the 300-m performance ( $41.52 \pm 2.45$  vs  $42.45 \pm 2.64$ ,  $p=0.009$ ) and significant decreases in pH ( $P<0.01$ ), excess-base ( $P<0.001$ ) and increase in lactate concentration ( $P<0.001$ ) have been observed compared to pre-training, with no difference between the two groups. **Discussion** Whatever the duration of the recovery, six sessions of a specific long sprint training program have been shown to be sufficient to obtain a significant improvement in the 300-m performance even in our trained subjects. Although muscle data are lacking, we can suggest that doubled recovery duration (12 min) is not sufficient to re-establish homeostasis after long sprint running exercises. Therefore, the repetition of such exercises separated by recovery duration of 4-5 or even 12 minutes is always performed with an incompletely restored homeostasis and could induce near similar adaptations. 1) Bangsbo J, et al. *J. Appl. Physiol.* 77(4): 1890-1895, 1994 2) Newsholme EA, et al. *The science of training and performance*. Chichester, England: John Wiley & Sons, Ltd, 1994

### METABOLIC ADAPTATIONS DURING INTENSE EXERCISE FOLLOWING LONG-SPRINT TRAINING OF SHORT DURATION

THOMAS, C., BERNARD, O., ENEA, C., JALAB, C., HANON, C.

INSEP

**METABOLIC ADAPTATIONS DURING INTENSE EXERCISE FOLLOWING LONG-SPRINT TRAINING OF SHORT DURATION** Claire THOMAS<sup>1,2</sup>, Olivier BERNARD<sup>3</sup>, Carina ENEA<sup>3</sup>, Chadi JALAB<sup>3</sup>, Christine HANON<sup>1</sup> 1 INSEP, Mission Recherche, Paris, France. 2 Université Evry Val d'Essonne, Département STAPS, France, 3 Université de Poitiers, Faculté des Sciences du Sport, EA 3813, Poitiers, France **Introduction** This study aimed to determine metabolic adaptations during intense exercise and improvement of long-sprint performance following six sessions of long-sprint training. **Methods** Nine subjects performed before and after training 1) a 300-m test, 2) an incremental exercise up to exhaustion to determine the velocity associated with maximal oxygen uptake ( $v\text{-VO}_{2\text{max}}$ ), 3) a 70-s constant exercise at intensity halfway between the  $v\text{-VO}_{2\text{max}}$  and the velocity performed during the 300-m test, followed by a 60-min passive recovery to determine an individual blood lactate recovery curve fitted to the bi-exponential time function:  $La(t) = La(0) + A1(1 - e^{-\gamma_1 t}) + A2(1 - e^{-\gamma_2 t})$ , and blood metabolic responses. The training program consisted of 3 to 6 repetitions of 150 to 250 m interspersed with rest periods with a duration ratio superior or equal to 1:10, 3 days a week, for 2 weeks. **Results** Whereas blood lactate concentration ( $La_{lb}$ ) did not change at the onset of recovery after training, significantly lower peak in  $La_{lb}$  was observed ( $P < 0.05$ ), which was related to a significant decrease in net amount of lactate released (NALR) ( $r = 0.78$ ,  $P < 0.05$ ). Furthermore, training also induced a significant decrease in the net lactate release rate (NLRR) at the beginning of recovery. Lastly, a significant improvement of the 300-m performance was observed after training, which was related to intra-individual alterations in blood lactate removal ( $\gamma_2$ ) ability. **Discussion** These results suggest that a lower amount of lactate was released from skeletal muscles after long-sprint training of short-duration, which results from rapid alterations in lactate exchange, and allowed long-sprint performance improvement. **References** Freund H, Gendry P (1978) Lactate kinetics after short strenuous exercise in man. *Eur J Appl Physiol Occup Physiol* 39, 123-35. ### RELATIONSHIPS AMONG SPRINT ABILITY, AGILITY AND VERTICAL JUMP PERFORMANCE IN YOUNG SOCCER PLAYERS

KOZ, M.

ANKARA UNIVERSITY

**RELATIONSHIPS AMONG SPRINT ABILITY, AGILITY AND VERTICAL JUMP PERFORMANCE IN YOUNG SOCCER PLAYERS** KOZ M\*.; KÖKLÜ Y\*\*.; ALEMDAROĞLU A\*\*.; ERSÖZ G\*. \*Ankara University, School of Physical Education and Sports, Ankara \*\*Pamukkale University, Schools of Sport Sciences and Technology, Denizli The capacity of soccer players to produce varied high-speed actions is known to impact soccer match performance (1-2). Although high-speed actions only contribute to ;11% of the total distance covered, they in fact constitute the more crucial moments of the game and contribute directly to winning possession of the ball and to scoring or to conceding of goals (1-3). The purpose of this study was to examine relationships among speed, agility and jump performance in young soccer players. Fifteen soccer players (height  $168.46 \pm 4.72$  cm; body mass  $62.60 \pm 7.74$  kg ; average age  $16.00 \pm 0.84$  years; training age  $6.0 \pm 2.03$  years ) participated in this study voluntarily. Sprint-ability of the soccer players was determined by 10-30 meter single-sprint, zig-zag test times (with ball and without ball) were used for the determination of agility (Newtest PowerTimer, Finland) (1), squat and counter movement jump was used for the determination of vertical jump (Newtest PowerTimer, Finland). Results of Pearson Product Moment correlation analysis indicated significant correlation between 10 meter sprint times and 30 meter sprint times ( $r=0.74$ ;  $p=0.01$ ), zig-zag without ball ( $r=0.56$ ;  $p=0.027$ ). Similarly 30 meter sprint times was significantly correlated with counter movement jump ( $r=-0.57$ ;  $p=0.027$ ), zig-zag without ball ( $r=0.76$ ;  $p=0.01$ ). Counter movement jump was significantly correlated with squat jump( $r=0.71$ ;  $p=0.03$ ), zig-zag without ball ( $r=-0.79$ ;  $p=0.00$ ). In addition to, squat jump was significantly correlated with zig-zag without ball ( $r=-0.73$ ;  $p=0.02$ ). Finally zig-zag without ball was significantly correlated with zig-zag with ball ( $r=0.57$ ;  $p=0.02$ ). As a conclusion, while the findings of the present study indicated significant

positive correlation between sprint ability and agility, the finding indicated significant negative correlation both vertical jump-sprint ability and vertical jump- zig-zag agility tests performance in soccer players. The findings suggest that specific testing and training procedures for each speed and jump component should be utilized when working with young soccer players. References : 1. ## RELATIONSHIPS BETWEEN STRENGTH QUALITIES BOTH IN RESISTED SPRINT AND VERTICAL JUMPS WITH 20-M SPRINT PERFORMANCE

ALCARAZ, P.E.1, MARTINEZ-VALENCIA, M.2, ROMERO-ARENAS, S.1, GARCÍA, J.A.1, ELVIRA, J.L.L.3

1 UCAM (MURCIA, SPAIN), 2 UCLM (TOLEDO, SPAIN), 3 UMH (ELCHE, SPAIN)

**Introduction:** The ability to optimise muscular power output is considered fundamental to successful performance of many athletic activities. Consequently, a great deal of research has investigated methods to improve power output and its transfer to athletic performance, i.e. resisted sprinting and/or loaded vertical jumps. One variable that is considered important in increasing power and performance in explosive tasks such sprinting is the training load that maximises the mechanical power output (PP) of muscle (Alcaraz et al., 2011). Other strength quality such rate of force development (RFD) may predict athletic performance too, however this issue is quite controversial (Cronin & Sleivert, 2005). In this sense, the aims of this study were to investigate the relationship between relative PP and RFD developed in unloaded and loaded vertical jumps (JRFD) with the RFD produced on resisted sprints (RRFD), and finally, correlate these variables with 20-m sprint performance. **Methods:** Thirteen men active competitive athletes specialized in sprinting were recruited for the study ( $18.7 \pm 3.4$  years,  $1.79 \pm 0.06$  m, and  $70.2 \pm 8.8$  kg). The participants, who had previously sled-towing training experience, performed two tests in two days. The first day, 10 countermovement jumps (CMJ) were performed (unloaded jumps and jumps with a weighed vest ranging from 5 to 20% of Body mass (Bm)) on a force plate. Absolute and relative PP (vertical force x instantaneous vertical velocity of the system's center of mass), and RFD (calculated using the following equation in a 0.002 s interval:  $RFD = \Delta F / \Delta t$ ). 48 hours after, four 20-m sprints (unloaded sprints and sprints pulling resistances of 10, 15 and 20% of Bm) from a crouched start were done. The participants were placed 1-m behind the starting line. The resisted sprint trials were performed using a weighted sled (4.7 kg) attached to each athlete by a 3.6-m cord and waist harness. The sprint times were recorded by photocells system placed at 0, and 20-m. A load cell was attached between waist harness and cord to assess changes in force production over the run. Maximum force production and RFD were recorded for each trial in the first stride. For both test, the trials' order was randomized for each participant, and an unlimited rest period was given between trials to minimize the effects of fatigue. **Results:** A Pearson's Product moment correlation showed that there was no significant association ( $p \leq 0.05$ ) between JRFD vs. RRFD. Only a significant correlation was found between RRFD and relative PP at 15% Bm ( $r = -0.666$ ). No significant correlations were found between these variables and 20-m time. In this sense, changes in these strength qualities are not necessarily representative of changes in sprint performance (Cronin & Sleivert, 2005). **Conclusion:** Neither measure analyzed (SRFD or JRFD) is representative of the acceleration phase of sprinting. **References:** 1. Alcaraz et al. (2011). Power-load curve in trained sprinters. A preliminary study. *J Strength Cond Res.* 2. Cronin & Sleivert (2005). *Sports Med*, 35, 213-234

## DIFFERENCES IN PERFORMANCE BETWEEN STARTERS AND SUBSTITUTES DURING SPECIFIC REACTION TEST IN YOUNG ELITE SOCCER-GOALKEEPERS

KNOOP, M., FERNANDEZ-FERNANDEZ, J., FERRAUTI, A.

RUHR UNIVERSITÄT BOCHUM

**Introduction** In the last few years feasible specific diagnostics has gained more importance modern in high-level soccer. Up to now most of the soccer specific tests have been created for field players. Although even the FIFA World Championship 2010 has shown the necessity of having a strong goalkeeper (GK) in the team, there are still only a few useful tests evaluating the goalkeeper's abilities. In order to reduce this scientific gap we have designed a testing device that can provide information about the reaction and action velocity (RAV) of the soccer GK. **Methods** RAV is measured with the "Keepers Time Detector" ("KTD 4pro") testing device, consisting in a display panel which randomly lights up four LEDs (symbolizing the four corners of the goal) fixed on it, and four contact sensitive balls placed at each corner of the goal. The fourfold panel gives an initial signal for the GK, who has to deflect the determined balls. We analyze time and split time for single or complex diving actions of the GK. The RAV test was conducted with 21 junior GK of nine German 1st division teams, and one Polish "Młoda Ekstraklasa" Team (U19;  $18.8 \pm 0.8$  yrs;  $187 \pm 5$  cm;  $79.9 \pm 7.4$  kg). Moreover we tested 13 elite goalkeepers from DFB U14-talent spots ( $14.1 \pm 0.3$  yrs;  $176 \pm 8$  cm;  $63.0 \pm 10.8$  kg). **Results** RAV single action bottom U19 1st GK (left:  $1.25 \pm 0.07$ s; right:  $1.21 \pm 0.06$ s), substitutes (SB) (left:  $1.30 \pm 0.05$ s; right:  $1.24 \pm 0.06$ s), U14 (left:  $1.39 \pm 0.09$ s; right:  $1.39 \pm 0.12$ s). RAV single action top U19 1st GK (left:  $1.38 \pm 0.06$ s; right:  $1.38 \pm 0.04$ s), SB (left:  $1.44 \pm 0.08$ s; right:  $1.41 \pm 0.07$ s), U14 (left:  $1.59 \pm 0.13$ s; right:  $1.58 \pm 0.11$ s). RAV complex action U19 1st GK top-left/ bottom-right ( $4.30 \pm 0.27$ s), SB ( $4.48 \pm 0.23$ s), U14 ( $5.19 \pm 0.41$ s). RAV complex action U19 1st GK top-right/ bottom-left ( $4.25 \pm 0.30$ s), SB ( $4.38 \pm 0.09$ s), U14 ( $5.06 \pm 0.55$ s). **Discussion** The differences in reaction and action times between the 1st GKs and substitutes may be an indicator for a different degree of quality or expertise. The 1st GKs are faster in all action directions than the substitute keepers. Moreover the 1st GKs have a smaller time discrepancy between the left and the right side, which can imply a higher motoric skill level. The results of the tests can be a useful diagnostic tool for a coach to work specifically in detail on individual weaknesses of the athlete related to diving techniques.

## THE RELATIONSHIP BETWEEN REPEATED SPRINT PERFORMANCE AND MEASURES OF SPRINT AND JUMP PERFORMANCE IN YOUNG, WELL-TRAINED ELITE MALE SOCCER PLAYERS

SHALFAWI, S.1, DILLERN, T.1, SABBAH, A.2, ENOKSEN, E.3, TØNNESSEN, E.4

(1) UNIVERSITY OF NORDLAND, (2) DNA PERSONAL TRAINING STUDIOS, (3) THE NORWEGIAN SCHOOL OF SPORT SCIENCES, (4) NORWEGIAN OLYMPIC SPORT CENTRE.

**Introduction:** There are two purposes for assessing athletic performance. First, and most common, is to quantitatively determine improvements made following a training cycle. This allows the athlete and sport performance professional to examine if a training stimulus was sufficient to cause a positive adaptation. This method does not, However, lead the professionals in the direction that they should focus the training on (1). Therefore, the purpose of this study was to examine the relationship between repeated sprint performance and measures of sprint and jump performance. **Methods:** Thirty young well-trained elite males' soccer players aged ( $\pm$  SD) ( $16.2 \pm 0.9$  years),

body mass ( $68.3 \pm 9.0$  kg) and stature ( $177.6 \pm 7.4$  cm) volunteered to participate in the present study. All participants and their parents gave their written voluntary informed consent and the local ethics committee at the Norwegian School of Sport Sciences approved the study. All participants were tested on 10x40 m repeated sprint, 40 m maximum sprint, CMJ. 0-20 m acceleration speed and 20-40 m maximum speed were measured at the same run as 40 m maximum sprint test. Results: The results showed a high and significant correlation ( $p < 0.01$ ) between 10x40 m mean repeated sprint time and measures of running speed over 40 m maximum sprint time, 0-20 m acceleration time and 20-40 m flying speed time of  $r = 0.961$  ( $r^2 = 92\%$ ),  $r = 0.925$  ( $r^2 = 86\%$ ), and  $r = 0.801$  ( $r^2 = 64\%$ ), respectively. Furthermore, the 40x10 m mean sprint time had a statistically significant relationship with all measures of jumping performance (for CMJ in absolute term the results was  $r = 0.667$  ( $r^2 = 44\%$ )  $p < 0.01$ , for peak power relative to body weight  $r = 0.590$  ( $r^2 = 35\%$ )  $p < 0.01$ , and for CMJ relative to body weight  $r = 0.423$  ( $r^2 = 18\%$ )  $p < 0.05$ ) except for peak power in absolute term  $r = 0.321$  ( $r^2 = 10\%$ ). Discussion: The significant correlations found between repeated sprint performance and measures of acceleration and maximum sprint indicate a large share of variance, which shows that any increase in 40 m performance whether in the acceleration phase or in maximum speed phase would affect the 40 m repeated sprint positively. Peak power and Jump height were found to correlate positively and significantly with repeated sprint performance except for jump height relative to body weight. However, jump measure explained just a little of the performance on repeated sprint. Generally, previously published data show that correlations between acceleration, sprint and jumping performance exist. How the repeated sprint ability correlates with these measures are, on the other hand, not well documented. References: 1. Brown, T.D., J.D. Vescovi, and J.L. VanHeest, Assessment of linear sprinting performance: A theoretical paradigm. *Journal of Sports Science and Medicine*, 3(4): 203- 210. 2004.

## PHYSIOLOGICAL AND NEUROMUSCULAR INDICES ASSOCIATED TO THE REPEATED SPRINT ABILITY IN COLLEGE SOCCER PLAYERS

FERNANDES DA SILVA, J.

FEDERAL UNIVERSITY OF SANTA CATARINA

PHYSIOLOGICAL AND NEUROMUSCULAR INDICES ASSOCIATED TO THE REPEATED SPRINT ABILITY IN COLLEGE SOCCER PLAYERS Fernandes da Silva, J.I., Baldi, M.I., Floriano, L.T.I., Dittrich, N.I., Guglielmo, L.G.A.I. 1: UFSC (Florianópolis, Brazil) Introduction The performance of repeated sprint ability (RSA) is a multifactorial phenomenon, influenced not only by physiological aspects, but also by neuromuscular aspects (Billaut and Bishop, 2009). However, no studies were found that investigated the correlation of these indices with RSA of soccer players. Thus, the aim of this study was to investigate the association between physical indices of aerobic power ( $\text{VO}_{2\text{max}}$  and  $\text{vVO}_{2\text{max}}$ ), aerobic capacity ( $\text{vOBLA}$ ) and neuromuscular indices of muscle power: squat jump height (SJh), countermovement jump height (CMJh) and distance of the horizontal jump (HJdist) with RSA (fastest time (FT), mean time (MT), and the performance decrement (Pdec) in soccer players. Methods Twenty-six college soccer players (age:  $22.5 \pm 3.6$  years; height:  $177.5 \pm 6.3$ cm; weight:  $72 \pm 8.3$ kg) performed the following evaluations: a) vertical jump tests (SJ, CMJ); and horizontal jump (HJdist); b) maximal incremental treadmill test to determine: maximal oxygen uptake ( $\text{VO}_{2\text{max}}$ ), velocity at  $\text{VO}_{2\text{max}}$  ( $\text{vVO}_{2\text{max}}$ ) and onset of blood lactate accumulation (OBLA); c) RSA test (6 x 40 m (20+20m) interspersed with 20s of recovery) to identify the performance parameters FT, MT, Pdec. Pearson linear correlation was used to analyze the correlation between physiological and neuromuscular indices with RSA. Multiple regression (stepwise) was used to identify which indexes best predict the RSA performance ( $p < 0.05$ ). Results A significant correlation was found between  $\text{vOBLA}$  and the MT ( $r = -0.44$ ,  $p < 0.05$ ). No significant correlations were found between the physiological variables ( $\text{VO}_{2\text{max}}$ ,  $\text{vVO}_{2\text{max}}$ ) with RSA test scores (MT, FT, PD). Among the neuromuscular variables, there were very large and large significant correlations between the HJdist with the FT ( $r = -0.73$ ,  $p < 0.01$ ) and MT ( $r = -0.69$ ,  $p < 0.01$ ), respectively. Also, large correlations were found between CMJ and FT ( $r = -0.54$ ,  $p < 0.01$ ) and MT ( $r = -0.62$ ,  $p < 0.01$ ). The HJdist determined 54% of the variation in performance of the MT. HJdist and  $\text{vOBLA}$  explained 58% of MT. Discussion Based on the data obtained, it is possible observe that, among the physiological indices only OBLA and among the neuromuscular indices only the HJdist and CMJ explain the RSA performance. However, is possible to affirm that the RSA performance is determined primarily by neuromuscular indices (CMJ e HJdist) due to the use of elastic energy accumulated during the stretch-shortening cycle (SSC) (Bosco et al., 1982). UNIVERSITY OF CUMBRIA

Introduction Stretching routines are generally recommended as part of a pre-exercise warm-up as a means of reducing injuries (Woods et al., 2007). However, evidence exists that stretching also impairs muscular performance (Rubini et al., 2007). Researchers have primarily investigated static stretching, usually held over long periods (Rubini et al., 2007). However, a more typical stretching routine would include a combination of static and dynamic stretching, usually lasting shorter periods. Therefore, the aim of the present study was to compare the effect of different stretching routines used in athletics training practice on subsequent sprinting performance. Methods Ten sprint and jump athletes (mean  $\pm$  SD: age,  $22.7 \pm 1.5$  yr; body mass,  $79.4 \pm 8.7$  kg), ranging from regional to international level, free from injuries and familiar with the procedures, performed a flying 20m sprint, following a standardised warm-up consisting of static stretching (SS; hip flexors, quadriceps, hamstrings, hip extensors, and gastrocnemius), dynamic stretching (DS; leg swings, walking lunges, walking floor sweeps and heel-toe walking), SS followed by DS (SDS), or no stretching (CON), with each exercise lasting 30 seconds. Performance variables measured (Optojump, Microgate S.R.L, Bolzano, Italy) were sprint time, stride length, stride frequency, contact time, and sprint-specific power. A 4 (stretching protocols) x 5 (performance variables) repeated measures MANOVA was used and the significance level was set at  $P < 0.05$ . Results Results showed no effect of the stretching routine ( $P = 0.686$ ) on any of the performance variables measured (sprint time  $P = 0.731$ , stride length  $P = 0.741$ , stride frequency  $P = 0.224$ , contact time  $P = 0.185$  and power  $P = 0.210$ ), indicating that performance was maintained, irrespective of the type of stretch used. Discussion Our findings indicate that static stretching, dynamic stretching and their combination do not affect performance. Our results are in disagreement with Fletcher and Jones (2004), who reported a decrease in 20m sprinting, following a bout of static stretching. The differences may be due to the stretching protocols and durations used. Future studies should examine whether stretching protocols that do not impair performance are sufficient to maintain reductions in injury likelihood. References Fletcher IM, Jones B. **EFFECTS OF WELL-ROUNDED TRAINING ON WORKING WHEELCHAIR USERS**

SHIMURA, Y.1, YUKAWA, S.1, TANAKA, K.2

1: OSAKA INTERNATIONAL UNIVERSITY (OSAKA, JAPAN), 2: UNIVERSITY OF TSUKUBA (IBARAKI, JAPAN)

**Introduction** Reduction of muscle mass is associated with decreased functional performance and increased risk of disuse syndrome. Recent studies have shown that exercise training can improve muscle function, bone mineral density and quality of life in paraplegic persons using wheelchairs (Devillard et al., 2007). However, a lot of disabled persons can not participate in any exercise program, because they engage in normal work. Well-rounded training, composed of resistance training, aerobic training and flexibility exercise, has been shown to be beneficial for increasing the physical strength of the elderly (Harada et al., 2007). The purpose of this study was to investigate the intervention effects of well-rounded training on working wheelchair users. **Methods** Participants were four working wheelchair users (age  $43.5 \pm 6.6$  years). They performed 90-min well-rounded training after their working hours on a regular basis 1 day per week for 3 months. Additionally, we advised them to perform this training in their life style. Physical fitness (hand-grip strength test, muscle strength test of push and pull, shuttle run test, 20-m sprint test, and 5-minute distance test) and muscle mass in forearms, upper arms, lower legs, thighs and trunk were measured 2 times (first day session, 3 months after the initial session) of all participants. **Results** All subjects performed well-rounded training 2 times a week or more outside of the exercise class. Regarding physical fitness, the subjects had significant improvement in the shuttle run test (Pre:  $9.5 \pm 3.9$  times/30 sec., Post:  $10.5 \pm 3.9$  times/30 sec.,  $P < 0.05$ ). There were trends toward improvement in the 20-m sprint test and the muscle strength test of pull, although these changes were not statistically significant. In addition, the replies of almost participants to the following items of questionnaire were improved: "Are you confident in your present physical fitness?" On the other hand, there were no significant changes in the muscle mass of all regions. **Discussion** There is a practical issue for the working wheelchair users that almost of them cannot perform the exercise in their life because they have no time and no place to practice. This study showed that the well-rounded training has a beneficial effect for exercise adherence in working wheelchair users. Few studies reported similar results in the elderly (Harada et al., 2007). Moreover, the present study suggests that well-rounded training has some beneficial effects to improve or maintain the agility performance, the sprinting performance and the upper-extremity muscle strength in working wheelchair users. **References** Devillard X, Rimaud D, Roche F, Calmels P. **Poster presentations****PP-PM46 Physiology: Muscle Physiology 1****EFFECT OF DELAYED-ONSET MUSCLE SORENESS ON MAXIMUM VOLUNTARY TORQUE, VOLUNTARY ACTIVATION, H REFLEXES AND TWITCH RESPONSES OF THE QUADRICEPS MUSCLE**

BEHRENS, M., MAU-MÖLLER, A., WASSERMANN, F., BRUHN, S.

UNIVERSITY OF ROSTOCK

**Introduction** Delayed-onset muscle soreness (DOMS) reduces voluntary force but impaired neural drive to the muscle may also contribute. Studies have shown that the impairments in the neuromuscular system after muscle damage may be different depending on the muscle and the protocol used to induce DOMS (Prasartwuth et al., 2005, Racinais et al., 2008). The present study investigated isometric maximum voluntary torque (iMVT), voluntary activation (VA), twitch responses and DOMS of the quadriceps muscle as well as maximal H reflexes (Hmax) and maximal M waves (Mmax) of vastus medialis (VM) before and after concentric-eccentric exercise. Data of six subjects have been analyzed so far. Further results including a larger number of persons will be presented at the congress. **Methods** Data were obtained before, immediately after (post), 24h, 48h, 72h and 7days after four bouts of 25 maximal voluntary concentric-eccentric contractions. Measurements were made on the quadriceps of the right leg. Transcutaneous femoral nerve stimulation (rectangular pulses, 1ms duration) was used to produce Hmax, Mmax and twitches. The persons had to perform 5 iMVTs. VA was assessed using the twitch interpolation technique (doublets, two rectangular pulses of 1ms duration, 10ms apart). VA was calculated with the formula:  $[1 - (\text{superimposed twitch}/\text{control twitch})] \times 100$ . Paired t-tests were used for statistical analyses ( $p = 0.05$ ). **Results** Hmax, Mmax and the Hmax/Mmax-ratio of VM did not change after the intervention, whereas twitch responses of the quadriceps muscle were significantly reduced at post, 24h, 48h and 72h. The iMVT was significantly impaired at post, 24h and 48h, while VA was only significantly decreased at post. DOMS assessment using the Likert scale, visual analogue scale and pressure pain threshold revealed significant impairments at 24h, 48h and 72h. **Discussion** While iMVT recovered after 48h, the resting twitch remained depressed until 72h. It has been suggested that changes in excitation-contraction coupling and the length-tension relation underlie the prolonged reduction of the twitch responses (Prasartwuth et al., 2005). Furthermore, it has been postulated that DOMS might impair VA (Racinais et al., 2008). DOMS occurred 24h, 48h and 72h after concentric-eccentric exercise. However, changes in VA did not follow this time course indicating that muscle pain does not change VA of the quadriceps. Data suggest that reduced VA contributes to the early force loss after concentric-eccentric exercise, but that it is not due to muscle soreness. **References** Prasartwuth O, Taylor JL, Gandevia SC (2005). *J Physiol*, 567, 337-48 Racinais S, Bringard A, Puchaux K, Noakes TD, Perrey S (2008). *Eur J Appl Physiol*, 102, 439-46

**THE EFFECTS OF VOLUNTARY WHEEL RUNNING AND NUTRITION ON SKELETAL MUSCLE IN THE SENESCENCE-ACCELERATED MOUSE .**

NISHIZAWA, T., NORIKATU, K., ATUMU, Y., KENICHI, S., TAKEKURA, H.

SIGAKKAN JUNIOR UNIVERSITY

**Introduction** The purpose of this study was to investigate the effects of aging in skeletal muscle exercise and nutrition. Muscle force decreases with the aging. It is reported with that factors of the muscle force decrease are atrophy of the fast muscle fiber and decrease in number of muscle fiber. In the neuromuscular junction which is a field of information transfer from the nerve, the denervation is observed. For the resistance of the aging of muscle force decrease and morphological change, it is reported that the exercise is effective. The sesame has an antioxidant, has been reported to inhibit aging. In this study, the effect of the exercise and sesame in the aging on the skeletal muscle function is examined by examining the contraction force. **Materials and methods** SAMP6 (senescence-accelerated mouse prone 6) and SAMR1 (senescence-accelerated mouse resistance 1) 56weeks old, body weight, 30-50 g) were used. This model is useful for studying the acceleration of the aging process in skeletal muscle of the SAM. All procedures in the animal experiments were per-

formed in accordance with the guidelines presented in the Guiding Principles for the Care and Use of Animals in the Field of Physiological Sciences, published by the Physiological Society of Japan. The SAMP6 were classified into 4 groups: SAM control (C), SAM control and sesame (S), voluntary wheel running (T), voluntary wheel running and sesame (TS). The training groups carried out the voluntary wheel running (made by APTEC Co.) from 24 weeks. Single muscle fibers were dissected from the EDL, SOL, PLA, GAS, TA muscles in 54 weeks. Single muscle fibers were dissected from the EDL muscles. The contraction characteristic demonstrated by the nerve stimulation. The morphological observation of muscle fiber by optical microscope used HE staining. Evaluation of the degree of senescence: It used a grading score system (Takeda et al.). Results In 54 weeks the Bodymass of the C and S groups were heavier than that of the Training groups. On the other hand Training groups showed the high value on muscle weight per body mass. And, the Training groups showed the high value in comparison with the C and S groups on the muscle contraction force. The grading score, C and S groups are the evaluation of aging, and training groups did not appear. This suggests that age-related muscle function and morphological changes in C and S group. In addition, voluntary wheel running is more beneficial for aged muscle hypertrophy. References Sakakima H, Yoshida Y, Suzuki S, Morimoto N. (2004). *J Gerontol A Biol Sci Med Sci*. ## **FORCE – VELOCITY RELATIONSHIP FOR UPPER AND LOWER LIMBS: A COMPARISON OF THE RESULTS OF ARM AND LEG FORCE – VELOCITY TESTS**

VODICKA, P., HELLER, J.

*FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY,*

**FORCE – VELOCITY RELATIONSHIP FOR UPPER AND LOWER LIMBS: A COMPARISON OF THE RESULTS OF ARM AND LEG FORCE – VELOCITY TESTS** Vodicka, P., Heller, J. Faculty of Physical Education and Sport, Charles University, Prague, Czech Republic **Introduction** Maximal anaerobic power could be measured from the force-velocity (F–v) relationships on a friction loaded ergometer. In contrast with the hyperbolic F–v relationship of an isolated muscle or monoarticular exercise, the relationships between braking force and peak velocity seem to be linear both for arm as well as for leg exercise (Vandewalle et al. 1987). However, there is poor evidence on the differences in the F–v relationships for arm and leg exercise (Driss et al. 2002). Therefore, the aim of this study was to investigate the relationship of F–v characteristics between upper and lower limbs in the same participants, when they are measured in arm cranking and cycle ergometer tests, respectively. **Methods** A group of 17 male students of physical education (age  $25.2 \pm 3.7$  years, body mass  $74.2 \pm 9.8$  kg, height  $178.8 \pm 6.0$  cm, mean  $\pm$  standard deviation) realised arm cranking and cycle ergometer F–v tests in a randomised order. Both tests consisted from 5 short maximal sprints, with duration 7 s each one, against increasing breaking force, from 19.6 to 58.8 N for upper and 29.4 to 68.6 N for lower limbs. Individual linear regression relationship between breaking forces and pedalling frequencies were constructed to determine the theoretical values of maximal force (F0) and velocity (v0) indices for upper and lower limbs, the corresponding maximal anaerobic power (Pmax) and optimal braking force Fopt [% body mass] to elicit Pmax. Results Theoretical values of maximal force (F0) were higher for lower limbs than upper limbs ( $22.5 \pm 3.9$  vs.  $16.8 \pm 4.8$  kp,  $p < 0.01$ ), however maximal velocity (v0) for lower limbs and upper limbs was not significantly different ( $213.12 \pm 12.2$  vs.  $205.2 \pm 36.1$  rev.min<sup>-1</sup>, n.s.). Theoretical maximal anaerobic power (Pmax) for lower limbs ( $1148 \pm 167$  W,  $15.6 \pm 2.4$  W.kg<sup>-1</sup>) were higher ( $p < 0.01$ ) than for upper limbs ( $806 \pm 122$  W,  $11.0 \pm 1.8$  W.kg<sup>-1</sup>). Optimal braking force Fopt to elicit Pmax attained  $14.1 \pm 3.2$  % body mass and  $10.0 \pm 1.9$  % body mass, for lower and upper limbs, respectively. There were not found any significant correlation between the indices of lower and upper and lower limbs (F0:  $r = 0.085$ ; v0:  $r = -0.136$ ; Pmax [W]:  $r = 0.197$ ; Pmax [W.kg<sup>-1</sup>]:  $r = 0.385$ ; Fopt:  $r = -0.023$ , n.s.). **Discussion** The values found for the theoretical maximal force (F0), theoretical maximal velocity (v0), and maximal power output for upper and lower limbs were in agreement with the results of previous studies (Driss et al. 2007, Vandewalle et al. 1989) being attributable to differences in muscle mass and muscle fiber composition of lower and upper limbs. ## **MUSCLE OXYGENATION DURING FATIGUING CONTRACTIONS PERFORMED WITH DIFFERENT LOAD TYPES**

BOOGHS, C., BAUDRY, S., DUCHATEAU, J.

*UNIVERSITE LIBRE DE BRUXELLES*

**Muscle oxygenation during fatiguing contractions performed with different load types** Booghs C, Baudry S, Enoka RM, Duchateau J. Laboratory of Applied Biology, Université Libre de Bruxelles - Belgium **INTRODUCTION** Previous work has documented a briefer time to failure, which indicates greater fatigability, for tasks involving the support of an inertial load (high-compliance task) compared with exerting an equivalent torque against a rigid restraint (low-compliance task) (Enoka et al. 2010). The briefer time to failure for high-compliance tasks is accompanied with a faster increase in the amplitude of the electromyogram (EMG) for the active muscles (Klass et al. 2008). The purpose of the study was to determine if these differences in performance are influenced by metabolic and hemodynamic parameters. **METHODS** Eleven subjects (21-36 yrs) participated in two experimental sessions in which the two fatiguing contractions were performed for as long as possible. Subjects had to exert a constant torque (20% MVC) with the elbow flexor muscles either against a force transducer (low-compliance task) or while supporting an equivalent mass (high-compliance task). The elbow joint was kept at 90° during both tasks. The task was terminated when the subject was unable to maintain the required torque (low-compliance task) or joint angle (high-compliance task) within criterion values. The EMG was recorded for biceps brachii, brachioradialis and triceps brachii muscles. Spatial-resolved spectroscopy provided a measure of tissue oxygenation index (TOI), and the normalized hemoglobin concentration index (nTHI) indicated changes in local blood flow. **RESULTS** The time to failure was briefer ( $P = 0.02$ ) for the high-compliance task (411s) than for the low-compliance task (540s) despite a comparable decline in maximal torque at the end of both tasks (–24%). Moreover, the EMG activities increased to the same rate during the two tasks. TOI for biceps brachii was  $74.7 \pm 4.8\%$  and  $76.1 \pm 5.4\%$  at the start of the low- and high-compliance tasks, respectively, and decreased ( $P < 0.001$ ), to  $63.0 \pm 12.5\%$  and  $65.9 \pm 9.5\%$  at task failure (no difference between tasks;  $P > 0.05$ ). Moreover, nTHI for biceps brachii did not change during the two tasks ( $1.0 \pm 0.1$ , data collapsed across tasks). There was also no statistical difference in either TOI or nTHI for triceps brachii in either task. **DISCUSSION** These data indicate that there was an increase in oxygen consumption in the biceps brachii during the two fatiguing tasks and that local blood flow did not change during either contraction. Therefore, differences in muscle oxygenation and muscle blood flow did not appear to play a key role in the briefer time to failure observed for the high-compliance task. **ACKNOWLEDGEMENTS** This work was supported by the research council of the Université Libre de Bruxelles. **REFERENCES** Enoka et al. *J Electromyogr and Kinesiol* 21: 208-219, 2011 Klass et al., *J Neurophysiol* 99: 1096-1104, 2008

## RELATIONSHIP AMONG LOAD TRAINING, AEROBIC/ANAEROBIC PARAMETERS AND PERFORMANCE DURING 22-WEEKS OF SLALOM KAYAKERS TRAINING

VIEIRA, N.

UNIMEP

RELATIONSHIP AMONG LOAD TRAINING, AEROBIC/ANAEROBIC PARAMETERS AND PERFORMANCE DURING 22-WEEKS OF SLALOM KAYAKERS TRAINING VEIRA NA1, MESSIAS LHD1, TEREZANI D1, BORIN JP2, CUNHA SA2, OLIVEIRA RM1, MANCHADO-GOBATTO FB1 1:UNIMEP (Piracicaba, Brazil), 2: UNICAMP (Campinas, Brazil) Introduction The manipulation of intensity and volume training are important to the athletes training program (LAURSEN, 2010) and the intensity appears to be the most important for well trained athletes (IAIA, BANGSBO, 2010). The aim of the study was to verify the relationship among training load, aerobic/anaerobic capacity and performance in slalom kayakers during 22-weeks training program. Methods Six slalom kayakers (K1) (17±4yrs) were evaluated at three moments of the training program: linear base (T0), after 14-weeks (T1) and after 22-weeks (T2). The training was only monitored, without intervention of the researchers in the planning of the technical team. The intensity training was determined from the individual rating of perceived exertion (RPE) measured at the end of training session. The weekly training load (average) was determined using the product of duration session (min) by RPE session. The critical velocity model was used to estimate the aerobic and anaerobic capacities. The athletes were submitted to four maximal paddling exercises at 150,300,400 and 600-m with minimum 1hr recovery among them. The slope and y-intercept of linear mathematical model 'distance vs time' were CV (aerobic) and anaerobic paddling capacity (APC), respectively. The simulation competition of slalom kayak were used to evaluate the performance. There were registers of time race (s), distance travelled (m) and mean velocity (mv) using a GPS (Polar G3). For comparison among aerobic/anaerobic conditioning, performance and load training parameters among moments were used ANOVA One-Way. Correlation between training variables and others parameters were proceeded by a Person Correlation ( $P < 0.05$ ). Results Despite the oscillations among volume and intensity in several weeks during 22-weeks of training, there were not changes in weekly mean load, volume and intensity when two moments were compared. No differences were found in CV ( $6.8 \pm 0.1$ ;  $6.8 \pm 0.47$  and  $6.7 \pm 0.0$  Km/h, respectively) and APC ( $67.2 \pm 1.8$ ;  $60.7 \pm 2.1$  and  $64.1 \pm 3.4$  m) in T0, T1 and T2, respectively). The anaerobic parameter showed significant correlation in T0 and T1 ( $r = 0.91$ ) and at all moments, mv and CV were obtained in similar intensity. Discussion The maintenance of aerobic/anaerobic and performance parameters during the three moments seemed to be attributed to non-changes of the volume and intensity training. In this way, to improve significant modification in CV, APC and mv, the training parameters modifications is recommended. Supported by FAPESP and CNPq References IAIA, FM, BANGSBO J. (2010). ## THE EFFECT OF SKIN FRICTION, DIRECTLY ABOVE BICEPS BRACHII, ON RATE OF FORCE DEVELOPMENT DURING ELBOW FLEXION

SHIMOSE, R.1, TADANO, C.1, KOGA, H.1, SUGAWARA, H.1, TANAKA, M.1, MACDONALD, G.1, YONA, M.2, NAITO, Y.3, SEKI, H.1, SAKAMOTO, M.4, USHIGOME, N.5, MURO, M.1

1: TOHO UNIVERSITY SCHOOL OF MEDICINE, 2: TOKYO UNIVERSITY OF PHARMACY AND LIFE SCIENCE, 3: KOKUSHIKAN UNIVERSITY, 4: KITASATO UNIVERSITY, 5: TOHO UNIVERSITY OMORI MEDICAL CENTER (JAPAN)

Introduction Rate of force development (RFD), which is obtained from the initial portion of a time-force curve during a muscle contraction, provides us with important information on neuromuscular function. Previously, we reported that RFD increases with skin cold stimulation (SCS) applied directly above agonist muscles during isometric knee extension, suggesting that cutaneous input improves neuromuscular function (Shimose R. et al, 2010). However, it is unclear whether RFD changes with different cutaneous input such as skin friction (SF). Therefore, the purpose of this study was to investigate the effect of SF and SCS on RFD. Methods Five healthy adults (35[9] yrs), who gave informed consent, participated in this study. Subjects sat in an adjustable chair with both their shoulder and elbow joints at 90 degrees flexion. Subjects performed maximal voluntary isometric elbow flexion three times. This procedure was done with SF, SCS or without any form of stimulation (CON). SF was applied to the front of the upper arm by moving a piece of fabric back and forth at a slow speed using an electrical shaking device. SCS (skin temperature 25 degrees) was applied on the same area using a cooled gel pad. Force and EMG of biceps brachii were measured simultaneously during elbow flexion. Peak force, RFD and root mean square EMG (rmsEMG) at periods 0-30, 0-50, 0-100, and 0-200msec were investigated in all the trials. Results There was not much difference between peak force among all trials. RFD of SF at 0-30-50 ms tended to increase by about 3-5%, and RFD of SCS tended to increase by about 7-12%. But there was not much difference in rmsEMG at every interval among the trials. Discussion RFD tended to increase with SF and SCS during isometric elbow flexion. The amount of increase in RFD was a little different between SF and SCS, suggesting different cutaneous input has a different effect on RFD. In comparison to our previous data from knee extension, there was a smaller increase in RFD with SCS during elbow flexion, most likely, because biceps brachii is more sensitive than quadriceps. These results suggest that RFD differs among limb muscles. Although further investigation will be needed to elucidate the effects of different cutaneous input on RFD, the present study suggests that skin friction improves initial force response in biceps brachii during elbow flexion. ## EFFECT OF HYDROTHERAPY, ACTIVE AND PASSIVE RECOVERY ON REPEATED MAXIMAL CLIMBING PERFORMANCE

BALAS, J., CHOVAN, P.

FACULTY OF PHYSICAL EDUCATION AND SPORT

Introduction Hydrotherapy is commonly used in sport practice to enhance recovery from exercise (Wilcock et al., 2006). Cold water immersion and contrast water therapy are effective in minimising the physiological and functional deficits associated with delayed onset of muscle soreness. The effect on subsequent performance is not clear. To date, only three studies (Draper et al., 2006; Heyman et al., 2009; Watts et al., 2000) have investigated recovery in rock climbing. The aim of the study was to compare the effect of four recovery methods (PAS-passive, ACT - active, CW - cold water, CWW - cold and warm water) on repeated climbing performance. Methods Five advanced climbers (mean age 28.6,  $s = 4.0$  years) performed, in a random cross-over design, 4 sessions with 3 repeated climbing tests to exhaustion. The effect of the recovery methods on climbing performance (number of movements, climbing time), heart rate and grip strength was assessed by 4 x 3 RM ANOVA (recovery method x climbing test number). Results Significant interaction between recovery and the climbing test number for climbing performance was found (number of climbing movements:  $F_{6,32} = 2.23$ ;  $p = 0.65$ ;  $\eta^2 = 0.30$ ; climbing time  $F_{6,32} = 2.90$ ;  $p = 0.02$ ;  $\eta^2 = 0.35$ ). The decrease of performance between the 1st and 3rd test was after PAS 41%, CWW 24%, CW 0% and ACT 14% of the number of climbing movements. The average decrease in grip strength was 30% after climbing and was

significantly correlated with the number of climbing movements ( $r = 0.80$ ) and climbing time ( $r = 0.72$ ). Discussion There were two hydrotherapy methods used in the present study. While the CW immersion maintained the subsequent performance, there was a decrease of performance after the CWW immersion. The CW and ACT were the most efficient recovery methods in the current study confirming the results of Heyman et al. (2009). The ACT recovery was performed by walking at 65% of HRmax instead of the cycle ergometer used in the previous study. The recovery method did not have any effect on grip strength. ## RELATIONSHIP BETWEEN THE SILENT PERIOD AND THE AMPLITUDE OF V-WAVE DURING %MVC WITH SKIN COOLING

YONA, M.1, TADANO, C.2, SHIMOSE, R.2, SUGAWARA, H.2, NAITO, Y.3, MURO, M.2

1: TUPLS (JAPAN) 2: TOHO UNIV. MED. (JAPAN) 3: KOKUSHIKAN UNIV. (JAPAN)

**Introduction** We have demonstrated that the amplitude of H-reflex is unchanged and the amplitude of V-wave with skin cooling increases more than under normal skin temperature conditions in the latter half of the %MVC. However, there is no clear effect on central motor command with skin cooling. The purpose of this study was to investigate the effects on the magnitude of the descending motor drive with skin cooling by analysing V-wave and silent period. **Methods** Eleven healthy adults volunteered for this study. All measurements were taken from left leg muscles. The force of the isometric contraction and twitch of the triceps muscle of calf were established by a force transducer attached to a footplate apparatus. Electric signals were picked up by surface electrodes (10mm) on the belly of the SOL. This experiment was performed under two conditions that consisted of skin cooling (skin temp. 26 deg.; SC) and without skin cooling (skin temp. about 33 deg.; NSC). Under cooling conditions, the skin temperature was cooled to 26°C through application of a cooling pad, attached to the skin, for 3 minutes. 2 maximal voluntary isometric contractions (MVC) for 2 seconds were performed at the control temperature. The force of every 10%MVC was calculated using MVC under control temperature. H-reflexes, M-wave and V-wave were evoked in the soleus muscle by electrical stimulation of the posterior tibial nerve via a cathode ball electrode (5 mm in diameter) pressed into the popliteal fossa. H-reflex and Mmax were obtained under both conditions at rest. During sub-maximal contractions (10, 20, 30, 40, 50, 60, 70, 80, 90% of one MVC) and MVC performance, a supra-maximal stimulus was delivered at supra-maximal intensity, which allowed us to record the superimposed M-wave (Msup) and V-wave of the SOL. **Results and Discussion** There was no significant difference in Hmax, Mmax and H/M ratio under each condition. M-wave amplitude recorded during maximal voluntary plantar flexor contractions (Msup) was significantly greater than that recorded at rest (Mmax) in each condition. However, there was no significant difference between SC and NSC. There was an interrelation between the amplitude of V-wave and silent period in SC and NSC. The amplitude of V-wave increased gradually with increased %MVC under both conditions. With skin cooling the amplitude of V-wave increased in the latter half of the %MVC more than control. The polynomial relation indicated with skin cooling was higher than that without skin cooling over 80%MVC ( $p < 0.05$ ). On the other hand, the silent period decreased gradually with increased %MVC under both conditions. However, there was no significant difference between SC and NSC. However, there was no significant difference between SC and NSC. These results suggest that the increase in V-wave response with skin cooling are related to the elevated motoneuron excitability, however, skin cooling has less effect on the magnitude of the descending motor drive (silent period) than on the spinal cord.

**Changes in total daily energy expenditure and its components during high- and low-volume training periods in male endurance athletes.** Drenowatz C., Eisenmann JC. Human Energy Research Laboratory, Michigan State University (USA) **Introduction** Various studies have examined total daily energy expenditure (TDEE) or exercise energy expenditure (EEE) in endurance athletes. There is, however, limited research on the contribution of various components contributing to TDEE and the specifics of EEE during different training periods. The purpose of this study was to examine changes in TDEE and its components, specifically EEE, non-exercise activity energy expenditure (NEAT), and resting metabolic rate (RMR), in male endurance trained athletes during high- and low-volume training periods. **Methods** Energy expenditure was measured in 15 male endurance athletes (age  $23.6 \pm 2.4$ ) during 2 non-consecutive weeks – one week with about 13 hours of training (high volume) and another week with about 6 hours of training (low volume). Anthropometric measurements including %fat via BodPod were taken according to standard procedures at the beginning and end of each week of data collection. RMR was measured in the middle of each week using indirect calorimetry. The SenseWear Pro 3 Armband was used to measure NEAT and EEE was assessed via heart rate using individual regression equations established during a VO2max test performed at the beginning of each week. **Results** There was no difference in body weight ( $73.4 \pm 9.7$ ) or %fat ( $10.8 \pm 3.8$ ) between the two weeks of training. TDEE and EEE were significantly higher during the high volume week ( $4824 \pm 773$  vs.  $4080 \pm 637$  and  $1285 \pm 269$  vs.  $639 \pm 267$  kcal/day, respectively), but there was no difference in training intensity. While there was no difference in NEAT ( $1262 \pm 350$  vs.  $1291 \pm 285$  kcal/day), a trend towards higher RMR was observed ( $2276 \pm 383$  vs.  $2150 \pm 240$  kcal/day) ( $p = 0.08$ ). Time spent in sedentary activity was significantly reduced during the high volume week ( $1051 \pm 91$  vs.  $1108 \pm 89$  min/day), but there were no differences in light, moderate, or vigorous activity. NEAT was also inversely correlated with time spent sedentary ( $r = -0.8$ ), while a positive relationship between NEAT and time spent in light and moderate activity was observed ( $r = 0.7$ ). Further, RMR was positively correlated with time spent in vigorous activity ( $r = 0.5$ ). **Discussion** These endurance athletes did not show a compensatory behavior in response to high volume training – that is, there was no decrease in NEAT during the high volume training. The difference in TDEE was greater than what could be attributed to differences in TEE and the present data suggests an increase in RMR during high volume training. In addition increased training time did not reduce light and moderate activity, but rather reduced sedentary time in trained endurance athletes. Results of this study also support the importance of time spent in light and moderate activity concerning NEAT and TDEE.

## TRAINING LOAD IN A ULTRATRAIL PREPARATION MACROCYCLE

BLANCO, A., ENSENYAT, A., SERRA, N.

NATIONAL INSTITUTE FOR PHYSICAL EDUCATION AND SPORTS OF CATA

**TRAINING LOAD IN A ULTRATRAIL PREPARATION MACROCYCLE** Blanco, A., Ensenyat, A., Serra, N. INEFC (Lleida, Spain) **Introduction** Ultra Trail events are competitions of mountain running on various terrain trails that exceed 6 h in duration. Due to its prevailing aerobic demands, from a physiological point of view, Ultra Trail is considered an ultra-endurance effort. During the training process, it is essential to determine and evaluate the training load in order to quantify the magnitude of the effort done, and to control the degree of fatigue of the athlete. Quantification of the load, by means of rating of perceived exertion (RPE), can be done easily using RPE of each session (session RPE method) and microcycle (fatigue index). The aim of this study was twofold; (a) to determine the training load in a 13 weeks macrocycle for the preparation of two Ultra Trail competitions, and (b) to relate the session and microcycle training load with the volume (time and distance) and the physical intensity (mean speed) of training. **Methods** An experienced amateur athlete (36 years, 172 cm of height, 80 kg of weight), with a best performance of 7 h 26 min in 100 km road running. Along a 13 weeks macrocycle, distance covered and time expended in each training session were measured using a GPS Garmin Forerunner 301. Session and microcycle training load were registered by means of session RPE method and fatigue index, respectively (Foster, 1998; Foster et al., 2001). **Results** The athlete did 78 training sessions and two Ultra Trail competitions. He devoted 124 h 55 min to cover 1921.2 km running with a mean speed of 15.4 (SD 1.8) km.h<sup>-1</sup>. Training volume and training intensity decrease along the 13 microcycles of macrocycle. The mean training load was 298.4 (SD 91.1) arbitrary units (AU), ranking from 298 to 454 AU. Monotonia ranked between 0.91 and 4.06. The mean of fatigue index was of 3976.4 (SD 1907.9) AU, ranking from 403 to 6082 AU. Ultra Trail competitions (112 and 96 km) were covered in 28 h 48 min and 13 h 51 min, with a global ascent of 9700 m and 5950 m, respectively. **Discussion** The fatigue index of each microcycle correlates significantly with distance ( $r = 0.76$ ) and time ( $r = 0.77$ ) but not with the mean speed ( $r = -0.34$ ) and monotonia ( $r = 0.47$ ). Correlation was not significant for training volume (distance or time) and microcycle mean speed. The findings suggest that to assess the physical strain of the training load, fatigue index, is more sensitive to microcycles training volume, than to the mean speed. This may allow controlling the dynamics of the training process of the athlete. **References** Foster C. (1998). ## THE EFFECT OF 5 WEEK OF HIGH- INTENSITY TRAINING ON AEROBIC AND ANAEROBIC FIELD TEST PERFORMANCE IN YOUNG FEMALE SOCCER PLAYERS

OLSEN, A., NYGAARD, O., INGEBRIGTSEN, J.

UNIVERSITY OF NORDLAND

**Introduction** Previous studies has shown that high- intensity training (HIT) such as repeated sprint and interval training is important for soccer players (Bradley, et al., 2009), and it has been suggested that HIT can improve physical soccer performance (Bravo, et al., 2008; McMillan, et al., 2005). Also, HIT has proven to better test results in a test of repeated sprint ability (RSA) and Yo-Yo IR1. However, little research on the effect of this type exercise training on young female soccer players exists. Therefore, the aim of this study was to investigate the effect of HIT on RSA and Yo-Yo IR1 in young female soccer players. **Methods** 23 young female soccer players (age 15.7  $\pm$  1.2 y) participated in this study. Pre- and post- tests included a Yo-Yo IR1 test, a test of 6\*25m RSA and 10m and 25m sprint. Further, players were randomly assigned to either the HIT group (TG, n=11) or the control group (CG, n=12) based on their Yo-Yo IR1 performances. TG did 20min of HIT (3x6x25m repeated sprint or 4x3.5min intervals in a soccer specific "dribbling track") twice during their six weekly soccer team practices, while CG continued to do their regular soccer activities. We applied paired t-tests to compare the pre and post test within the groups, while the independent samples t-test were used to evaluate possible differences between groups. Differences were considered significant at  $p < 0.05$  and results are presently expressed as mean  $\pm$  standard deviations (SD). **Results** TG showed significant ( $p < 0.05$ ) improvement in Yo-Yo IR1 (+77.3  $\pm$  37.7m,  $p = 0.03$ ), 10m mean (-0.093  $\pm$  0.006s,  $p = 0.02$ ) and 10m total (-0.464  $\pm$  0.086s,  $p = 0.02$ ) RSA time, and 0-10m sprint time (-0.076  $\pm$  0.001s,  $p = 0.002$ ). CG experienced a significant ( $p < 0.05$ ) decreased performance in 0-10m sprint time (0.211  $\pm$  0.06s,  $p = 0.00$ ). No further significant changes were observed. **Discussion** Present results indicates that 5 weeks of HIT twice weekly cause significant effect on Yo-Yo IR1, 10m mean and 10m total RSA time, and 0-10m sprint time, while not leading to any changes in 25m mean or total RSA time. Changes in 10m performances could be due to an increased amount of high speed acceleration during training compared to previous soccer practices. Based on previous research, these improvements could also indicate an improved ability to perform high- intensity running in soccer matches for the present group of young female soccer players. **References** Bradley, P. ## DELAY EFFECT BETWEEN STRENGTH AND ENDURANCE SEQUENCES DURING A 7-WEEKS CONCURRENT TRAINING.

ROBINEAU, J.

FRENCH RUGBY FEDERATION

**Delay effect between strength and endurance sequences during a 7-weeks concurrent training.** Robineau, J.I, Piscione, J.I, Lacome, M.I, Bigard, X.2, Babault, N.3 1: FFR (Marcoussis, France), 2: CRSSA (Grenoble, France), 3: CEP (Dijon, France) **Introduction** Previous studies emphasised an impairment of strength development following concurrent resistance and endurance training, in comparison to resistance training alone (Hickson, 1980). Because the recovery time between sessions could be a limiting factor of the expected responses to physical training, we aimed to examine the role played by the delay between strength and endurance training sessions on performance (0, 6 and 24h). Therefore, the aim of this research was to identify a training model to optimise strength adaptations induced by concurrent training. **Methods** Twenty five amateur rugby players volunteered for the experiment. Subjects mean ( $\pm$ SD) age, height and mass were 26.4  $\pm$  4.1 yrs, 180.3  $\pm$  7.2 cm and 87.9  $\pm$  11.0 kg, respectively. They were shared out three 7-weeks concurrent training groups with strength performed first and followed immediately (0h), 6h or 24h by endurance training. Strength training consisted in 3-4 sets of 3-10 RM for bench press (BP), bench row (BR), half-squat (HS) and leg press exercises. Endurance training aimed to develop aerobic maximal power using intermittent running exercises (15/15s). Training sessions were performed twice a week. Muscular strength was evaluated before (pre) and after (post) each 7-weeks training period. The 1RM was evaluated on BP, BR and HS exercises. Power of the lower limb was determined during counter movement jumps (CMJ) using an Optojump system (Microgate, Italy). Muscular endurance has been evalu-

ated through 20 maximal isometric knee extensions, (75°, 5s contraction and 15s recovery) on an isokinetic dynamometer (Contrex, Switzerland). Results Significant increases were observed, between pre and post training ( $p < 0.05$ ), for BP ( $10.7 \pm 7.2\%$ ), BR ( $11.8 \pm 7.7\%$ ), HS ( $25.2 \pm 18.2\%$ ) and CMJ ( $7.8 \pm 9.1\%$ ). No significant difference was found for muscular endurance between pre and post training. However, there was no significant effect of the time recovery on responses to physical training. Discussion Our study highlighted strength gains of both lower and upper-limb, following the 7-week period, independently of the delay between strength and endurance sessions. In contrast, muscular endurance failed to be improved after the 3 concurrent training models. In conclusion, the between-sessions delay (0, 6 and 24h) did not seem to markedly affect the neuromuscular responses to concurrent training. References Hickson RC. (1980). ## WALKING TRAINING PROGRAM AND ITS INFLUENCE ON AEROBIC FITNESS AND BODY COMPOSITION IN SENIOR WOMEN

BUNC, V.

*FACULTY OF P.E. AND SPORTS CHARLES UNIVERSITY*

**WALKING TRAINING PROGRAM AND ITS INFLUENCE ON AEROBIC FITNESS AND BODY COMPOSITION IN SENIOR WOMEN** Bunc, V., Štilec, M. UK FTVS (Prague, Czech Republic) Introduction An effect of physical exercise may be assessed by level of aerobic fitness (AF) and body composition (BC). Dynamic work of cyclic character like walking or running requires the large muscle masses and thus the changes of actual state could be the biggest. The walking is probably the most easily accessible, and often underestimated as a general way to increase a subject's level of AF and improvement of BC. The aim of this study was to verify the moving programme based on walking for influence AF, and BC in women seniors. Method The exercise intensity (minimally of 90% was walking) at a level of 50 to 70% VO<sub>2</sub>max (HR ranged from 65 to 85 % of HRmax) was used in a group healthy senior women ( $n=53$ , age= $68.7 \pm 5.0$  years, BM= $69.9 \pm 7.9$  kg, height= $161.0 \pm 2.8$  cm, %BF= $37.5 \pm 5.1\%$ , VO<sub>2</sub>max.kg<sup>-1</sup>= $25.9 \pm 4.3$  ml.kg<sup>-1</sup>.min<sup>-1</sup>). The time of exercise session ranged from 20 to 50 min, and exercise was performed 3-5 times a week. The time spent by exercise per week ranged between 90-250 min (mean  $156.8 \pm 48.9$  min). Walking time ranged between 82-233 min (mean  $142.8 \pm 45.7$  min). Results The energy output of exercise ranged from 650 kcal (2675 kJ) to 1780 kcal (7740 kJ) (mean  $950 \pm 230$  kcal -  $3970 \pm 960$  kJ) per week. After 6 months of training, non-significant BM increase (mean  $0.8 \pm 1.7$  kg), %BF decrease ( $0.6 \pm 1.5\%$ ;  $1.6 \pm 2.2\%$ ; NS), and BCM increase ( $2.3 \pm 1.7$  kg;  $10.0 \pm 2.3\%$ ;  $p < 0.01$ ) was found. VO<sub>2</sub>max increased significantly by  $2.1 \pm 1.2$  ml.kg<sup>-1</sup>.min<sup>-1</sup>;  $8.0 \pm 3.3\%$ ; ( $p < 0.01$ ) of initial value. Similarly was increased the v<sub>max</sub> of walking by  $0.5 \pm 0.3$  km.h<sup>-1</sup>;  $7.8 \pm 1.5\%$ ; ( $p < 0.01$ ) of starting value. Discussion Major advantage with walking over running is that it has a lower frequency of injuries and that in a group of patients the probability of exceeding of security level is lower than in running. FFM is significantly lower in elderly women than in younger women, and it is estimated that FFM decreases 3kg per decade, on average, in middle-aged to elderly sedentary healthy adults. This loss is almost 1-1/2 times as great in men as women, because men were found to lose FFM at the rate of 0.34 kg.year<sup>-1</sup> whereas women lost FFM at the rate of 0.22 kg.year<sup>-1</sup>. Between 40 and 80 years of age, men lose FFM at the rate of 5% each decade, whereas women lose about 2.5% FFM each decade. At these rates, men and women lose approximately 20% and 10% of total FFM, respectively, between ages 40 and 80 years. After the 6 months of aerobic training the values of AF were significantly better than Czech population standards, and data of BC non-significantly were improved. Conclusions We may conclude that physical exercise realized mainly by walking lasting 6 months with total energy content of 950 kcal (3970 kJ) during a week is enough for significant improvement of AF and BC in senior women. The study was supported by grant of Czech Ministry of Education MSM 0021620864

## COMPARISON OF THE EFFECTS OF ISOKINETIC VS ISOTONIC ECCENTRIC TRAINING ON MUSCLE STRENGTH AND MASS.

CORATELLA, G., IMPELLIZZERI, F.M., SCHENA, F.

*UNIVERSITY OF VERONA*

**Introduction** Eccentric(ECC) training has been shown to induce higher improvements than concentric training on muscle strength and mass (Roig, 2009).The majority of the studies have used isokinetic (ISOK) dynamometers for investigating the acute and chronic effects of ECC training. However, isotonic (ISOT) devices are more commonly available in real sport setting. Aim of the study was to compare ISOK to ISOT ECC training by assessing the effects on muscle strength and mass. **Methods** Forty-nine healthy sport science students were randomly divided in 3 groups: isokinetic eccentric training (ISOK,  $n=14$ ), isotonic eccentric training (ISOT,  $n=17$ ) and control group (CON,  $n=18$ ).Both training groups performed 50 ECC repetitions of knee extension at 120% of their maximal strength measured in concentric modality (1RM for ISOT and peak concentric torque for ISOK), for a total of 14 times in 6 weeks. Isometric maximal voluntary contraction (MVC), concentric and eccentric strength at 60 °/s, 1RM, and muscle mass (using DEXA) were measured pre and post training. All dependent variables were analyzed after log transformation using ANCOVA,entering the baseline values as covariate and factor "group" as independent variable. **Results** Compare to CON,the ISOK group showed higher 1RM (12%, CI95% 6 to 19%), concentric (15%, 8 to 22%), eccentric (35%, 25 to 45%) and isometric (25%, 18 to 34%) maximal strength ( $P < 0.001$ ). Compare to CON, ISOT showed higher 1RM (14%, 9 to 20%), concentric (17%, 11 to 24%), eccentric (25%, 16 to 34%) and isometric (22%, 15 to 29%) maximal strength ( $P < 0.001$ ). No differences between ISOK and ISOT were found in 1RM (2%, -3 to 7%), concentric (-2%, -4 to 8%) and isometric (-3%, -8 to 3%) maximal strength. Only eccentric strength was higher in the ISOK compare to the ISOT group (8%, 1to 14%). No differences between groups were found in muscle mass( $0.419 < P < 0.769$ ). **Discussion** This study showed that ECC training using both ISOK and ISOT improved maximal strength in physically active people. The lack of muscle mass changes suggests that the increase in muscle strength was mainly due to neural adaptations (Hortobagyi, 1996).ISOK showed higher improvement in ECC strength measured on the isokinetic dynamometer but this may be due to similarity between testing and training conditions. Nevertheless, considering ISOT devices are more easily available, this training modality seems to be a good alternative to ECC training using isokinetic dynamometers. References Roig et al., 2009, Br J Sports Med 43(8): 556-68. Hortobágyi et al.,J Appl Physiol. 1996 Oct;81(4):1677-82.

## EFFECT OF HIGH-INTENSITY SPRINT TRAINING WITH ACTIVE RECOVERY ON AEROBIC ENERGY SYSTEM AND PERFORMANCE DURING EXERCISE

OMORI, K.I, OKUMOTO, T.2

*1:SURUGADAI UNIVERSITY (SAITAMA, JAPAN), 2:UNIVERSITY OF EAST ASIA (YAMAGICHI, JAPAN)*

[Introduction] Active recovery (AR) after high-intensity exercise enhances blood lactate removal (Bonen and Belcastro 1976; Gisolfi et al. 1966). However, no study has examined the efficacy of AR during high-intensity exercise training. In this study, we investigated training

effects with respect to the presence or absence of AR during high-intensity exercise training. [Methods] We divided 12 college soccer players into 2 groups: a group in which AR at an intensity of 80% lactate threshold (LT) was continued for 20 minutes after sprinting at 130 to 150% VO<sub>2</sub>peak (n=6, AR group), and a group in which subjects rested in a seated position for 20 minutes after a similar sprint (n=6, passive recovery (PR) group). Such sprint training was conducted 5 times a week for 6 weeks. The VO<sub>2</sub>peak, LT and OBLA running velocity were measured before and after training. The subjects were also instructed to sprint at an intensity of 130 to 150% VO<sub>2</sub>peak until they become exhausted before and after training. We measured the duration of exercise and total oxygen consumption during sprinting. [Results] In the two groups, the duration of exercise significantly increased after training (PR group: from 130.0±18.0 to 145.8±20.0 seconds, AR group: from 130.0±30.6 to 156.7±37.8 seconds, p<0.05). At this time, the rate of increase in the duration of exercise was greater in the AR group (p=0.06). Similarly, the total oxygen consumption during sprinting significantly increased after training in the two groups. However, the increase was more marked in the AR group (p=0.07). Both the LT and OBLA velocity in the AR group significantly increased after training (p<0.05), but there were no changes in the LT or OBLA velocity in the PR group. [Discussion] The rate of increase in performance after training was larger in the AR group. At this time, the AR group showed a more marked increase in the total oxygen consumption during sprinting. Therefore, in this group, the aerobic energy system during sprinting may have been greater than in the PR group. In the AR group, the LT and OBLA velocity increased after training. Therefore, improvement in the oxidation capacity of lactate and pyruvate may have contributed to the increase in the total oxygen consumption during sprinting in the AR group (Bergman et al., 1999; Burgomaster et al., 2006). These results suggest that sprint training with AR improves the aerobic energy system and performance during exercise in comparison with AR-free training. ### THE EXECUTION OF WUSHU FORMS MEETS THE INTENSITY RECOMMENDATIONS FOR THE DEVELOPMENT OF AEROBIC FITNESS

SCHWARTZ, J.1,2, PURIFICAÇÃO, S.1, CARVALHO, G.B.1, SOUSA, P.C.R.3, FRANCHINI, E.2

1: CITY UNIVERSITY OF SAO PAULO (BRAZIL), 2: MARTIAL ARTS AND COMBAT SPORTS RESEARCH GROUP, SCHOOL OF PHYSICAL EDUCATION AND SPORT, UNIVERSITY OF SAO PAULO (BRAZIL), 3: BRAZILIAN WUSHU CONFEDERATION

**Objective** The wushu practice basically involves fighting (sanshou) and the execution of forms (taolus), both handsfree and with the use of implements. Being the wushu increasingly practiced, and given the high rates of physical inactivity among the population, this modality, specifically taolu, may be an interesting strategy to engage people in the appropriate amount of exercise (Haskell et al., 2007). Thus, the purpose of this study was to verify whether the practice of the taolus – with and without weapons – result in heart rate values (HR) compatible with the recommendation of the ACSM (2006). **Methods** The sample included six subjects (male and female), all members of the Brazilian taolu team (age: 22.3±4.3 years, body mass: 61.5±10.6 kg, height: 163.3±7.6 cm; VO<sub>2</sub>peak: 48.8±7.5 ml/kg/min, years of experience: 9.1±5.1, practice time per week: 15±5 h; HRmax: 191±8 bpm). The participants underwent a maximal graded test with a gas analyzer (Aerograph VO2000), in a motorized treadmill (ATL Inbrasport) and performed two taolus, handsfree (HF) and with short weapons (SW). The taolus were performed in different days, but at the same time of the day, and at the subject's regular practice place. The HR was monitored by heart rate monitor (Polar s610). The conditions were compared using a Student t test for paired data. **Results** The values (mean and standard deviation) of HR (bpm) in the taolus were: HF – 174±9.65 and SW – 171.5±13.59. As a percentage of HRmax, these figures represented: HF – 91.78±2.52 and SW – 90.71±3.85. No significant differences were found between both absolute and relative values (p> 0.05). **Discussion** It was noted that all athletes have reached the heart rate values recommended by the ACSM (2006) for improving aerobic fitness in both taolus. Therefore, according to the data from the sample in question, regardless of the use of short weapons, the practice of taolu can contribute to the improvement or maintenance of cardiorespiratory fitness. Similar results were found in studies cited by Tsang et al. (2008), who analyzed the performance of the mode's specific techniques. **References** American College of Sports Medicine (ACSM) (2006). *Guidelines for Exercise Testing and Prescription*, 141-142. ### PP-PM48 Rehabilitation 1

#### A NOVEL SHOULDERS TRAINING/REHABILITATION DEVICE BASED ON THE CONCEPT OF PERCENT OF MUSCULAR ACTIVATION

BUI, H.T.1, DUCHESNE, S.2, DESJARDINS, P.1, COMTOIS, A.S.3, LEONE, M.1

1UNIVERSITÉ DU QUÉBEC À CHICOUTIMI, 2CEME ERGONOMIE, 3UNIVERSITÉ DU QUÉBEC À MONTRÉAL

**Introduction** For most training/rehabilitation devices, the external load is calculated on the basis of the "one repetition maximal" (1 RM). Recently, a new concept has been tested using electromyogram signal (EMG) that activate a motor unit in order to assist the participant during four different shoulder movements: flexion, extension, abduction and adduction. The assistance begins when a predetermine percent of the maximal muscle activation (PMA) of the shoulder is reach. The EMG is used as a monitoring system to ensure that the participant works within the prescribed workload. That is, when the participant's muscular efforts surpass a certain threshold, the system will automatically and progressively reduce the load to bring the deployed effort back into the desired zone. To do so, each training session must begin by determining the EMG level corresponding to the participant's maximum effort assessed during a maximal isometric contraction for each of the four movements. Depending on the goal of training, a participant may be prescribed to work at a given percentage of is maximum values. The system will monitor the EMG signal during normal exercise, and when it surpasses the limit, the desired weight will be decreased. When the EMG signal is below the prescribed threshold, the operation of the system continues normally. **Methods** 8 healthy active adults (4 men and 4 women, mean age 34.8.1±17.2 years old) were trained 3 times a week for a period of 8 weeks. Each training session last 45 minutes during which, four exercises have been realize. The maximal isometric contractions (kg) were measured for each training session for the shoulder flexion and abduction. During this process, percent of maximal muscle activation was recorded via the EMG and the percent of workload fixed at 80% of the PMA. **Results** After 8 weeks of training, a significant strength gain of 11.8% and 26.3% respectively for right and left shoulder flexion and 14.0% and 25.5% respectively for right and left shoul-

der abduction. Likewise, the assistance of the motor unit dropped by an average of  $\approx 15.0\%$  by the end of the 8 weeks training. Discussion The EMG feedback system seems to be an attractive procedure to modulate strength muscular training. The present results are particularly interesting because all participants were trained persons. The impressive gains on the left shoulder (weakest one), as much as for flexion as for abduction, suggest that injured patients could find a particular benefit by using that device. The drop of the motor assistance was also an objective measurement of strength improvement. Conclusions The EMG feedback system appears to be an innovative and effective way to train healthy or injured shoulders.

### PREDICTORS OF RISKY REHABILITATION BEHAVIORS AMONG US COLLEGIATE ATHLETES

PODLOG, L., KENOW, L., TAI, Y.L., GRANQUIST, M., JOHNSON, U., IVARSSON, A.

UNIVERSITY OF UTAH AND THE GERMAN SPORT UNIVERSITY

Competitive athletes may risk their health and well-being in an attempt to return to sport following injury (Charlesworth, & Young, 2004). The purpose of this study was to examine whether impression management concerns and a high athletic identity were associated with risky rehabilitation behaviors (e.g., overdoing rehabilitation) and a willingness to make a premature return to sport. Sixty-seven (32 males and 35 females) NCAA Division I, II and III collegiate athletes from the United States completed measures assessing impression management concerns, athletic identity, risky rehabilitation behaviors and beliefs, and a willingness to make a premature return to sport. Impression management concerns about appearing athletically untalented (AAU,  $\alpha = .93$ ), physical appearance (PA,  $\alpha = .73$ ), fatigued/lacking in energy (FLE,  $\alpha = .97$ ), and mental composure inadequacies (MCI,  $\alpha = .88$ ) were assessed using the Self-Presentation in Sport Questionnaire (SPSQ). Athletic Identity was measured using the Athletic Identity Measurement Scale (AIMS;  $\alpha = .84$ ). Injury risk behaviors were measured using the Rehabilitation Behaviors and Beliefs Questionnaire (RBBQ) and a modified version of the Injury Psychological Readiness to Return to Sport Scale (I-PPRS;  $\alpha = .88$ ). As the RBBQ was a novel instrument, an exploratory factor analysis (EFA) was conducted. EFA results indicated two distinct interpretable factors with eigenvalues exceeding 1.0—Ignoring Medical Recommendations (RBBQ-IMR,  $\alpha = .93$ ) and Attempting an Expedited Rehabilitation (RBBQ-AER,  $\alpha = .75$ ). Subsequent correlational analysis revealed significant correlations between PA ( $r = .50$ ,  $p < .01$ ), FLE ( $r = .38$ ,  $p < .01$ ), MCI ( $r = .40$ ,  $p < .01$ ), AIMS ( $r = .27$ ,  $p < .05$ ) and the IMR factor. In addition, PA was positively correlated with risking a premature return (I-PPRS;  $r = .25$ ,  $p < .01$ ). Finally, linear multiple regression analyses indicated that PA predicted 29.2% (23.4 % adjusted) of the variance in risky rehabilitation behaviors and beliefs (RBBQ-IMR;  $\beta = .328$ ,  $p < .05$ ). These findings suggest that athletes with impression management concerns and a high athletic identity may be more likely to ignore medical recommendations such as avoiding specific activities/exercises and by hiding pain. A focus on diminishing physical appearance concerns and mental composure inadequacies may be useful in minimizing engagement in risky rehabilitation behaviors. To this end, medical practitioners may wish to employ confidence building techniques such as relaxation, imagery, and goal-setting. Charlesworth, H., & Young, K. (2004). Why English female university athletes play with pain: motivations and rationalizations. In K. Young (Ed.), *Sporting bodies, damaged selves: Sociological studies of sports-related injury* (pp. 163-180). Oxford, UK: Elsevier.

### THE EFFECT OF A PROGRAMME OF SWISS BALL EXERCISES ON SOME OF PHYSICAL FITNESS ELEMENTS AS A TRAINING STYLE OF PHYSICAL PREPARATION FOR EGYPTIAN FENCERS.

ABOALMATY, H.

TANTA UNIVERSITY

THE EFFECT OF A PROGRAMME OF SWISS BALL EXERCISES ON SOME OF PHYSICAL FITNESS ELEMENTS AS A TRAINING STYLE OF PHYSICAL PREPARATION FOR EGYPTIAN FENCERS. Heba Abu El-Maaty, Lecturer in Sports Training Dept. Faculty of Physical Education /Tanta University (Tanta, Egypt). Introduction Exercise is considered to be one of the most important factors of developing the body's vital systems, especially the neuromuscular system along with the circulatory and respiratory systems, which lead to improving functional performance (Elhagrsy, 2004; Saad Eldin, 2001). Swiss balls are one of today's top fitness tools. Since the Swiss ball is unstable, balance need to be adjusted constantly, this in turn improves proprioception and flexibility. Using the Swiss balls during fencing training in regular basis will develop many of the physical qualities such as muscular strength and endurance, agility, balance and coordination. Moreover, it aid in improving the fencers' psychological state and temperament (Mousa, 2006). Despite the significance of using Swiss balls during fencing training, there has been no any publication or assessment to date of its effect on the physical and psychological fitness of Egyptian fencers. Therefore, this study was undertaken. Methods Of the 12 Egyptian fencers from Muslim Youth Club team in Tanta (Egypt), 8 fencers were included in performing the experiment. The Restameter was used for measuring the body's total height in centimetres, standardised medical scales for measuring weight in kilogrammes, a stopwatch for measuring time to the closest 1/100 second, 10 Swiss balls were enough to suit the study sample. T test was used to measure the element of physical fitness. Results The arms' muscular strength variable in the pre-training was 3.74 times while in post-training was 5.52 times whereas the legs' muscular strength in the pre was 60.55 cm and in the post was 75.00 cm. Coordination in the pre was 6.20 degrees and in the post was 9.00 degrees. Abdominal muscles endurance variable in the pre was 5.18 counts and was 8.88 counts in the post, while back muscles endurance in the pre was 3.80 counts and 6.96 counts in the post. Static balance in the pre was 4.14 second and was 8.33 second in the post. Agility in the pre was 3.78 degrees and 5.52 degrees in the post. Discussion This study found that exercise program using Swiss balls has significant effect in improving some of the element of physical fitness as (arms' muscular strength – legs' muscular strength – muscular endurance of abdomen muscles – muscular endurance of back muscles – balance –agility) of Egyptian fencers. It also has significant effect in improving Egyptian fencers' physical performance during training and competitions. References Elhagrsy S, (2004). *Swiss Ball: for Strength, Tone and Posture*. ### EFFECTS OF ENDURANCE AND STRENGTH TRAINING IN REHABILITATION OF WOMEN WHO HAVE FINISHED TREATMENT FOR GYNAECOLOGICAL CANCER, - A RANDOMIZED TRIAL.

HAUSMANN, F.1, IVERSEN, V.V.1, SEKSE, R.J.T.2, VIK, M.2

1 DEPARTMENT OF SPORT AND PHYSICAL EDUCATION, BERGEN UNIVERSITY COLLEGE, BERGEN; NORWAY, 2 HAUKELAND UNIVERSITY HOSPITAL, BERGEN / UNIVERSITY OF BERGEN; NORWAY

Introduction Previous studies have shown that participation in physical training and educational and counseling groups may have positive effects on quality of life and coping for women treated for gynaecological cancer. However, as far as we know no RCT has measured and compared the effects of both physical training groups with those of educational and counseling groups for women's self reported

quality of life and coping. In this study there are two interventions. In the following the intervention physical training in groups will be presented. The purpose of this study intervention is to evaluate the effect of endurance and strength training in group for women treated for gynaecological cancer. Methods: Subjects: Women who completed curative treatment for gynaecological cancer at Kvinneklínikken, Haukeland University Hospital, Bergen, between January 2007 and June 2011. This study has a randomized controlled design: 1) Physical training in group, 2) Education and counseling groups, 3) Controlled group. The participants completed measurement three times, at pre-intervention, post-intervention and after one year. All the participants were measured for VO<sub>2</sub>peak by a walking treadmill test in addition to measurements of maximal strength; leg press, leg extension and chest press. Oxygen consumption was measured using a Jaeger Oxycon Pro in mixing chamber mode (Jaeger, Germany). The physical training group had two sessions a week (90 min) for 16 weeks. The group training was carried out in a gym to music as follows; warmup (15 min), endurance training (25 min) moderate to hard intensity, strength training (25 min) and finally stretching and relaxation with focus on body awareness (25 min). The strength training was performed using simple tools such as elastic ropes and weights. Other outcome variables: quality of life (global and health related), coping, fatigue, sexuality, anxiety and depression. Results: Preliminary data will be presented. Conclusion: Of about 300 women that were invited to participate in the study, 50 women volunteered. So far, three groups have concluded the physical training program and a 4th group has just started in Bergen. To include sufficient participants as estimated in power analysis, the study has just been extended to become a multicenter study. It now includes two other health regions in Norway; Stavanger and Kristiansand besides Bergen.

### INTENSITY/DURATION OF GAIT TRAINING & PRACTICE DURING INPATIENT REHABILITATION OF STROKE SURVIVORS

GERRITS, K.H.L., VAN NUNEN, M., PIJERS, E., VAN DER WOUDE, L.H.V.

RESEARCH INSTITUTE MOVE, VU UNIVERSITY AMSTERDAM

Intensity/duration of gait training & practice during inpatient rehabilitation of stroke survivors K.H.L. Gerrits(a), M. van Nunen(a), E. Pijpers(b), and L.H.V. van der Woude(b) a) Research Institute MOVE, Faculty of Human Movement Sciences, VU University Amsterdam; b) Center for Human Movement Sciences, Center for Rehabilitation, University Medical Center Groningen, the Netherlands Introduction. An important goal of stroke rehabilitation is improving/restoring walking ability. It has been suggested that stroke rehabilitation should be intensive and task specific to reach optimal outcomes of activities of daily living (ADL) including gait (1). Yet, it is unclear how intense, in terms of duration and cardio-metabolic intensity, stroke survivors practice their walking ability during therapy and daily life of inpatient rehabilitation (in the Netherlands). Therefore, the present study describes the duration and intensity of walking during gait training and during daily activities of the clinical rehabilitation in stroke patients and investigates whether these relate to functional ability. Methods. The local ethical committee approved this study, which included a convenience sample of patients with stroke (n=17), who were inpatients of Reade (Amsterdam, the Netherlands). During the day (8 hours) and for an observation period of 4 consecutive days, the amount of time spent on walking activities was monitored with an activity monitor (activPAL, PAL Technologies Ltd). In the same time period, and during one session of gait training, heart rate was monitored (Polar) and used to 1) determine % heart rate reserve (%HRR) and 2) calculate the % of time in which HRR exceeded 40%HRR (%T>40). Because of possible confounding effects, data were analyzed for patients that did (B+, n=6) or did not (B-, n=11) use beta-blocking medication. Results. The mean time spent on walking activities in B+ (38±34 min.day<sup>-1</sup>) was not different from B- (61±55 min.day<sup>-1</sup>). Across groups, high and significant correlations were found between duration of walking and functional ability (r=0.59-0.91, P<0.05). Intensity of walking was significantly (P<0.05) higher in B- compared to B+ across a 4-day period (37±12% versus 21±7% HRR, respectively) as well as during the gait training session (40±13% HRR versus 23±8% HRR, respectively, P<0.05). Intensity of walking was not related to functional activities. Finally, the %T>40 during 4 days of monitoring was significantly higher in B- (9±10%) compared to B+ (0.2±0.4%). Conclusion. These results indicate that although patients practice walking for on average 0.5-1 hour.day<sup>-1</sup>, at a sufficiently high intensity (>40% HRR, AHA guidelines for stroke survivors), the total amount of time in which intensity exceeds the appropriate training intensity is very limited. Current rehabilitation programs should therefore increase the time spent on gait training/practice and stimulate an active lifestyle. 1) Kwakkel G. et al. Stroke. 2004 Nov;35(11):2529-39.

### THE EFFECT OF LOW-VOLUME ENDURANCE AND STRENGTH TRAINING ON MUSCLE PHOSPHOCREATINE RECOVERY AND PERFUSION DURING 3-WEEK UPPER LIMB IMMOBILIZATION

NAKAMURA, F., HAMAOKA, T., OSADA, T., MURASE, N., KIME, R., HOMMA, T., KUROSAWA, Y., ESAKI, K., SHIROISHI, K., ICHIMURA, S., KATSUMURA, T.

COMMUNITY HEALTH PROMOTION CENTER

Introduction During a 3-week upper limb immobilization (3W-IMM), muscle phosphocreatine (PCr) recovery after submaximal exercise (SubEx) was delayed (Kitahara et al, 2003; Homma et al, 2009) and the brachial artery peak blood flow (BF) was decreased (Ohmori et al, 2010). However, it is unclear whether the delayed PCr recovery is due to a blunted BF response. Therefore, we examined the relationship between the delayed PCr recovery and muscle perfusion and the effect of exercise training on PCr and BF. Methods Twenty-one male volunteers participated in the experiment after having been approved by the institutional ethical committee and obtained a written informed consent. They were divided into three groups (Immobilization, IMM-G (n=7); IMM with endurance and strength training of twice weekly, TR-G (n=7); and control, CNT (n=7)). Strength training consisted of intermittent isometric (2 sec on / 2 sec off) contractions (70% of maximum voluntary contraction (MVC), 10 times), whilst exhaustive exercise (EEx) training consisted of contractions with one repetition per 1 sec. at 30% MVC. Non-dominant arm was immobilized with a cast for 3 weeks. Exercise training was performed during 3W-IMM once weekly. SubEx test at a frequency of one contraction every 4 s at the 40% MVC, EEx test and MVC measurement were performed before and after 3W-IMM. The time constant for PCr recovery (PCrTc) was examined using <sup>31</sup>-phosphorus magnetic resonance spectroscopy after SubEx with no pH drop. The blood velocity and vessel diameter (D) of the brachial artery were measured using ultrasound Doppler and B-mode methods at rest and immediately after SubEx test. BF was calculated from the blood velocity and D. Results In the TR-G, the training was effective for preventing the decrease in MVC. EEx performance showed no significant interaction between the groups. A significant delay was found in PCrTc in the IMM-G (p < 0.05) and a protective effect in the TR-G. No significant IMM interaction was found for BF after SubEx between the groups. Discussion The delay of PCr recovery induced by the 3W-IMM was not associated with muscle perfusion, but presumably related to intrinsic factors such as attenuated muscle oxidative capacity. The endurance and strength training used in this study was effective for preventing delayed PCr recovery. References Kitahara et al. (2003). Med Sci Sports Exerc, 35, 1697-702. Homma et al. (2009). ## DOSE-RESPONSE EVALUATION OF EXERCISE PROGRAMS IN THE EARLY REHABILITATION PHASE FOLLOWING KNEE AND HIP ARTHROPLASTY

ZECH, A.1, HENDRICH, S.2, SCHMITT, B.3, PFEIFER, K.2

1:UNIVERSITY OF HAMBURG, 2:UNIVERSITY OF ERLANGEN-NUREMBERG, 3:KAISERBERGKLINIK BAD NAUHEIM

**Introduction** Rehabilitation programs following knee and hip arthroplasty predominantly focus on strengthening and functional exercises. However, although exercise programs are generally considered essential for regaining joint stability and mobility in daily living, the dose-response relationship between exercise load and functional improvements remains questionable. In this study, we evaluated the dose-response relationship of exercise programs in the early rehabilitation phase following knee and hip arthroplasty. **Methods** 65 patients with elective total hip or total knee replacement were included in this cohort study. All participants underwent a postoperative rehabilitation program in the same setting. Functional outcomes were assessed at the first as well as at the last day of the exercise intervention program. Additionally, type, intensity (Borg scale 6-20), duration and frequency of exercise interventions were recorded by using rehabilitation and training diaries. The primary outcome was physical function (Western Ontario and McMaster Universities Arthritis Index = WOMAC). Secondary outcomes were the SF36 and the hip or knee range of motion. Linear regression analysis with multiple independent variables (e.g. intensity, frequency) was performed to assess the dose-response relationship between the intervention dosage and changes in the primary and secondary outcomes. **Results** The mean duration of the exercise program was  $18.9 \pm 3$  days for hip and  $14.7 \pm 2.4$  days for knee patients with a frequency of 6 days per week and an intensity of Borg  $11 \pm 1$  (hip) or  $12 \pm 1$  (knee). Participants performed strength, functional, mobility and flexibility exercises in group or individual training sessions. The physical function (hip:  $14.1 \pm 31.8\%$ , knee:  $19.8 \pm 8.0\%$ ) and range of motion ( $11.1 \pm 10.7\%$ ,  $6.7 \pm 12.1\%$ ) improved significantly ( $p < 0.05$ ) in both patient groups. Multiple regression analysis revealed that there was no association between changes in these outcomes and duration, intensity, frequency or type of exercise. **Conclusions** Although the participants improved their physical function and range of motion throughout the early rehabilitation phase, no association was found between changes in these outcomes and the intervention dose. This implies that the postoperative exercise therapy had little impact on the changes in function or mobility. However, these findings should be viewed cautiously as the overall exercise intensity might have been too small for training-induced structural or functional adaptations. In future, randomized controlled trials are needed to establish dose-response effects of exercise programs after knee and hip arthroplasty.

## THE EFFECT OF SELF-PACED WALKING ON PSYCHOLOGICAL AND PERFORMANCE MARKERS IN PHASE II AND III CARDIAC REHABILITATION PATIENTS WITH MODERATE TO HIGH LEVELS OF ANXIETY

FAULKNER, J., WESTRUPP, N., ROUSSEAU, J., LARK, S.

MASSEY UNIVERSITY

**Introduction** Greater attention is necessary to detect and treat anxiety with cardiac rehabilitation (CR) patients (Lavie & Milani, 2004). The purpose of this study was to assess whether a short-term, self-paced walking programme reduces anxiety, improves self-confidence and elicits physiological and perceptual benefits to phase II and III CR patients. **Methods** As a pre-requisite for recruitment, all participants experienced moderate to high levels of anxiety, according to the modified Hospital Anxiety and Depression Scale (HADS; Zigmond & Snaith, 1983), when considering the prospect of walking. Twenty-two CR patients completed a HADS, exercise self-efficacy (ESE) questionnaire and two walking tests (Incremental shuttle walking test [ISWT]; 1.6 km assessment walk) during a baseline assessment. Participants were randomized to either standard CR care (cycle exercise; control group [CG];  $n = 11$ ) or a walking programme (WP;  $n = 11$ ). The WP involved a 1.6 km self-paced walk on a variable topographic course, twice a week for 6 weeks. Post-intervention assessments replicated the baseline assessment. A series of repeated measures ANOVAs (Condition [CG, WP] x Test [Baseline, post-intervention]) were used to analyse the data. **Results** A Condition by Test interaction for anxiety revealed a significantly greater reduction in anxiety from the baseline to the post-intervention assessment for WP ( $7.9 \pm 1.5$  v  $3.9 \pm 1.9$ ) compared to CG ( $8.1 \pm 1.9$  v  $6.8 \pm 2.7$ ) ( $P < .01$ ). A similar interaction was observed for ESE, with significant improvements in walking confidence observed for WP ( $78.1 \pm 22.8\%$  v  $84.7 \pm 21.7\%$ ) but not for CG ( $76.1 \pm 22.8\%$  v  $69.7 \pm 21.7\%$ ) ( $P < .01$ ). There were, however, no statistical differences in heart rate, ratings of perceived exertion (RPE), and exercise duration for the ISWT between conditions ( $P > .05$ ). Nevertheless, participants randomised to the WP not only reduced the time to complete the 1.6 km assessment walk from the baseline to post-intervention assessment (19 min 32 s v 18 min 16 s, respectively;  $P < .01$ ), they also significantly reduced their RPE ( $11.5 \pm 1.4$  v  $10.9 \pm 1.3$ , respectively;  $P < .01$ ). Such findings were not observed for CG. **Discussion** This study provides evidence that a 6-week self-paced walking programme can reduce anxiety and improve self-confidence in phase II and III cardiac rehabilitation patients. The study also demonstrates that patients can complete a set amount of work (1.6 km walk) at a higher relative intensity without inducing increases in the perception of exertion following a 6-week walking programme. **References** Lavie C, Milani, R. (2004). The American Journal of Cardiology, 93, 336-339. Zigmond AS, Snaith RP. (1983). Acta Psychiatrica Scandinavica, 67, 361-370.

## BETTER CARE THROUGH PHYSICAL ACTIVITY? – EFFECTS OF AN EXERCISE INTERVENTION FOR PATIENTS WITH CHD WITHIN A DISEASE MANAGEMENT PROGRAM

ECKERT, K.1, LANGE, M.1, HUBER, G.2, WAGNER, P.1

1:UNIVERSITY OF LEIPZIG, 2: UNIVERSITY OF HEIDELBERG

**Introduction** Disease management programs (DMPs) have been established in Germany in 2002 with the goal to meet the growing requirements for an efficient health care for chronic patients. So far DMPs exist for the indications coronary heart disease (CHD), diabetes mellitus type-1/2, asthma, chronic obstructive pulmonary disease and breast cancer. Exercise interventions don't rate among the main treatment methods used in DMPs up to now, although the evidence of physical activity as a therapeutic mean is given (Capewell et al., 2010). Therefore this analysis deals with the effects of a behaviour-oriented exercise intervention within the framework of a DMP for CHD. **Methods** A total of  $n=98$  (age:  $65.2 \pm 6.6$ ; BMI:  $32.89 \pm 4.03$ ) adults participated in the controlled intervention study (IG=75; CG=23). The exercise program took place once a week (á 90 min.) for a period of 10 weeks. With a pre- (t1) and posttest (t2) data of health related quality of life (HRQoL) (Bullinger&Kirchberger, 1998), of physical activity levels (Frey et al., 1999) and of exercise self-efficacy (Lippke et al., 2005) has been assessed through questionnaires. Additionally the BMI and the endurance capacity through a 2km Walktest were documented. **Results** 86 completed data sheets (t1-t2) could be included in the analysis. The following results have been found: • Significant improvements ( $p < .001$ ) could be found by measuring the HRQoL in the subscale 'physical functioning' and 'pain' in the IG ( $n=66$ ). • The participants in the IG increased their health related activity level (leisure time) statistical significant and practical relevant ( $p < .05$ ;  $d=0.35$ ) over the time, the CG showed no changes. • The IG showed significant improvements in the 2km Walktest ( $p < .001$ ), whereas the CG

remained inconspicuous. Discussion The results proof that a multi-dimensional exercise intervention within a DMP for CHD has a positive impact on the endurance capacity, the physical activity level and the HRQoL. The revealed effects are first indicators, that the integration of exercise interventions into DMPs provide an important contribution to improve the health care quality. Further research with a larger sample is needed to proof these results as well as the verification of the longterm effects of such a program. References Bullinger M & Kirchberger I (1998). ### INTELLIGENT PHYSICAL EXERCISE AT WORK: EFFECT OF SUPERVISION ON MOTIVATION AND REDUCTION IN NECK-SHOULDER PAIN? RESULT FROM VIMS-STUDY.

GRAM, B.1, ZEBIS, M.K.1, PEDERSEN, M.T.2, ANDERSEN, L.L.2, SJØGAARD, G.1

1. UNIVERSITY OF SOUTHERN DENMARK, 2. INST. OF EXERCISE AND SPORT SCIENCES, UNIVERSITY OF COPENHAGEN, DENMARK, 3. NATIONAL RESEARCH CENTRE FOR THE WORKING ENVIRONMENT, DENMARK

Introduction It is well known that sedentary occupation with computer work is associated with development of pain in neck and shoulder. Studies have shown that physical exercise at work is effective in managing musculoskeletal pain (1,2). However, the effect of supervision during training sessions in workplace interventions needs to be clarified. Thus, the aim of this study was to evaluate the effect of different amount of supervision on training motivation and neck/shoulder pain during a worksite physical exercise intervention. Method The study was conducted as a cluster randomized controlled trial in Denmark; study design is previously published (3). The participants were office workers and recruited from 12 different work units in Denmark. Three hundred and six participants were randomized in 3 groups; 2 exercise groups performing specific strength training 3 x 20 min a week, with supervision half of the sessions throughout the training period (WS) or supervision only initially for 2 sessions to learn the exercises correctly (MS), respectively, and 1 reference group who did not exercise (REF). The intervention period was 12 weeks. Structured e-mail based on questionnaires was sent to the participants every week. The intensity of pain was registered on scale 0-9. Results One hundred and ninety women and 116 men participated in the study. Replies were collapsed from week 1 and 2 and week 11 and 12, respectively, and the response rate was: WS: 47%, MS: 29%, and REF: 49%. ANOVAs showed significant reduction in neck pain in WS compared to REF;  $\Delta -1.3 \pm 1.8$  (SD),  $p < 0.05$  but not in MS compared to REF;  $\Delta -0.8 \pm 1.5$  (SD)  $p = 0.54$ . There were no significant changes in shoulder pain. Looking at pre vs. post data (paired t-test) in the exercise groups shoulder pain reduced significantly in both groups but not the REF group. Between the two exercise groups motivation to training did not change. In both groups motivation decreased significantly in the interventions period: WS:  $-0.5 \pm 1.7$ , MS:  $-1.1 \pm 1.1$ . Discussion A continuously supervision gave significant reduction in pain compare to reference group. Pain did not significantly change in the group only with start-up/minimal supervision. These results indicate that supervision has positive effect on neck pain outcome. But low response rate makes it difficult to conclude on supervision in general. References 1. Proper KI et al. ### MIXED EXERCISE PROGRAM AND AEROBIC CAPACITY IN LOWER LIMB OSTEOARTHRITIS

SAAVEDRA, J.M.1, ESCALANTE, Y.1, GARCIA-HERMOSO, A.1, DOMINGUEZ, A.M.1

UNIVERSIDAD DE EXTREMADURA

1: Facultad de Ciencias del Deporte. AFIDES Research Group, Universidad de Extremadura (Caceres, Spain) Introduction The reduced aerobic capacity of patients with lower limb osteoarthritis affects their independence in performing everyday activities. The purpose of this review was to summarize evidence for the effectiveness and structure of mixed exercise programs on functional aerobic capacity in patients with lower limb osteoarthritis. Methods A computerized search was made of the most important databases. Effect sizes (ES) and 95% confidence intervals (CI) were calculated. The criteria for inclusion were the following: (i) adults diagnosed with lower limb OA according to the criteria of the ACR; quasi-experimental or experimental studies; (iii) type of intervention: mixed exercise program; (iv) minimum duration of program: 4 weeks; and (v) assessment of aerobic capacity using the 6-minute walk test. Results The eight studies (see references) that satisfied the inclusion criteria were selected for analysis. The functional aerobic capacity improved in mixed exercise programs (ES=0.47; 95% CI, 0.32 to 0.62). Their content was based on developing aerobic endurance, strength, and flexibility. On the other hand, the structure of the programs, the duration ranged between four and 72 weeks. The weekly frequency was two or three sessions. The session durations were between 60 and 90 minutes. Discussion Numerous studies have investigated the effects of different types of exercise programs, but these programs consisted almost exclusively of aerobic, resistance, or flexibility exercises, with some containing a mixture of two types of exercises. The study that gave the best results (Aglamis et al., 2008) employed an individual manually applied treatment, which allowed the therapist to focus treatment on the specific structures that caused pain and limited function for each patient. It is interesting to note that this program uses purely unloaded aerobic work on a static bicycle. However, other studies in this group obtained similar improvements (Deyle et al., 2000; Hughes et al., 2004). The main conclusion was the structure of the mixed exercise programs was very heterogeneous but this program was effective to improve the aerobic capacity in patients with lower limb osteoarthritis. ### RESISTANCE TRAINING AND DIETARY SUPPLEMENTS AS INTERVENTION FOR REGAINING MUSCLE MASS FOLLOWING RADIOTHERAPY IN HEAD AND NECK CANCER PATIENTS.

LONBRO, S., OVERGAARD, K., PRIMDAHL, H., OVERGAARD, J.

AARHUS UNIVERSITY

Resistance training and dietary supplements as intervention for regaining muscle mass following radiotherapy in head and neck cancer patients. Lønbro, S. 1,2; Overgaard, K. 2; Primdahl, H. 3 & Overgaard, J. 1, Dept. of Experimental Clinical Oncology, Aarhus University Hospital 2, Inst. of Sports Science, Aarhus University, 3 Dept. of Oncology, Aarhus University Hospital Background: In patients with head

and neck cancer (HNC), a loss of body mass of around 10 % is seen - mainly due to loss of muscle mass [1]. Since muscle mass reduction is an independent mortality predictor and lowers muscle strength and functional capacity, interventions to regain muscle mass are warranted. Progressive Resistance Training (PRT) has been shown most effective in regaining these parameters among young and elderly healthy individuals and various groups of patients (e.g., breast-, prostate cancer). HNC patients could benefit from this as well. In addition, a timed dietary supplement of protein and creatine can enhance the positive effects induced by PRT as shown in healthy individuals. Objectives: The aims are to: 1) investigate whether PRT +/- protein and creatine ingestion is tolerable among HNC patients following curative radiotherapy, 2) determine the effects on body composition, muscle strength and functional capacity of a PRT intervention with or without supplementation with protein and creatine. Methods: 30 HNC patients are randomly assigned into two groups. During the first week Group 1 completes an oral creatine loading regime, whereas Group 2 ingests placebo. In the following 12 weeks, Group 1 completes a PRT protocol combined with a timed protein and creatine supplement, whereas Group 2 completes the same PRT protocol with placebo supplement. Pre and post radiotherapy treatment, total body weight (BW) is recorded. Before the first week and pre and post the 12 weeks of PRT, lean body mass (LBM, DXA scans), maximal muscle strength (isometric dynamometry), functional capacity (e.g. 30 s arm curl test, 30 s sit-to-stand test) are measured. Preliminary results: At abstract deadline 21 subjects were randomized (ongoing). 8 dropped out - 7 due to causes unrelated to the training and supplementation intervention, 9 are ongoing and 4 completed the protocol. Preliminary analyses show a mean loss of BW of 14.7 (12.5-17.9) % following radiotherapy. In the 4 patients who completed the PRT BW increased 1.6 (-2.1-4.4) %, LBM increased 7.1 (4.6-11.5) %, Fat Mass decreased 8.3 (-3.1-45.3) %, isometric knee extension and flexion increased 26 (9-52) % and 16 (6-27) %, respectively. Arm curl and sit-to-stand performance increased by 15.9 (0-42.3) % and 25.5 (0-50) %. Conclusions: Despite a large total dropout rate from the study, the PRT seems to be well tolerated among the participants who received training. The preliminary results from completers indicate a positive effect on LBM, muscle strength and functional capacity. References: 1. Silver HJ et al. #### COMPARATIVE EVALUATION OF BODY POSTURE FUNCTIONAL STATUS IN CHILDREN AGED 8-11, 12-14 AND 15-16

SHKLYARENKO, A., KOVALENKO, T., ULYANOV, D., YAHNIK, Y., SUHORUCHKO, A.  
VOLGOGRAD STATE UNIVERSITY

COMPARATIVE EVALUATION OF BODY POSTURE FUNCTIONAL STATUS IN CHILDREN AGED 8-11, 12-14 AND 15-16 A. SHKLYARENKO, T. KOVALENKO, D. ULYANOV, YA. YAHNIK, A. SUHORUCHKO. Volgograd State University Slavenskiy-on-Kuban Pedagogical State Institute, Russia Introduction. Body posture was treated like a dynamic stereotype obtained in the process of individual development, upbringing and training. Methods. With the use of special tests we evaluated the functional state of children posture in the upright and seated positions. Power and endurance rates, muscle contractility were measured; these indicators assure locomotorium stability. Results. Girls and boys, aged 8-1, kept the preset position during 6,2 and 7,0 minutes. We observed no statistically significant differences between gender groups ( $p>0,1$ ). During the growth spurt (12-14 years) temporal testing characteristics in various genders varied considerably, correspondingly 12,8 and 9,4 minutes. ( $p<0,05$ ). The results were clearly different in adolescences aged of 14. The test results of females aged 15-16 showed that the improvement reduced while males of the same age had gradually continued positive dynamics. Females had a lower endurance rate in keeping the preset seated position (without relaxing back and abdominal tight muscles) than male of the similar age. Furthermore, the girls' task performance time increased by 23 percent on the average; the boys' indicator was slightly below 19 percent. As for the 12-16 age range the polar opposite results were observed (correspondingly 17% and 29%). Duration of test exercise to determine power endurance of back and adnominal muscles among girls of 12-14 year old was substantially lower than that of similar aged boys. Isometric index of rectus abdominal and back straightening muscles of boys is 88 и 111 s., that of girls is 66 and 81 s. Positive spine stability indicator among boys aged 12-16 is high endurance rate of abdominal and back straightening muscles. Conclusion. Comparing the data obtained from representatives of both sexes of different age we observed that their body posture functional status differs considerably. We assume that risk reduction of growing body posture fault is connected with prevention and correction of functional static abnormalities in muscle function.

#### PHYSICAL ACTIVITY PATTERNS AND FATNESS IN SPANISH CHILDREN: THE EUROPEAN YOUTH HEART STUDY

LAGUNA, M., LARA-HERNÁNDEZ, M.T., RUIZ, J.R., AZNAR, S.  
UNIVERSITY OF CASTILLA LA MANCHA

Introduction Spain has one of the highest rates of childhood overweight and obesity in Europe [1]. The majority of Spanish children do not engage in enough physical activity (PA) to be beneficial for health [2, 3]. Recommendations for healthy levels of PA for children have been established [4] but there is a need for objective and accurate assessment of the proportion of overweight/obese vs non overweight/obese children meeting the PA guidelines. Moreover, assessing time spent in moderate to vigorous PA (MVPA) both between days (during weekdays and weekend days) and within days is of interest to improve our understanding to provide more efficient intervention programs. The aim of this study was to examine the patterns of MVPA in Spanish school children measured by accelerometers and determine if there were differences between overweight/obese vs non overweight/obese children. Methods A total of 665 children (438 9 year old [214 boys, 224 girls] and 227 15 year old [101 girls and 126 boys]) from private and state schools in Madrid, Spain participated in the study. The variables measured were: anthropometric characteristics (height, weight, body mass index (BMI), waist circumference and sum of 4 skinfold thickness). PA was measured during 4 consecutive days using the GT1M accelerometer. Fatness was estimated from BMI and dichotomized using cut-points of International Obesity Task Force (IOTF). Results We found that 72.4% 9 year old boys and 49.6% 9 year old girls, and 39.7% and 29.7% 15 year old boys and girls respectively, achieved the level of MVPA recommended for health. Non-overweight children (both 9 and 15 year old) achieved significantly ( $p<0.01$ ) more MVPA and less sedentary time than overweight/obese children. Non-overweight 9 year old children were significantly ( $p<0.01$ ) more active than non-overweight 15 year old. No differences in MVPA were found in overweight/obesity children by age groups. Non-overweight 9 year old boys and girls achieved significantly ( $p<0.05$ ) more MVPA during weekdays than their overweight/obese counterparts respectively. In the 15 year old group, there were no significant differences in MVPA between no-overweight and overweight/obese boys and girls respectively. Conclusion Few children achieved the level of MVPA recommended for health: at particular risk were all 15 yr old children and overweight and obese 9 yr old

children. More effort needs to be devoted to promoting appropriate opportunities for Spanish overweight and obese children across the day and to promoting PA during weekends for all children.

## A PRELIMINARY INVESTIGATION OF RELATIVE AGE EFFECT IN GAELIC GAMES

HORGAN, B.1, COLLINS, K.2

1: ECU (PERTH, AUSTRALIA), 2: ITTD (DUBLIN, IRELAND)

**Introduction** Annual age-grouping is a regular organisational strategy in sport; however, such a strategy appears to promote a relative age effect (RAE) (Mujika et al., 2009). Relative age effect occurs as a result of chronological age and associated physical, emotional and psychological differences due to an asymmetrical distribution of birth date, favouring subjects born earlier in an annual competitive cycle (Cobley et al., 2009). The aim of the current study was to identify if a similar pattern exists at the representative (inter-county) level in Gaelic football and hurling (Gaelic games). **Method** Gaelic games player (n = 604) data was collected for under-14, under-15, under-16, under-17, under-18, under-21 and adult representative selections for the 2010 season. Players were grouped into one of four yearly quartiles according to their month of birth. The Chi-square and Kruskal Wallis statistic was used to examine differences between observed birth date distributions. Results From the total sample obtained, the percentage of players born in Q1, Q2, Q3 and Q4 were 33%, 29%, 21% and 18% respectively. A chi-square analyses revealed that the birth date distribution of the group of players differed significantly from that of the theoretical distribution ( $\chi^2 (3) = 34.795, P < 0.001$ ). The results indicates a RAE exists within the sample of representative players. When juvenile (U14 to U18) players (n = 485) were taken in isolation, the birth date distributions differed significantly from that of the theoretical distribution ( $\chi^2 (3) = 46.885, P < 0.001$ ). Within the sample, 64% of those juvenile players were born in the first half of the calendar year, indicating RAE inequalities are pronounced at juvenile level and continue into adult representative levels. **Discussion** The findings of the current study are consistent with that of Cobley et al. (2009), who also identified that juvenile players at representative levels (U14 to U18) appear to be at a higher risk of RAE inequalities. Researchers can assist national governing bodies (NGB), players, sport coaches, teachers and parents by providing suggestions regarding the origins of RAE, its implications in player development and drop-out from sport, and how NGB can address the RAE in their own context specific manner (Cobley et al., 2009). The current findings provide a platform for further research in the areas of talent identification and player development within the Gaelic games. **References** Cobley S., Baker J., Wattie N., McKenna, J. (2009). *J Sports Med*, 39(3), 235-256. Mujika I., Vaeyens R., Matthys S., Santisteban J., Goiriena J., Philippaerts R. (2009). *J Sports Sci*, 27(11), 1153-1158.

## EVALUATION OF AEROBIC ENDURANCE CHARACTERISTICS IN ADOLESCENT AND YOUNG ROAD CYCLISTS

PONTAGA, I.

LATVIAN ACADEMY OF SPORTS EDUCATION

**Introduction** There is a close correlation between the aerobic capacity and the results in endurance sports in adult athletes (Shave, Franco, 2006). An endurance of adolescent road cyclists depends on an aerobic capacity and a process of growth. An aim of our investigation is to compare 14 – 15, 16 – 17 and 18 – 21 years old road cyclists' endurance characteristics. **Methods** Thirty-eight road cyclists participated in the investigation. They are divided into three age groups: 14–15 (N=11), 16–17 (N=13) and 18–21 (N=14) years old. Every road cyclist performed incremental load test to exhaustion on a mechanical bicycle ergometer (Monark, Sweden). An initial load intensity was 27 W, then it increased step by step for 12 W every two minutes. A cardiopulmonary diagnostic equipment „Oxygen Mobile Via Sys“ (Via Sys Healthcare GMBH, Germany) is used during the test to register an electrocardiogram and respiratory characteristics. A lactic acid concentration in the capillary blood is detected by special lactate analysers „Biosen 5030“ (EKG – diagnostic, Germany) every two minutes. **Results and discussion** The mean weight of 16–17 years old cyclists ( $71 \pm 6$  kg) is significantly greater than in 14 – 15 years old ( $66 \pm 7$  kg),  $p < 0.007$ . Growth of the weight with age is none significant in 18–21 years old cyclists ( $73 \pm 4$ ) in comparison with 16–17 years old,  $p > 0.05$ . The absolute workload and oxygen uptake significantly increases in every older age group of cyclists. The correlations between the body weight and workload and between the body weight and oxygen uptake are significant positive in 14 – 15 and 16 – 17 years old cyclists ( $p < 0.02$ ), but in the 18–21 years old cyclists these correlations disappear. The relative workload is the same in the age groups of 14–15 and 16–17 years, but in the oldest cyclists it is significantly greater,  $p < 0.003$ . It means that the oxygen uptake in adolescent cyclists (14–17 years) depends mostly on the weight increase process in this age, but in the age of 18 years and older it depends on training in endurance sports. The relative oxygen uptake does not differ significantly in 14–15 and 16–17 years old cyclists at different intensities of load ( $p > 0.05$ ). In 14 – 15 years old cyclists correlations between the relative oxygen uptake and workload are none significant ( $p > 0.05$ ). The relative oxygen uptake in 18–21 years old cyclists is significantly greater than in younger cyclists ( $p < 0.0002$ ). In 16–17 and 18-21 years old cyclists the correlations between the relative oxygen uptake and workload on bicycle ergometer at aerobic, anaerobic thresholds and maximal aerobic load are significant positive ( $p < 0.04$ ). **References** Shave R, Franco A (2006) The physiology of endurance training. ## IMPROVING 1000M RUNNING TIME IN 14 YEAR-OLD SCHOOL CHILDREN

KRUEGER, M.1,2, SPERLICH, B.1, ZINNER, C.1,2, MESTER, J.1,2

GERMAN SPORT UNIVERSITY COLOGNE

**INTRODUCTION:** The 1000m personal best time is commonly used in German schools to test endurance performance. The aim of the study was to examine the effect of two different 5-week training strategies (high intensity vs. high volume) on 1000m- running performance (T1000m), maximal oxygen uptake ( $\dot{V}O_{2max}$ ), velocity at lactate threshold (VLT) and running economy (RE; oxygen uptake at 3.2 m/s). **METHODS:** 20 boys (means  $\pm$  SD: age  $13.5 \pm 2.8$  yrs; height  $160.4 \pm 6.8$  cm; body mass  $50.9 \pm 9.7$  kg) participated in the present study. They were divided into two training groups who either mainly focused on high intensity intervals (HIIT, n=10) or continuous loads of endurance training (HVT, N=10). Heart rate was monitored during all sessions, HIIT were performed at 90-95%, HVT at 50-70% of individual maximal heart rate. Total exercise time of HIIT- sessions did not exceed 30min (including warm up and rest); HVT- sessions lasted up to 60 min. Before and after the training-phase (5 weeks in total) the subjects performed an incremental step test on the treadmill (2.4 m/s; increase 0.5 m/s every 5 min) and a 1000m run. **RESULTS:** RE improved significantly in both training groups (HIIT: pre  $47.8 \pm 5.6$  post  $40.7 \pm 4.8$  ml/min/kg,  $p < 0.01$ ; HVT: pre  $47.7 \pm 7.0$  post  $43.0 \pm 5.6$  ml/min/kg,  $p < 0.01$ ).  $\dot{V}O_{2max}$  increased significantly only in the HIIT- group (pre  $55.0 \pm 5.2$  post  $58.7 \pm 4.9$  ml/min/kg,  $p < 0.01$ ; HVT: pre  $55.3 \pm 4.3$  post  $56.4 \pm 4.7$  ml/min/kg,  $p = 0.24$ ). Similar results were found regarding VLT (HIIT: pre  $3.2 \pm 0.2$  post  $3.4 \pm 0.3$  m/s,  $p < 0.01$ ; HVT: pre  $3.3 \pm 0.3$  post  $3.4 \pm 0.2$  m/s,  $p = 0.85$ ). and T1000m (HIIT: pre  $3:56.6 \pm 10.7$  post  $3:46.8 \pm 12.9$  min,  $p < 0.01$ ; HVT: pre  $3:55.3 \pm 12.8$  post  $3:50.7 \pm 17.3$  min,  $p = 0.10$ ). **DISCUSSION:** In five weeks of HIIT, with 3

training sessions per week 1000m running time decreased significantly in (pre) pubertal boys. This was associated with improvements in VO<sub>2</sub>max, velocity at lactate threshold and running economy. These findings are supported by literature where comparable improvements are described (McMillan et al. 2005). Exercise time, especially for endurance training is limited in school sports as well as in most team sports due to other school or recreational activities and sport-specific training. Thus, time saving strategies are necessary to enhance physical fitness. The present study suggests that HIIT performed 3 times per week (in total 1.5 hours/week) over a period of 5 weeks leads to a significant improvement of endurance performance in 14-year old children.

## RESULTS OF A PROGRAMME FOR IMPROVING JUMPING ABILITY IN TWO CHILDREN'S VOLLEYBALL TRAINING GROUPS

STAMM, M., STAMM, R., SORGINA, N.

TALLINN UNIVERSITY

**Introduction** The subjects of the study were children who practiced volleyball regularly in two training groups. The first group consisted of 6 boys and 6 girls aged 16-17 years, the second group of 6 boys and 4 girls aged 8-13 years; in total 22 young volleyballers. **Methods** In both groups, in addition to regular practice, a special programme for improving jumping ability was applied. The programme had been compiled by the Moscow Institute of Physical Culture (Beljaev, Bulõkina 2004). According to the programme, the children were taught to do certain exercises daily for 19 days. In the next two periods (both 19 days) more difficult exercises with great intensity were done over the day. During the training days, the exercises were done under the supervision of the coach. At the beginning and end of the programme, volleyballers were measured anthropometrically – height, weight, upper and lower circumference of lower leg, waist circumference and the height of the arm. Height of standing jump (SJ), running jump (RJ) and block jump (BJ) were measured. Running speed was tested by the shuttle run test. **Results** At the beginning of the study the mean height of the boys in the older group was 185.6 cm and at the end of it 185.6 cm. Their weight was 71.3 and 71.5 kg respectively. The height of the girls in the same group was 167.5 and 167.6, and their weight 61.1 and 60.3 kg respectively. The height of boys in the younger group was 161.9 cm at the beginning of the study and 163.0 cm at the end; their weight was 49.0 and 49.7 kg respectively. The height of the girls of the same group was 161.3 and 161.6 cm, and their weight 52.0 and 51.3 kg. Jumping tests results and running speed improved in both groups. Thus, in the older group the height of SJ increased by 7.83 cm on average in boys and by 6.17 cm in girls. The height of RJ in this group increased by 7.33 and 6.83 cm respectively. In the younger group the height of SJ increased by 5.0 cm in both boys and girls. The height of RJ increased by 8.33 cm in boys and by 3.50 cm in girls. In the older group, the height of BJ increased by 6.0 in boys and by 4.5 cm in girls; in the younger group the respective changes were 5.5 and 3.25 cm. The speed of shuttle run improved by 0.9 and 1.1 sec in the older group and by 0.7 and 1.0 sec in the younger group. **Discussion** Correlations between the anthropometric data and tests results at the beginning and end of the study were found. All the data were in statistically significant correlation, and there was also a significant correlation with age. For conclusion we can say that the programme for improving jumping ability (Beljaev, Bulõkina 2004) is suitable for the younger (8-13 years) and older (16-17 years) volleyballers. **References** Beljaev A.V, Bulõkina L.V. (2004) Theory and Practice of physical education, 3, 37-38.

## A STUDY ON CARDIOPULMONARY FUNCTION AND EXERCISE CAPACITY OF ADOLESCENTS SUFFERED FROM KAWASAKI DISEASE IN CHILDHOOD

LAI, C.H., LIN, K.L., FANG, C.L., LIN, C.W., CHIANG, Y.L.

TZU-HUI INSTITUTE OF TECHNOLOGY

**Introduction** Kawasaki Disease (KD) is an acute systemic vasculitis which was first found in 1967 in Japan. The diagnosis of typical or incomplete KD is based on clinical criteria. The clinical features, especially cardiac complications are the leading causes of childhood acquired heart disease (Wang et al, 2004). There were only a small number of reviews related to exercise performance on KD (Paridon et al.,1990). Therefore, cardiopulmonary function and exercise capacity in adolescents post-KD were evaluated through this study. **Methods** Maximal anaerobic capacity as well as factors of restrictive exercise capacity were evaluated in the study. A cardiopulmonary exercise stress assessment (Wang et al., 2008) was performed upon 13 adolescents post-KD among the experimental group along with 13 healthy adolescents in the control group. **Results** Based on the finding, no significant differences were found in VO<sub>2</sub> max, maximal systolic blood pressure and maximum heart rate. Pulmonary function tests also showed no significant differences in forced vital capacity (FVC), forced vital capacity second (FEV<sub>1</sub>), ventilation (MVV), nor FEV<sub>1</sub>/FVC. **Discussion** In the presented study, adolescents post-KD showed normal cardiopulmonary function (Paridon et al.,1995) and exercise capacity comparing to those from the healthy group; no limitations in exercise were observed additionally. Thus keep average exercise to maintain quality of life was suggested. **References** Paridon SM, Galioto FM, Vincent JA, Tomassoni TL, Sullivan NM, Bricker JT. (1995). ## COMPARISON OF MUSCLE AND JOINT FLEXIBILITY BETWEEN PRIMARY SCHOOL AND LOWER SECONDARY SCHOOL IN JAPANESE SOCCER PLAYERS

FUJII, M., WATANABE, H., ASHIHARA, M., NISHIMURA, M., UCHIDA, Y., TAKAHIRA, N.

GRADUATE SCHOOL OF MEDICAL SCIENCE, KITASATO UNIVERSITY

**Introduction** The efficiency of skill acquisition is high at 10-14 years old (adolescence in males) on the sports field. It is accompanied by a second growth spurt at this age. However, this is also a time when the occurrence of sports injury among adolescent sports players increases. It is, therefore, important to understand the physiological characteristics of sports players at this age. The purpose of the present study is to compare the physiological characteristics of lower secondary school soccer players with those of primary school soccer players. **Methods** We divided one hundred and sixteen subjects volunteered to participate in this study into two groups. The first group was primary school soccer players (9-11 years old). This group included 55 soccer players. Another group was lower secondary school soccer players (13-14 years old). This group included 61 soccer players. The physiological characteristics measured were height, weight, and joint laxity. We also evaluated muscle flexibility in the lower extremities (e.g., iliopsoas, hip external rotators, quadriceps femoris, hamstrings, gastrocnemius and soleus). **Results** The lower secondary school soccer players exhibited significantly lower joint laxity than the primary school soccer players. The lower secondary school soccer players also had significantly less muscle flexibility of the iliopsoas, quadriceps femoris, hamstrings and gastrocnemius on the kicking leg side, and the iliopsoas and gastrocnemius on the support leg side. No other differences were found in terms of muscle flexibility. **Discussion** We found that the lower secondary school soccer players

had less joint laxity than the primary school soccer players, and concluded that the flexibility of the joint of the lower secondary school soccer players was lower than those of the primary school soccer players. The lower secondary school soccer players also had significantly lower flexibility in many of the lower extremity muscles compared to the primary school soccer players. We supposed that the kicking leg would have lower muscle flexibility than the support leg, since the load of the kicking leg's muscles was larger than the support leg's muscles in soccer. These data suggested that the lower secondary school soccer player's muscle flexibility was low in order to accomplish a second growth spurt and repeat the kicking ball. Therefore, to prevent sports injury among lower secondary school soccer players, the flexibility of the soft tissues needs to be maintained by conditioning such as active stretching and mobilization, starting at primary school.

## PHYSICAL ACTIVITY CHANGES FROM ADOLESCENCE TO ADULTHOOD FOUR YEARS OF LONGITUDINAL APPROACH

CESCHINI, F.

SÃO JUDAS TADEU UNIVERSITY

PHYSICAL ACTIVITY CHANGES FROM ADOLESCENCE TO ADULTHOOD? FOUR YEARS OF LONGITUDINAL APPROACH Fábio L. Ceschini, Ms1, Aylton J. Figueira Junior, PhD1, Victor K.R. Matsudo, MD2. - 1São Judas Tadeu University, Faculty of Health and Biological Sciences São Paulo, Brazil and 2 Physical Fitness Research Center - CELAFISCS, São Paulo, Brazil. Email: flceschini@yahoo.com.br Introduction: The physical activity daily is an important factor to promote health in adolescence. This paper longitudinally evaluated the physical activity level in both sex subjects from adolescence to adulthood living at an urban area of São Paulo City. Methods: During four years (2006-2010) it was followed 344 adolescents of the both sex (184 boys and 160 girls). The boys mean of age was 16.8±1.2 (2006) and 20.4±1.1 years old (2010); and the girls group were 16.4±1.0 years old (2006) and 20.1±1.0 years old (2010). Daily physical activity level (PAL) was assessed through International Physical Activity Questionnaire (IPAQ short version) that allows to classify the physical activity level in insufficiently active (when subject reports less than 300 minutes of moderate to vigorous physical activities per week) and physically active (when subject reports more than 300 minutes of moderate to vigorous physical activities per week). It was evaluated the body dimensions [body weight (Kg); stature (cm); body mass index (BMI= Kg/m<sup>2</sup>) and waist circumference (WC-cm)]. The statistical analysis issue was the Chi Square test (X<sup>2</sup>) and Paired Student's t Test to compare 2006-2010 data. The level of significance was p<.05 for all statistics analysis. Results: Physical activity longitudinal comparison from 2006 to 2010 presented for both sex significant physical activity decrease (18.9%) from adolescence to adulthood between 2006 and 2010 (p<.05). Boys became more physically inactive (28.7%) than girls (11.4%), suggesting different impact over time in the PAL, probably cultural and gender behaviors. Body dimensions presented in general stability no significant changes on WC (p=.07). However it was observed that both sex presented little increase in WC (boys: 2.34 cm; girls: 2.02 cm), suggesting that the increase of abdominal area must be controlled in the close future to do not increase the metabolic diseases. BMI data did not present significant changes (p=.09) in both sex. Boys presented 2.89 (kg/m<sup>2</sup>) and girls 2.89 (kg/m<sup>2</sup>). Conclusion: The transition from adolescence to adulthood presented higher impact on PAL than in body dimensions variables. Also, our data allow us to suggest that health professionals, family and teachers must advice the risk of sedentary behavior and body composition changes in lifespan. ## PHYSICAL FITNESS AND PHYSICAL ACTIVITY AS DETERMINANTS OF HEALTH DEVELOPMENT OF CHILDREN AND ADOLESCENTS - THE MOMO-LONGITUDINAL SECTION STUDY

WAGNER, M.1, BÖS, K.2, OPPER, E.3, WORTH, A.1, WOLL, A.4

1 UNIVERSITY OF EDUCATION SCHWÄBISCH GEMÜND (GERMANY), 2 KARLSRUHE INSTITUTE OF TECHNOLOGY (GERMANY), 3 UNIVERSITY OF EDUCATION KARLSRUHE (GERMANY), 4 UNIVERSITY OF KONSTANZ (GERMANY)

Starting Point: The MoMo-Cross-sectional Study At present, the health of German children and adolescents has not been sufficiently studied. In order to remedy this situation, the cross-sectional and nationwide-representative "German Health Interview and Examination Survey for Children and Adolescents" (KiGGS, www.kiggs.de; N=18.000; age: 0 to 17 years) was administered by the Robert Koch-Institute (RKI, Berlin) from 2003 to 2006. KiGGS is constructed modularly. The aim of the Motorik-Modul (MoMo; www.motorik-modul.de; N=4.529; age: 4 to 17 years), which was carried out simultaneously by the University of Karlsruhe in cooperation with the RKI, was a baseline-assessment of the physical fitness and physical activity status of German children and adolescents. The results of this assessment have been published in a comprehensive research report (see Bös, Worth, Oppen, Oberger & Woll, 2009). Current Research: The MoMo-Longitudinal Section Study The MoMo-Cross-sectional study will continue longitudinally in 2009 as a joint project between the University of Konstanz, the Karlsruhe Institute of Technology and the University of Education Schwäbisch Gmünd with the continuing cooperation of the RKI. The objectives of this follow-up study are to analyse the development of physical fitness and physical activity as well as the complex interrelations between physical fitness, physical activity and health and a continuous reporting on the physical fitness and physical activity status of German children and adolescents. In this context, the following research-questions are of particular interest: How does the development of physical fitness and physical activity proceed in childhood and adolescence? Which relationships exist between the development of physical fitness, physical activity and health in childhood and adolescence? Which historical trends can be identified in the stage of development of physical fitness and physical activity in childhood and adolescence? Data will initially be collected in two waves (2009-2011; 2012-2014) using motor tests, physical activity and health questionnaires as well as medical examinations. First results are expected to be published in the second half of 2012. References Bös K, Worth A, Oppen E, Oberger J, Woll A (Eds.) (2009). Das Motorik-Modul: Motorische Leistungsfähigkeit und körperlich-sportliche Aktivität von Kindern und Jugendlichen in Deutschland. [The Motorik-Modul: Motor fitness and physical activity of children and adolescents in Germany]. Nomos Verlag: Baden-Baden.

## 'BICYCLE-CLASS': A SCHOOL-BASED EXERCISE INTERVENTION TO SUPPORT PHYSICAL ACTIVITY AND HEALTH

HACKL, M., TSCHAN, H., NIMMERICHTER, A., VIDOTTO, C., BACHL, N., WESSNER, B.

UNIVERSITY OF VIENNA

Introduction Juvenile obesity and sedentary lifestyle in children are increasing worldwide [1]. One way to counteract this could be the increased use of school-based physical activity additionally to the regular physical education curriculum. The aim of this study was to increase physical performance and to decrease metabolic risk factors in 12-y-old schoolchildren by using bicycle ergometers during the normal school lessons. Methods Before and after an exercise intervention period of 5 months, the intervention group (IG) (10 girls, 13 boys; age (y): 11.7 ± 0.42; height (cm): 151.7 ± 6.9; weight (kg): 40.4 ± 6.8) performed an incremental graded exercise test (GXT) on an electro-

magnetically braked ergometer to determine maximal oxygen uptake (VO<sub>2</sub>max), ventilatory threshold (VT), respiratory compensation point (RCP) and relative and absolute maximal Power (rPmax; Pmax). Fasting blood samples were taken before and after the training period to determine metabolic risk factors (blood glucose, cholesterol, triglycerides and insulin). Each member of the IG performed 3 trainings sessions per week (à 50 min) during ordinary teaching. Therefore, six bicycle ergometers were placed in the back part of a classroom and five teachers supported the study by allowing the IG to exercise during their lessons. The IG was instructed to cycle as long and as intense as possible during the 50 minute lesson without losing attention or disturbing the teaching. The matched control group (CG) (10 girls, 11 boys; age: 11.8 ± 0.28; height: 153.8 ± 7.0; weight: 43.8 ± 10.7) was examined in the same way without participating in the additional exercise intervention. Results A significant improvement during the GXT was observed in VT (Watt) (IG: 58.6 ± 11.5 to 66.5 ± 12.5; CG: 65.4 ± 16.6 to 65.0 ± 20.2; p<0.001), rPmax (Watt/kg) (IG: 3.45 ± 0.62 to 3.56 ± 0.60; CG: 3.38 ± 0.66 to 3.30 ± 0.76; p<0.05) and Pmax (Watt) (IG: 136.6 ± 19.9 to 151.1 ± 21.6; CG: 143.6 ± 23.1 to 149.0 ± 27.5; p<0.05) when IG was compared with CG. Changes in VO<sub>2</sub>max and RCP were not sig. different. Blood glucose values (IG: 89.6 ± 4.8 to 86.1 ± 3.7; CG: 91.2 ± 6.3 to 91.6 ± 4.6; p < 0.05) and triglyceride values (IG: 74.4 ± 40.3 to 63.5 ± 26.0; CG: 72.9 ± 43.5 to 89.5 ± 76.4; p < 0.05) decrease significantly for IG compared with CG. No differences were found in cholesterol and insulin values. Discussion The results of the current study suggest that a 5 month school-based bicycle ergometer intervention can significantly improve some indices of endurance measures (VT, Pmax, rPmax) and metabolic risk factors (blood glucose, triglycerides) in comparison to a control group. Therefore, this form of intervention could be an appropriate method to enhance physical activity and physiological performance and to reduce risk factors in school children. ### THE CHANGE! PROJECT: GROUP AND GENDER DIFFERENCES IN BODY COMPOSITION, CARDIORESPIRATORY FITNESS, AND CARDIOMETABOLIC VARIABLES AT BASELINE

GOBBI, R.1,2, DAVIES, I.G.2, FAIRCLOUGH, S.J.1,2, HACKETT, A.F.1,2, MACKINTOSH, K.A.1,2, WARBURTON, G.L.2, STRATTON, G.1,3, GEORGE, K.P.3, BODDY, L.M.1,2,3

LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: The CHANGE! Project is a cluster randomised intervention which aims to educate children about leading a healthy lifestyle through a 20 week school based PSHE curriculum. The aim of this paper is to describe the differences in groups at baseline. Method: Participants (n=317) were recruited from 12 primary schools (mean age =10.6 ± 0.3 years) in Wigan. Six schools were randomly assigned to an intervention group with the other six schools acting as controls. A subsample of children (n=60), were randomly selected to take part in further measurements. Anthropometrics (height, sitting height, weight, waist [WC] and hip circumference [HC]), resting blood pressure, cardiorespiratory fitness (CRF) (20 m multi-stage shuttle runs test) and habitual physical activity (PA) (7 day accelerometry) were measured in the whole cohort. Additional measurements completed for the subsample included fasting capillary blood total cholesterol (TC), high density lipoprotein cholesterol (HDL-C) and glucose; body composition (DEXA); CRF (VO<sub>2</sub>peak) left ventricular diastolic filling (E/A Ratio); septal myocardial tissue velocities (E'/A'), and left ventricular mass (LV mass). LV mass index was calculated to account for body size. Group differences were examined using ANCOVA controlling for somatic maturation and gender. Gender differences were also assessed at baseline controlling for somatic maturation. Results: There were no significant differences between the participants in the subsample and whole cohort. There was a significant difference between groups (control and intervention) for the whole cohort for CRF (20m shuttles) (f(1,299)=4.2, p=0.041), and in the subsample for HDL-C (f(1,26)=5.114, p=0.032). There were no other significant group differences. In the subsample there were significant gender differences when controlling for somatic maturation in the following variables; height (f(1,19)=27.194, p<0.001); sitting height (f(1,19)=28.90, p<0.001); weight (f(1,19)=19.3, p<0.001); WC (f(1,19)=6.27, p=0.022); HC (f(1,19)=6.02, p=0.024); Moderate to Vigorous PA (f(1,19)=4.812, p=0.041); and E'/A' (f(1,19)=4.67, p=0.04) In the whole cohort there were also significant gender differences in CRF (20m shuttles)(f(1,310)=21.38, p<0.001). Discussion: There were few group differences at baseline; this suggests the intervention and control groups were well matched at baseline. To account for the observed gender differences all future analyses will control for gender, and maturation, as well as baseline measurements.

### PP-PM50 Training and Testing: Jumping Performance

#### ENDURANCE, STRENGTH AND JUMPING ABILITIES OF NORWEGIAN POLICE ACADEMY STUDENTS

JENSSEN, O., NYGÅRD, Ø., INGEBRIGTSEN, J.

UNIVERSITY OF NORDLAND

Introduction Police officers typical work involve long periods of relatively low activity or even inactivity, but is often punctuated by periods of unpredictable bursts of potentially life threatening activities and high intensity that is experienced as stressful (Kales, S. N., Tsismenakis, A. J., Zhang, C., & Soteriades, E. S., 2009). Hence, to cope with the daily demands of the profession you need to hold certain levels of physical fitness. Therefore, physical tests, and requirements, is a major part of the selection of Police academy students overall (Kales et al., 2009), as well as in Norway. Hence, the aim of this project was to establish and identify endurance, strength and jumping performance of first year students in the Norwegian police academy 2010. Secondly we wanted to compare endurance and strength performances with graduate students from year 2000 (as shown in Lagestad, 2006). Methods Participants went through testing of 3000m running, bench press, pull ups, squat jump and counter movement jump, as well as standard anthropometric measures. All statistical analysis was carried out with SPSS 14.0 (SPSS Inc., Chicago). Results are reported as mean ± standard deviations of the mean (SD). Results 91 male (age 22.7±2.3yrs, body mass 80.7±10.8kg, stature 180.3±7.5cm, BMI 24.8±2.6) and 48 female (age 22.0±1.7yrs, body mass 65.2±5.9kg, stature 168.8±5.6cm, BMI 23.0±2.5) police students performed 3000m running on 13:19 (±1:48) min and 15:16 (±1:44) min respectively. In bench press and hang ups male students on average lifted 88.7 (±13.9) kg and 8.5 (±4.3) repetitions, while female lifted 48.5 (±8.7) kg and did 9.8 (±5.1) repetitions respectively. Considering counter movement jumping abilities we found male participants to jump on average 39.3 (±5.1) cm while female participants jumped 29.3 (±3.8) cm. Discussion We aimed to establish normative data from Norwegian first year police academy students, and to compare current performances to graduate students in year 2000. Results among male students reveal on average 1:40min slower, 14 kg and 3 repetitions less in 3000m running, bench press and hang ups respectively. Within female students, performances were 9kg less in bench press, 1:10min slower 3000m running time and 6.5 repetitions less hang ups compared to year 2000 graduate students. Jumping abilities previously not been investigated among Norwegian police students. Refe-

### CORRELATION BETWEEN VERTICAL JUMP VS REPETIBLY SPRINT ABILITY IN YOUNG SOCCER PLAYERS

ATTENE, G., IBBA, G., SORCI, A., CAVA, C., PITTORRU, G., MELIS, S., PINNA, M., DEGORTES, N.

UNIVERSITY OF CAGLIARI

Correlation between vertical jump vs repetibly sprint ability in young soccer players Attene G, Ibba G, Sorci A, Cava C, Pittorru G, Melis S, Pinna M, Degortes N 1 Corso di Laurea Specialistica in Scienze e Tecnica dello Sport, Università degli Studi di Cagliari 2 Scuola Regionale dello Sport della Sardegna, Italian Regional Olympic Committee, Sardinia Italy Aim The goal of this study was to investigate how the neuromuscular ability assessed during the performance of different types of vertical jump test can affect the performance of Repeated Sprint Ability (RSA) in a group of young players. Materials and Methods The experiment was conducted on a group of 16 male subjects practicing football (age  $18 \pm 0.8$  years, height  $173.6 \pm 4.9$  cm, weight  $63.4 \pm 7.6$  kg), participants in the FIGC championship Juniors class. In the first test session the following tests of neuromuscular jump ability were evaluated: Squat Jump (SJ) and the Counter Movement Jump (CMJ) (platform in conductance, TTSport, Galazzano-Republic of San Marino). During the second session the RSA test was conducted (6 reps for 40m sprint with a change of direction to 20 m, 20 s of passive recovery between the tests). Travel times were measured with a photocell timing system (MICROTAC, TTSport, Galazzano-Republic of San Marino). For the measurement of blood lactate (LA) at the end of the test, the tool Lactate Scout (SensLab GmbH, Leipzig, Germany) was used. The index of fatigue (IFF) for the RSA was calculated according to Fitzsimons et al. (1993). The relationship between variables was evaluated using the Pearson correlation coefficient. The significance level was set equal to 5% [ $p < 0.05$ ]. Results The results obtained are as follows: SJ  $35.3 (\pm 5.1)$  cm, CMJ  $42.2 (\pm 4.9)$  cm, best time over 20m (20m BT)  $3.30 (\pm 0.15)$  s, 6 total sprint time (TT)  $43.98 (\pm 1.71)$  s, IFF  $5.31 (\pm 1.58)\%$ , the one-minute post-test RSA  $9.6 (\pm 1.7)$  mmol / l, LA to three minutes post-test RSA  $9.7 (\pm 1.6)$  mmol / l. Statistical analysis has revealed statistically significant correlations between the IFF and the SJ (P value: 0.0181,  $r^2$  0.2770; the IFF and the CMJ (P value: 0.0041,  $r^2$  0.4041); the IFF and the BT 20m (P value: 0.0130,  $r^2$  0.3065), the IFF and the TT (P value: 0.0033,  $r^2$  0.4201), the IFF and the variation of lactate the first and third minute ( $\Delta$  LA1'-LA3', P value: 0.0279,  $r^2$  0.2370) and the SJ BT 20m (P value: 0.0028,  $r^2$  0.3617), the CMJ and the BT about 20m (P value: 0.0069,  $r^2$  0.4316). Conclusions Our results show that the height of jump, the power index of the extensor muscles of the lower extremities positively affects the RSA in young players. In addition, the contribution for the provision of the RSA system in anaerobic metabolism is essential. 1. Rampinini E, Bishop D, Marcora SM, Ferrari Bravo D, Sassi R, Impellizzeri FM. ### THE EFFECT OF PLYOMETRIC TRAINING ON AGILITY, LEG POWER, AND FLEXIBILITY OF HIP JOINT OF BADMINTON PLAYERS

SAFARI ZANJANI, F.

HEALTH SCIENCES- ISLAMIC AZAD UNIVERSITY- ZANJAN BRANCH

The effect of plyometric training on agility, leg power, and flexibility of hip joint of Badminton players Safari zanjani, F1.Karbasi, S2. Tarassi, Z1. 1: Department of Physical Education and Sport Sciences, Islamic Azad University- zanzan Branch[IRAN] 2: General administration education and training of province of zanzan[IRAN] Introduction Plyometric training helps train explosive strength by shortening the time taken to switch from an eccentric action to the concentric action. Athletes are basically training the muscle fibers and motor neurons to work more quickly and in synchronization with each other. The purpose of this study was to investigate the effects of the plyometric training on improvements of total agility, leg power, and flexibility of hip joint of young male Badminton players (17-19 years old). Methods 40 young male Badminton players who took part province competition, in order to participate in country is school championship were selected randomly. The subjects then were divided into the two groups. The experimental group consisted of 20 Badminton players with the average height who performed plyometric training (one hour per session) for a period of 8 weeks. Control group involved of 20 Badminton players with the average height who merely performed general badminton training programs. Pre- Tests were taken from each group subjects, which involved 4\*9m for Total Agility (TA) measurement, Vertical Jump (VJ) test for leg power measurement, and lateral R.O.M (LROM) of hip joint for flexibility measurement. Post-Test were taken of both groups after 8th week. Results After recording the datum, statistical analysis was used by using method of t-test. The results have shown that the TA, VJ, and LROM significantly improved in experimental group [ $p < 0.01$ ] but these improves were not significantly in control group. Discussion Using a variety of plyometric exercise can improve motor performance. While the majority of studies have focused on untrained subjects, trained athletes such as badminton players have improved their performance with plyometric trainings. References: 1- JSCR 23[2009]. ### CHANGES OF JUMPING SKILL IN FEMALE VOLLEYBALL PLAYERS

LIPÍŃSKA, M.1, BUŠKO, K.1,2, MICHALSKI, R.2, LEWANDOWSKA, J.1, PASTUSZAK, A.1

1: JOSEF PILSUDSKI UNIVERSITY OF PHYSICAL EDUCATION (WARSAW, POLAND), 2: INSTITUTE OF SPORT (WARSAW, POLAND)

Introduction Changes of the maximal muscle torques and the lower extremities power are indicative of the athlete's training level and effects of applied training loads. Volleyball players' fitness relies on their strength, power output and jumping ability (Buško, 2009; Smith et al., 1992). The aim of the study was to follow the changes of the maximal power and height of jump measured in spike jump and counter movement jump in female volleyball players during training. Methods Twelve female volleyball players took part in the study. Their mean ( $\pm$ SD) age, body height, body mass and duration of training practising amounted  $21.6 \pm 1.6$  years,  $176.7 \pm 6.1$  cm,  $74.1 \pm 6.6$  kg and  $8.9 \pm 3.3$  years, respectively. The maximal power output of lower extremities and the height of rise of the body mass center during vertical jumps were measured on a force platform for counter-movement jumps (CMJ) and spike jumps (SPJ). Three measurements were carried out: before the preparatory period (I), after the preparatory period (II) and after the end of first competitive season (III). The results were statistically processed using analysis of variance (ANOVA) with repeated measures (post-hoc Tukey test). Results The values of CMJ relative maximal power output increased from  $21.62 \pm 2.9$  W/kg before the preparatory period (I) to  $22.68 \pm 3.3$  W/kg after the end of preparatory period (II) and  $24.21 \pm 3.07$  W/kg after the end of first competitive season (III,  $p < 0.05$ ) while the height of rise of the body mass center were  $0.336 \pm 0.043$  m,  $0.336 \pm 0.038$  m and  $0.349 \pm 0.040$  m, respectively. The relative maximal power output values of SPJ changed from  $34.26 \pm 6.0$  W/kg (I) to  $33.22 \pm 7.11$  W/kg (II) and  $37.53 \pm 7.6$  W/kg (III,  $p < 0.05$ ). The height of jump were  $0.410 \pm 0.049$  m,  $0.429 \pm 0.054$  m and  $0.460 \pm 0.064$  m ( $p < 0.05$ ), respectively. Discussion The preparatory training period is usually devoted to the training of motor skills,

while the competitive season focuses primarily the improvement of volleyball technique and tactics (Häkkinen, 1993). In our study, in female volleyball players insignificant increases occurred in the maximal power output and the height of jump measured in CMJ and SPJ during the preparatory period. Significant increases of the maximal power output and the height of jump in both jumps were noted during first competitive season. The results obtained in this study are in good agreement with the results of the paper of Häkkinen (1993) and Buško (2009). Acknowledgements The study was supported by Ministry of Science and Higher Education (Grant No. AWF - Ds.-150). References Buško K. (2009). Human Movement, 10(2), 149-152. Häkkinen K. (1993). ## RELATIONSHIPS AMONG JUMP TEST PERFORMANCES AND SPEED OF CONTINUOUSLY CYCLICAL STEPS DURING ACCELERATION PHASE OF SPRINTING

NAGAHARA, R., NAITO, H., MIYASHIRO, K., ZUSHI, K.

UNIVERSITY OF TSUKUBA

**Introduction** The sprint performance during acceleration and maximal speed phase relate to several jump performances (Morin and Belli, 2003; Maulder et al., 2006; Kale et al., 2009). Previous studies investigated the relationships among jump performances and the performance in each wide partition during sprint running. Then, the purpose of this study was to investigate the relationships among the jump test performances and continuously cyclical steps during acceleration phase of maximal sprint running. **Methods** Nineteen male sprinters (age  $20.1 \pm 1.2$  yr, height  $1.75 \pm 0.04$  m, weight  $66.1 \pm 4.0$  kg and the best time of 100m race  $11.19 \pm 0.34$  s) participated in this study. The subjects performed the 60m sprint running with maximal effort started by crouching style as used in 100m race. The running motion was recorded by six high-speed cameras (300Hz). The step times were counted with recorded videos and the coordinates of toe at each support phase were obtained by digitizing. After the sprinting test, subject performed several jump tests (Standing Long Jump: SLJ, Standing Five Jump: SFJ, Counter Movement Jump without arm action: CMJ, Rebounding continuous Jump without arm action: RJ, rebounding continuous Ankle Jump without arm action: AJ). The AJ is our original jumping test which is performed by only plantar flexion of ankle joint without any other joint movement. The measures of SLJ, SFJ and CMJ were the distance and height (m). On the other hand, the measure of RJ and AJ was the jump index that is the ratio of jumping height (m) divided by the contact time (s). Correlation coefficients among the jump performances and the each running speed were calculated. **Results and Discussion** There was no significant relationship among running speeds and SLJ & RJ. The significant relationships were showed among running speeds and CMJ during initial acceleration until the 4th cyclical steps. From the 4th to the 8th cyclical steps, there were significant relationships among running speeds and SFJ. The AJ showed significant relationships against each running speed in whole acceleration phase, and correlation coefficient became high in the 2nd half of acceleration phase. Thus, we concluded that there is different demand of jump performance for obtain of high running speed during each acceleration phase of sprinting. **References** Morin, J.B. & Belli, A. ## STIFFNESS AND VERTICAL JUMP HEIGHT ARE AFFECTED BY THE PREVIOUS COUNTER MOVEMENT

ALEGRE, L.M., MARTIN-CASADO, L., MARTIN-ACERO, R., MARQUEZ, G., AGUADO, X.

UNIVERSITY OF CASTILLA-LA MANCHA. UNIVERSITY OF A CORUÑA

**Introduction** A greater insight into the influence of the counter movement phase of a jump on the vertical stiffness can help to assess whether the vertical path during the counter movement is optimal to achieve the greatest possible jump height. It could also allow to rank athletes from different populations, based on the vertical stiffness levels measured during the counter movement phase. We aimed to assess the effect of vertical jumps (CMJ) performed with different magnitudes of counter movement on peak mechanical power and vertical stiffness during the push off phase. **Methods** Seventeen young subjects ( $21.1 \pm 3.1$  years), 9 women and 8 men, volunteered for the study. They performed 6 CMJs, 3 trials each, with different levels of knee flexion on a force plate (Quattro Jump, Kistler, Switzerland). The levels of knee flexion were classified as (1) Very low flexion ( $70-78^\circ$ ), (2) Low flexion ( $80-88^\circ$ ), (3)  $90^\circ$  of knee flexion, (4) Free, (5) High flexion ( $100-108^\circ$ ) and (6) Deep flexion ( $>110^\circ$ ). **Results** Jump height in the Free condition ( $27.3 \pm 6.6$  cm;  $15.8 \pm 3.6\%$  of standing height) was significantly greater ( $P < 0.05$ ) than those observed in the other conditions, followed by the one measured at  $90^\circ$  of knee flexion ( $26.3 \pm 6.1$  cm;  $15.3 \pm 3.3\%$  of standing height). Jump height in the Free condition was a 10% higher than the one at the Very low flexion condition. When comparing Free condition with each of the other levels there were significant differences ( $P < 0.05$ ) in all the variables. Peak power in the Very low flexion condition was significantly higher than the one found in Free ( $46.5 \pm 7.9$  W/kg vs.  $44.0 \pm 7.6$  W/kg,  $P < 0.01$ ). Vertical stiffness was gradually decreasing from the Very low flexion condition to the Deep flexion condition, with a plateau of similar values in the Free and  $90^\circ$  conditions. Vertical stiffness in Free and  $90^\circ$  were greater than the one measured in the Deep flexion condition ( $P < 0.001$ ), and the stiffness value measured in the Very low flexion condition was greater than the one measured in the other conditions ( $P < 0.001$ ). **Discussion** The greatest jump heights were achieved when the participants freely chose the magnitude of the counter movement. This should be taken into account during the jump protocol design, because the differences between the highest and lowest jumps were the 10% of jump height. The greatest power was measured in the jump with very low flexion. The highest jump heights were found in a plateau of the stiffness values, which could be utilized as a reference to study the optimal counter movement level during the push off phase.

## COMPARISON OF THE FREE FALLING DISPLACEMENT OF THE CENTER OF GRAVITY WITH THE HEIGHT OF THE PLATFORM

CARVALHO, L.A.C.M.1, CANÇADO, G.H.C.P.1, ANDRADE, A.G.P.1, CHAGAS, M.H.1, MENZEL, H.J.K.1

<sup>1</sup> UNIVERSIDADE FEDERAL DE MINAS GERAIS

**INTRODUCTION** One problem in the evaluation of the stretch-shortening cycle through the drop jump technique, is to consider the height of the drop platform as the FFDCG, which can result in calculating jump heights with 4.2% error (SD 9.6%) (Baca, 1999). Moreover, the increment intervals on the drop platform are normally 20 cm (Sale, 1991). Therefore, the aim of this study was to analyze the difference between the height of the drop platform and FFDCG, as well as the differences among the FFDCG obtained from four heights of the drop platform using intervals of 10 cm. **METHODS** Through the impulse method with one force plate the FFDCG were determined. The subjects were 22 young physical active males who were familiarized with the DJ technique (Age  $21.4$  years SD  $2.2$ ) (BW  $74$  kg SD  $9.2$ ) (BH  $1.72$  m SD  $0.11$ ) (BMI  $23.6$  SD  $2.1$ ). Two perfect jumps were performed from each height of the drop platform (20, 30, 40, 50 cm) with 3 minutes rest

period between jumps. The jumps were performed in a random order. Before each jump the following command was given systematically: "With your hands on your hips, try to fall from the height that you were in, using the minimum contact time and maximum jump effort". For the FFDCG variable the mean and SD were obtained from values of the subject's two jumps mean. For the statistical analysis the t test and one way ANOVA were used. RESULTS The FFDCG was different from the height of the respective drop platform ( $p < 0.0001$  for every drop platform). Each FFDCG of the four drop platform were different among each other ( $p < 0.001$ ). DISCUSSION This result supports Bobbert et al. (1987), who found FFDCG values smaller than drop platform heights, increasing the difference as the height of the drop platform increased, indicating a possible protection mechanism against increasing impacts (Schmidtbleicher, 1992; Leukel et al., 2008). Therefore, we can categorically reaffirm that using the impulse method, the utilization of the height of the drop platform as the value of FFDCG to calculate jump height in DJ will result in non confident values of jump height (Baca, 1999). Moreover, differences were observed among FFDCG for each drop platform, indicating that the utilization of 10 cm increment intervals are more adequate than 20 cm or more as generally used in studies with DJ (Sale, 1991). ## INFLUENCE OF MODIFIED BOSCO REBOUND JUMP TEST FOR EVALUATING PHYSICAL STRENGTH FACTORS IN ALPINE SKIERS DURING THE COMPETITION SEASON

HOSHINO, H., TSUNODA, K., SASAKI, T.

HOKUSEI GAKUEN UNIVERSITY

**Introduction** In the present study, this test was performed for 90 seconds, and the power output characteristics were added to the jump height as test parameters. Subsequently, in order to analyze the physical conditioning of Alpine skiers during the season on the basis of these parameters, measurements were conducted at two different times, during the physical training period prior to the competition season and the during the competition season. The objective of this study was to investigate the suitability of a modified version of Bosco et al.'s rebound jump test (BRJ) for evaluating the physical conditioning of competitive Alpine skiers. In the modified Bosco rebound jump test (call for BRJ), the duration of the test has been prolonged to 90 seconds. The physical conditioning of the subjects is then evaluated on the basis of the data generated in the modified BRJ for the jump height, power output and power components. **Methods** A total of 26 Alpine skiers, 15 men and 11 women, performed the modified BRJ test. Measurements of the test parameters, i.e., the jump height and power output characteristics, were conducted twice, during training (September) and during the competition season (January). The changes in the test parameter values were then analyzed. During the BRJ test, performed on a ground reaction force (Ex-Jumper; DKH Co., Ltd.), the subject jumped as high as possible on the rebound from a squatting position, repeating this for 90 seconds. The jump height and power output characteristics were determined on the basis of the time from vertical ground reaction force until landing, in accordance with the methods developed by Bosco et al. Results and discussion BRJ test was devised for evaluating the physical conditioning of competitive Alpine skiers during the competition season. The suitability of the modified BRJ test for this evaluation was also assessed. The mean test parameter data between the training-season and the competition season were compared for male and female skiers. The results show that the maximum jump height of the male skiers increased by 5%, from 39 cm to 41 cm, between training season and the competition season. The mean peak power of the male skiers also increased, from 52.51 watts/kg to 53.38 watts/kg. For the female skiers, the mean maximum jump height increased from 29 cm to 33 cm between the training season and the competition season. The mean peak power of female skiers also increased, from 43.16 watts/kg to 48.08 watts/kg. **Conclusion** To evaluate these factors, we devised a modified version of the BRJ test, in which the duration of the exercise was extended to 90 seconds. We then had Alpine skiers perform the modified test at two different times, during the physical training period and during the competition season. For both male and female skiers, the test parameter data were found to have improved during the training season and the competition season. In consideration of these test findings, the BRJ test may be a suitable method for evaluating the physical conditioning of Alpine skiers.

## TRAINING LOAD'S CONTROL BY THE CMJ TEST IN SPRINT EVENTS AND JUMPS TO OPTIMIZE SPORT'S PERFORMANCE IN ATHLETICS

JIMENEZ-REYES, P.1, CUADRADO-PENAFIEL, V.2, ORTEGA-BECERRA, M.A.3, GONZÁLEZ-BADILLO, J.J.4.

1: UAX (UNIVERSITY OF ALFONSO X, VILLANUEVA DE LA CAÑADA, MADRID), 2: UCLM (CASTILLA LA MANCHA, ESPAÑA), 3: US (SEVILLA, ESPAÑA), 4: UPO (SEVILLA, ESPAÑA)

**Introduction** The study of training load's dose always has provoked controversies and there is not solved which is the optimal training load to achieve the highest performance (Cronin and Sleivert, 2005). Most studies analyse the training's immediate effects without a scientific evidence exists, in many cases, on the most suitable loads and their effects in performance. Our aim was to obtain a more complete and actual information on training process' effects, verifying the evolution in time of these variables and their relationship to athletic performance. **Methods** Twenty four high level sprinters (age  $25.4 \pm 4.5$  yr, body mass  $75.5 \pm 7.3$  kg, height  $179.9 \pm 5.6$  cm; body fat  $9.9 \pm 2.3\%$ ) took part in the study. Over seventy-one training's week, subjects' physical condition was weekly tracked using "Counter-movement Jump" (CMJ) and by collecting other data of weekly training load athletes performed, strength and power measurements and the results in competition. **Results** We analyse the value in CMJ's evolution in the four weeks previous to a competition at best and worst performance peaks, at best performance peaks there is a tendency to an increase in vertical jump height upto approximately the 100% of the best value achieved during all the period studied (71 weeks). The variables measured to monitor specific performance were always taken at times closer to competitions. In relation to training load's evolution during the four weeks previous to competition, we highlight that maximum values of weekly training load no higher than 40-45% of the maximum weekly load conducted by the subject, tends to produce the best results in competition. **Discussion** Control of CMJ during the competition week could be a good indicator of the subject's performance during that same week on short-term events in which the performance depends largely on strength and ability to produce force. The information gathered in CMJ weekly should be used to control the specific performance's evolution. The results from the test enable us to introduce suitable changes in training load so as to control the performance tendency in cases where the latter is not satisfactory. **In conclusion**, if there is realized an exhaustive training load's control and its relationship to physical performance and athletic performance, it would allow to adjust training loads adequately and it would also provide valuable information for a rational training planning. **References** Cronin, J., and Sleivert, G. (2005). Challenges in understanding the influence of maximal power training on improving athletic performance. *Sport Med.* 35(3): 213-234.

## EFFECTIVENESS OF A MODIFIED BOSCO REBOUND JUMP TEST FOR EVALUATING PHYSICAL STRENGTH IN ALPINE SKIERS

HOSHINO, H., TSUNODA, K., SASAKI, T.

HOKUSEI GAKUEN UNIVERSITY

**Introduction** The purpose of this study was to investigate the suitability of a modified version of the Bosco Rebound Jump test (mBRJ) for evaluating the physical conditioning of competitive Alpine skiers. In the mBRJ, the duration of the test has been prolonged to 90 seconds. The physical conditioning of the subjects is then evaluated on the basis of the data generated in the mBRJ for the jump height, power output and power components. **Methods** A total of 26 Alpine skiers, 15 men and 11 women, performed the mBRJ. Measurements of the test parameters, i.e., the jump height and power output characteristics, were conducted twice, during pre-season training (September) and during the competition season (January). The changes in the test parameter values were then analyzed. During the mBRJ test, performed on a ground reaction force (Ex-Jumper; DKH Co., Ltd.), the subject jumped as high as possible on the rebound from a squatting position, repeating this for 90 seconds. The jump height and power output characteristics were determined on the basis of the time from the vertical ground reaction force until landing, in accordance with the methods developed by Bosco et al. **Results and discussion** The original BRJ was devised for evaluating the physical conditioning of Alpine skiers during the competition season. The suitability of the mBRJ for this evaluation was also assessed. The mean test parameter data between pre-season training and the competition season were compared for male and female skiers. The results show that the maximum jump height of the male skiers increased by 5%, from 39 cm to 41 cm, during the competition season. The mean peak power of the male skiers also increased, from 52.51 W/kg to 53.38 W/kg. For the female skiers, the mean maximum jump height increased from a pre-season training 29 cm to 33 cm during the competition season. The mean peak power of female skiers also increased, from 43.16 W/kg to 48.08 W/kg. **Conclusion** The speed endurance capacity and the ability to perform the stretch-shortening cycle exercise have been the focus as factors related to physical strength for Alpine skiers during the competition season. To evaluate these factors, we devised a modified version of the Bosco Rebound Jump test (mBRJ), in which the duration of the exercise was extended to 90 seconds. We then had Alpine skiers perform the mBRJ at two different times, during pre-season physical training and during the competition season. For both male and female skiers, the test parameter data were found to have improved between pre-season training and the competition season. In consideration of these test findings, the mBRJ may be a suitable method for evaluating the physical conditioning of Alpine skiers. **Reference** Bosco C., SCIENCE AND SKIING (1997) Bosco C., et al., Eur. ## EFFECTS OF PASSIVE STRETCHING IN THE VERTICAL JUMP OF BALLET DANCERS

CIARROCCHI, D.M.1,2, CONTE, M.1, LAGO, O.C.1

1: LAPEB-ESEF (UNIDIAÍ-BRAZIL) 2: FACULDADES ANHANGUERA (UNIDIAÍ-BRAZIL)

**Introduction:** Studies point out that strength and flexibility are competitive in relation to the mechanics of movement, therefore flexibility exercises can cause a temporary reduction in strength and performance. Ballet dancers intensively use their flexibility and strength capacity in order to assure the extent of movement and perfect execution of classical dance techniques. **Objective:** To verify the relationship between exercises of stretching and vertical jump among ballet dancers. **Methodology:** Fourteen dancers of both genders (21.21±2.72 years old) were studied. They performed successive jumps for 20s. two times: (S1) only vertical jump and (S2) vertical jump immediately after flexibility training. The variables related to jump were measured with the jump mat 'Jump System 1.0 Fit Cefise®'. The flexibility section had eight static stretching exercises, lasting for 20 seconds each. In line with statistic procedures, the t test (p <5%) was applied. **Results:** The amount of jumps in the S1 (30.7 ± 4.9) was lower than in S2 (32.0 ± 3.5). The average jump height was 22.4 ± 4.9cm and 22.0 ± 6.3cm respectively, however, no significant difference was found. **Discussion:** Previous studies showed that prior flexibility exercises can reduce the capacity of vertical jump and therefore it can cause deficit in the strength for up to one hour after the passive stretching (FIELD et al 2008). Furthermore, Cramer et al, (2004) verified that applying the maximum torque condition during the isokinetic extension of the inferior limbs, after one active exercise and three passive exercises of stretching, decreased strength. In the present study it was observed that the passive stretching did not affect the performance of vertical jump. In the same way it did not present negative effects in the explosive strength during the performance of jumps in controlled conditions (NOGUEIRA et al 2010). In this way it is suggested that the dancers were used to a routine of intensive stretching presenting chronic morphophysiological adaptation recurrent from constant flexibility training, and the section of passive flexibility of 20 seconds was probably not enough to influence the capacity of vertical jumps. It can be concluded that the prior passive stretching did not interfere in the performance of vertical jump of ballet dancers. **Bibliography** Cramer JT, Housh TJ, Johnson GO, Miller JM, Coburn JW, Beck TW. ## EFFECT OF JUMPING DIRECTION ON JOINT KINETICS DURING REBOUND-TYPE JUMPS: DIFFERENCES BETWEEN DOUBLE- AND SINGLE-LEG TAKEOFF

KARIYAMA, Y., MORI, K., OGATA, M.

UNIVERSITY OF TSUKUBA, JAPAN

**Introduction** Rebound-type jump (RJ) in the horizontal direction is widely used to enhance high power output, e.g., plyometric training. Many studies have investigated RJ in the vertical direction and double-leg takeoff jumps as experimental tasks (Bobbert, 1990; Markovic and Mikulic, 2010), while only few studies have examined joint kinetics in the horizontal direction. Joint kinetics of the takeoff leg should be studied to understand the training load and training objectives. This study aimed to clarify the effects of jumping direction on joint kinetics during RJ, with focus on the differences between double- and a single-leg takeoff. **Methods** Twelve male track and field athletes (age, 22.0 ± 2.2 years; height, 175.0 ± 6.1 cm; and weight, 65.8 ± 4.0 kg) performed repeated RJs with double-leg takeoff (vertical double [VD], 50% horizontal double [HD], and HD) and single-leg takeoff involving alternate left- and right-leg contacts (vertical single [VS], 50% horizontal single [HS], and HS). In 50%HD and 50%HS, they performed RJs in the horizontal direction at equal intervals of half the jump distance measured from HD and HS, respectively. Kinematics and kinetics data were recorded using a high-speed video camera (300 Hz) and force platforms (1000 Hz). The joint torque and torque power of the takeoff leg were calculated by inverse dynamics. The takeoff phase was divided into the eccentric phase (ECC; from the point at touchdown to the lowest point of the body's center of gravity [CG]) and the concentric phase (CON; from the lowest point of CG to toe-off). **Results and Discussions** With a change in jumping direction from

vertical to horizontal, the force and joint kinetics also changed: some changes were common (A) while others differed (B) between double- and single-leg RJs. (A) There was an increase in the braking and propulsive impulses of horizontal ground reaction force; the negative torque power at the knee joint; and the extension torque during ECC and positive torque power at the hip joint. (B) At the ankle joint: the extension torque during ECC and negative torque power decreased, but the extension torque during CON and positive torque power increased in single-leg RJ; no change in these parameters was noted in double-leg RJ. At the knee joint: the extension torque during CON and the positive torque power increased in single-leg RJ; these parameters decreased in double-leg RJ. At the hip joint: the increase in the maximum torque during ECC was greater in single-leg RJ than in double-leg RJ. Our results show that the torque and torque power outputs change with jumping direction, and these differ between double- and single-leg takeoff. References Bobbert, M. F. ### PP-PM51 Body Composition

#### CHANGES IN BODY MASS AND WAIST CIRCUMFERENCE OF CONSCRIPTS WITHIN DIFFERENT HEALTH GROUPS AND THEIR EFFECT ON THE CONSCRIPTS' PERFORMANCE ON THE EXAMPLE OF A UNIT IN THE ESTONIAN ARMY

ANTSON, H., MÄRK, H.

TALLINN UNIVERSITY

**Introduction** Estonian National Defence is based on a non-professional army with conscripts and reservists. Depending on health status the conscripts are divided into the categories Healthy and Healthy with Restrictions. Several studies indicate that the conscripts' body weight and waist circumference might shift upwards during a few weeks after start of military service and such an orientation might impose an unwanted influence on their operational effectiveness and health status. The current follow-up study continues the recent research among conscripts. The paper aims at eliciting influences of comparative body mass and waist circumference (described by body mass index (BMI) and waist circumference index (WCI) respectively) on conscripts' physical performance, wherein the health status of conscripts is taken into consideration. **Methods** 656 male conscripts at the start of service in 2009 (mean age 22) participated in the study of the training cycle in years 2009-2010. Individual APFT (army physical fitness test - 3 simple sports tests in three stages during the service period) results as well as their medical data and body measurement records were collected and stored in the data base and analyzed. **Results** The current study revealed the fact that both the body mass and the waist circumference of many conscripts varied distinguishably in two general stages – firstly, after entering the service and secondly, after the end of the basic training course (BTC). Division of health categories of freshmen who were engaged into the unit was 75% Healthy and 25% Healthy with restrictions. Diseases of the musculoskeletal system (M-type diseases) are considered to be a rather common health problem among freshmen (in current study 49% of all diseases). These are followed by mental and behavioral disorders (F-type diseases 16%), diseases of the eye (H-type 5.4%) and congenital malformations (Q-type 5%). **Discussion** Conscripts within health category Healthy with restrictions significantly performed at lower level in their physical abilities than conscripts within category Healthy. The most negative effect of the rise of conscripts' comparative BMI as well as comparative WCI (the results of APFT did not improve) was strongly correlated to the soldiers with F-type diseases within health group Healthy with restrictions. There is an indirect evidence that the rise of body mass, which is commensurately growing along with fat mass (described by WCI) is linked to the mental and behavioral stress. References Antson H, Märks H. Changes in BMI and its cohesiveness to physical performance and health condition of soldiers during their conscript time. ECSS Antalya 2010, Turkey

#### THE INFLUENCE OF BODY WEIGHT REDUCTION ON THE PARAMETERS OF BODY COMPOSITION IN JUDOISTS

COUFALOVÁ, K., KINKOROVÁ, I., HELLER, J.

CHARLES UNIVERSITY IN PRAGUE

**Introduction** In judo and other sports which have weight categories, it became customary to reduce weight of athletes just before the tournament. It is done by significant restriction of fluid intake, exercises for dehydration and sweating. In this way of the reduction it will not reduce only the total body water, but also the body fat, together with lean body mass (Forbes, 1987; Proteau, 2006). This body weight reduction has serious consequences. The aim of this study was to find differences in the particular parameters of body composition influence of body weight reduction in elite judoists. Monitoring these changes is important especially to avoid the negative impact of body weight reduction. **Methods** We measured the basic anthropometric parameters (body height, body weight, circumferences and transverse diameters and somatotype by Heath & Carter - 1967) and the thickness of the skinfolds by Best's caliper. For the measurement of body composition was used multifrequent bioimpedance analyzer BIA 2000 - M. **Results** The results of our study show that body weight reduction in judoists is greatly influenced by the individual variability and reflected in varying degrees in all parameters of body composition. Average of body weight reduction was 3.8 kg (i.e. 4.7%). The major changes in the parameters of body composition occurred in extracellular water (average difference 13,8%) and body fat (average difference 13,2%). Average decrease of lean body mass was 4,2%. Measured mean somatotype was 1,5: 5,7: 2,1, equivalent to a somatotype balanced mesomorph. In assessing the changes of parameters due to body weight reduction were found materially and statistically significant differences in all parameters, except intracellular water and body cell mass. **Discussion** As we expected major part of weight loss was composed of body water loss. We found large individual differences in fluid distribution between intracellular and extracellular water. It could be caused by redistribution of body fluid from intracellular to extracellular space or other way round, it is very individual and influenced by many factors. Even though there was a rapid body weight reduction lasting only a few days, we recorded a decrease of body fat. We also measured a decrease of lean body mass in most of the probands, what is undesirable. References Forbes, G. B. (1987). Human body composition. Springer Verlag, New York. Heath, B. H., Carter, J. E. L. (1967). A modified somatotype method. American Journal of Physical Anthropology, 27, 57-74. Proteau, S., Pelle, A., Collomp, K., Benhamou, L., Courteix, D. (2006). ## BODY IMAGE, OBESITY INDICES AND PHYSICAL FITNESS OF CYPRUS ELEMENTARY SCHOOL CHILDREN AGED 6 TO 12 YEARS OLD

PANAYIOTOU, G.1, DOUDA, H.2, MAKRIS, A.1, TOKMAKIDIS, S.P.2

1:EUROPEAN UNIVERSITY OF CYPRUS (CYPRUS), 2:DEMOCRITUS UNIVERSITY OF THRACE (GREECE)

**Introduction** Body image, a psychological variable enhanced by physical activity and subsequently influence weight control attitudes and behaviour, is defined as the interaction between the perceptive component and cognitive evaluation of body size (Baker & Brownell, 2000). However, when children participate in exercise programs, they experience feelings of satisfaction and success leading to the improvement of self-esteem and body image. Among children and adolescents, body image dissatisfaction is based on age, pubertal status, gender, body mass index and family relationship (Gilliland et al., 2005). The aim of the present study was to assess the correlations among body image, obesity indices and physical fitness level of elementary school children in Cyprus aged 6 to 12 years old. **Methods** A cohort of 816 healthy pupils, aged  $10.3 \pm 1.8$  yrs, participated in the study and were divided according to their gender (391 boys, 425 girls) and their obesity level (normal, overweight, obese) as defined by IOTF criteria (Cole et al., 2000). A self-report body image questionnaire was composed of thirty-six questions about body shape and overall physical appearance and anthropometrical (BMI, body composition, abdominal circumference) and physical fitness (flexibility, muscle strength, isometric strength, jumping ability, cardio-respiratory endurance) measurements were obtained. **Results** From the PCA analysis, seven components were extracted, with eigenvalue above 1, explaining 60.46% of the total variance, and were labelled in the following order: 1-Satisfaction (14.79%), 2-Appearance (13.34%), 3-Insecurity (10.49%), 4-Low Self-Esteem (7.59%), 5- Self-assurance (5.39%), 6-Sociability (4.71%) and 7-Positive attitude (4.13%). The data analysis showed that boys presented better values in the satisfaction of their body image ( $p < .01$ ) as compared to girls. Significant differences were also observed between obese and normal body mass children in 1-Satisfaction ( $p < .01$ ), 2-Appearance ( $p < .001$ ), 4-Low self-esteem ( $p < .01$ ) and 5-Self-assurance ( $p < .05$ ). Pearson correlation coefficient showed statistically significant association of BMI, waist circumference and body fat respectively with 1-Satisfaction ( $r = -.195$ ,  $r = -.240$ ,  $r = .253$ ,  $p < .01$ ), 2-Appearance ( $r = -.295$ ,  $r = -.284$ ,  $r = -.344$ ,  $p < .001$ ) and 4-Low self-esteem ( $r = .161$ ,  $r = .146$ ,  $r = .134$ ,  $p < .05$ ). Muscle strength and cardio-respiratory endurance correlated significant with 1-Satisfaction ( $r = .233$ ,  $r = .252$ ,  $p < .001$ ) and 2-Appearance ( $r = -.204$ ,  $r = -.192$ ,  $p < .001$ ). **Discussion** The above data revealed that girls, as well obese children, reported greater body image dissatisfaction than boys (Hausenblas et al., 2002) and a greater desire for thinness (Collins, 1991). Generally, boys had greater participation in physical activity than girls, were more active and presented better values of physical fitness and strength and overall self-esteem for their body image.

## RELATIONSHIP BETWEEN EXPENDITURE TIME, MENTAL HEALTH AND BMI IN SECONDARY SCHOOL PUPILS IN ALBANIA.

CANAJ, F.

UNIVERSITY OF SPORTS OF TIRANA

Çanaj ,F.1, Ikonimi E. 1, Qeleshi, A.1. 1: UNIVERSITY OF SPORT OF TIRANA **Introduction:** It is well know that activity habits are established at young age; studies show that those people, who can most readily be persuaded to take up more activity, are those who, as children, were physically active at school and during their leisure (1). There is such a thing as mental health just as there is physical health and the two are intertwined (2). The WHO has now tentatively recommended the use of BMI – for age as indicator of overweight or obesity (3). and high BMI in adolescence is predictive of adult mortality (4). But is the correlation between time expenditure, mental health and BMI in secondary school pupils in Albania? **Objectives:** To objectively investigate the relationship between mental health, time expenditure and BMI in secondary school pupils in Albania. **Subjects:** This study included the biggest city in Albania ,Tirana , Shkodra and Fieri ( 5, 6, 7, 8 grade), 950 children-boys and girls from 11 to 14 years old in public school. **Methodology:** Objective measurements of height, weight and waist circumference were obtained. BMI is measured by measuring Weight and Height at 9:00- 10:00 morning time Questionnaires of time expenditure (based on EPAQ2, Source: Wareham et al. IJE 2002) and mental health (Rate yourself from Poul M.Insel and Walton T .Roth 1988) Are fulfilled for one week with the parents support. As a quantitative study all data entry are elaborated in database. **Discussion.** Our study is tried to be realistic, honest and true. BMI itself seem to be lesser than the WHO standards, so we have no overweight and obesity. In Tirana, the correlation between them, mental health (>16 according to the scale) and time expenditure goes in right proportion, higher the PA (PA games Home Help, Stroll, Sp & GYM), higher Mental Health scale results we got. The same results seem to have also in other Cities. In five weeks adding three hours of PA per week (time expenditure) can not change BMI , but only Mental health was found to improve. **References** 1- James, W.P.T. 1995.A public health approach to the problem of obesity .International Journal of Obesity and Related Metabolic Disorders 19 (Suppl.3): S37-S43. 2 .Poul M.Insel and Walton T. ## THE BODY COMPOSITION CHART ANALYSIS FOR ELLITE ATHLETES

KIM, C.H.1, KIM, H.J.2

1. EULJI UNIVERSITY SCHOOL OF MEDICINE, 2. KOREA NATIONAL SPORT UNIVERSITY

**Introduction** The quantitative fat mass (FM), fat-free mass (FFM) and percent body fat (PBF) have been separately used for body composition status, although the optimal physical performance of athletes needs not only an amount of FM and PBF but also an amount of FFM (ADA et al., 2009). Profiles and changes of body composition for elite athletes have not been discussed. To show body components visually as a quantitative measure, a chart based on the fat-free mass index (FFMI, FFM/height square) and fat mass index (FMI; FM/height square) can be applied to investigate the nature of body composition changes with physical training and sport events (Hattori et al., 2004). Therefore, this study is aimed to address sport-specific profiles and change of athlete's body composition on a graphical chart called the FFMI-FMI chart. **Methods** A sample of 743 subjects (385 elite athletes, 358 control) aged 18 - 39 years was studied to determine body composition by DXA. Among the subjects, 27 soccer players participated in the 12-week intensive physical training and their body compositions were measured before and after the intervention for body composition changes. Among the body components, FFMI and FMI were put on an x- and y-axis in a body composition chart, where FMI, FFMI, PBF, and BMI (= FMI + FFMI) were visually analyzed together. Hotelling's T2 test, MANOVA and the overlap zone analysis were used for the exploratory and statistical analysis. **Results** There were significant differences between male athletes and male controls in FFM, FM, FFMI, FMI, and BMI ( $p < 0.001$ ) even though the body weights between the two groups were alike ( $p = 0.562$ ). All of the body components of Female athletes were different from them of

female controls ( $p = 0.001$ ). In the FFMI-FMI chart, body components were separately distributed by sport events and sex. The migration of body components from pre-training and post-training can be expressed distinguishing all body components including FFMI, FMI, BMI, and PBF vividly and quantitatively. Discussion The findings of this study show the distribution of FFM and FM are characteristically delineated on the FFMI-FMI chart, demonstrating clear exercise-induced body-component differences and changes. The FFMI-FMI chart can vividly evaluate the profiles and changes of body composition for elite athletes. References ADA, ACSM, et al. (2000). *Med Sci Sports Exerc*, 41(3), 709-31. ### THE DIFFERENCE OF VARIATION OF BODY COMPOSITION IN JAPANESE FEMALE UNIVERSITY STUDENTS.

YUMIGETA, R., TSUNODA, N., HORIKAWA, H.

SHOWA UNIVERSITY

**Introduction** In order to keep in good health, it is important for keeping health to recognize the change in the body composition. In recent years, bioelectrical impedance analysis method (BIA) has become available for determination of human body composition. However, it is not clear which part of the body's fat and muscle has change in term of body composition is not clear. The purpose of this study was to examine the difference of variation of body composition in Japanese female university students. **Methods** The participants were forty-five healthy female university students. Their mean (SD) values of age, height were 18.3(0.5) yrs, 159.4(6.1) cm respectively. Body weight(BW), percentage of body fat in whole body(FWB), left arm(FLA), right arm(FRA), left leg(FLL), right leg(FRL) and trunk(FTK) and muscle volume in whole body(MWB), left arm(MLA), right arm(MRA), left leg(MLL), right leg(MRL) and trunk(MTK) were measured by bioelectrical impedance analysis method(TANITA, Japan). Each item was measured in April and January. And also, each item was measured that subjects get up and after urination as soon as impossible. **Results** BW and FWB in January were significantly higher value than that of April. On the other hand, significantly difference was not observed between April and January in MWB. FLA, FRA and FTK in January were significantly increased than that of April. The volume of increase of fat in each part of body, FTK was showed the highest value, and the significant difference was observed between FTK and FLA. However, the difference was not significant between April and January in muscle volume of in each part of body. **Discussion** From these results, it was cleared that the increase of body fat caused the increase of body weight. It was considered that there were a part to which the body fat was like to be attached and a part not attached in human's body. And also, it was suggested that the part to which the body fat was likely to be attached most would be a trunk. Thus, we suggest that there is a possibility of accumulating the body fat in the order of the body trunk, the arm, and the foot. #### INFLUENCE OF COMFORTABLE SELF-PACED RUNNING AND IT'S EXERCISE INTENSITY ON THE STRESS BIOMARKER RESPONSE

KUDO, H., TAZAWA, T.

MEIJO UNIVERSITY

**Introduction** In recent years, the comfortable self-paced running is reported to be beneficial to the health maintenance (Mizuno et al., 2006). The salivary amylase has been known as one of the stress biomarker (Yamaguchi, 2007). Therefore, the purpose of this study was to elucidate the effect of comfortable self-paced running and it's exercise intensity on the salivary amylase. **Methods** This study comprised 33 healthy male volunteers, and the volunteers were classified into three groups (comfortable self-paced running group (CSPR group) of 11 people, comfortable self-paced running  $\pm 15\%$  of peakVO<sub>2</sub> load group ( $\pm 15\%$  group) of 11 people each). The volunteer of the three groups performed the treadmill run for 15 minutes at each loaded speed. The Rating of Perceived Exertion(RPE) and peakVO<sub>2</sub> were measured during exercise. In addition, the salivary amylase content was measured at time of pre-exercise, immediately after exercise, and 30 minutes after exercise. **Result** In both (CSPR and  $-15\%$ ) groups immediately after exercise, the salivary amylase content had not changed remarkably from pre-exercise value. However in  $+15\%$  group, the salivary amylase content increased by 34.18 KU/L. In addition, the meaningful correlation was accepted between RPE during exercise and value of fluctuation of the salivary amylase content immediately after exercise. **Discussion** These results suggests that the stress biomarker response such as salivary amylase content does not only depends on exercise intensity, but also RPE. #### ENDURANCE CYCLING EXERCISE INCREASES SERUM HEAT SHOCK PROTEIN 72 IN HUMANS

KAKIGI, R., NAITO, H., MURADE, S., YOSHIHARA, T., NAKAGATA, T., OZAKI, H., KATAMOTO, S.

JUNTENDO UNIVERSITY

**Introduction** Heat shock proteins (HSPs) play important physiological roles in various cells as a molecular chaperone. Some studies have shown that HSPs are released into the systemic circulation during exercise. Walsh et al. reported that extracellular HSP72 increases 30 and 60 min after treadmill running at 70% Vo<sub>2</sub>max. Suzuki et al. reported that plasma HSP72 concentration were elevated after Ironman triathlon race. However, the effect of endurance cycling exercise on extracellular heat shock protein 72 in human has not been established. **Purpose** To examine serum HSP72 after endurance cycling exercise in humans. **Methods** Recreationally male cyclists ( $n=25$ , age;  $42.7 \pm 11.7$  years, weight;  $65.2 \pm 7.1$  kg and Vo<sub>2</sub>peak;  $51.3 \pm 7.4$  ml·kg<sup>-1</sup>·min<sup>-1</sup>) volunteered and participated the endurance cycling race. Heart rate was recorded to estimate %Vo<sub>2</sub>peak during race. Before and immediately after race, blood sample were taken for determining blood lactate concentration and HSP72 concentration. HSP72 in serum were quantified by EIA methods. **Results** Mean exercise time was  $145 \pm 91$  min. In addition, estimated %Vo<sub>2</sub>peak during race was  $87.9 \pm 9.7\%$ . In addition, Serum HSP72 concentrations were signifi-

cantly increased after endurance cycling race (pre;  $0.52 \pm 0.47$  ng/ml, post;  $0.79 \pm 0.55$  ng/ml,  $p < 0.05$ ). Blood lactate concentrations were also significantly elevated after race. (pre;  $2.2 \pm 1.3$  mmol/l, post;  $4.6 \pm 2.4$  mmol/l,  $p < 0.05$ ). There was no relationship between serum HSP72 and blood lactate concentration, %Vo2max and exercise time. Discussion Previous studies showed that treadmill running and marathon increase extracellular HSP72 in humans. We also demonstrated that serum HSP72 was increased after endurance cycling exercise. Although cycling exercise is non-bearing weight and does not contain eccentric contractions, differences of exercise mode may not affect extracellular HSP72 during exercise. In addition, our data suggests that eHSP72 may constantly release into the systemic circulation during exercise, since eHSP72 concentrations were elevated after race regardless of exercise time. Conclusion Endurance cycling exercise increases serum HSP70 in humans.

#### **VISUALISATION OF GLUT4 LOCALISATION IN HUMAN SKELETAL MUSCLE WITH IMMUNOFLOUORESCENCE MICROSCOPY**

BRADLEY, H., SHAW, C.S., WAGENMAKERS, A.J.M.

UNIVERSITY OF BIRMINGHAM

**Introduction** Glucose transporter 4 (GLUT4) is an insulin and contraction responsive glucose transporter. Animal studies have shown that GLUT4 is primarily located in the membranes of intracellular vesicular organelles in the basal state. Upon stimulation these vesicular organelles translocate to and fuse with the sarcolemmal and transverse (T)-tubule cell surface membranes allowing glucose transport into skeletal muscle. We aimed to visualise the localisation of GLUT4 in human skeletal muscle in fasted conditions and to develop a method to quantify GLUT4 localisation, which could be used to investigate GLUT4 translocation in future studies. **Methods** A GLUT4 antibody was validated in experiments in GLUT4-GFP transfected L6 cells which showed strong colocalisation between GLUT4-GFP and GLUT4 antibody staining. GLUT4 localisation was subsequently investigated using immunofluorescence staining methods in skeletal muscle biopsies from 5 lean human males. T-tubules were stained using an antibody against the T-tubule-specific calcium channel DHPR, fibre type was determined using an antibody against myosin heavy chain type 1, and the cell basement membrane was stained with wheat germ agglutinin-350 or an antibody against collagen IV. Images were viewed using widefield immunofluorescence microscopy. **Results** GLUT4 staining in human skeletal muscle in basal conditions appears in type I and type II fibres as bright intracellular spots, which are particularly abundant in perinuclear and (sub)sarcolemmal regions. When fibres are oriented longitudinally a striated pattern of GLUT4 staining is observed, and co-staining with the T-tubule marker (DHPR) indicates association of GLUT4 with the T-tubule membranes. GLUT4 spot number and area in the immunofluorescence images obtained can be quantified in areas corresponding to sarcolemmal and cytosolic regions of the muscle fibre. T-tubule GLUT4 content can be measured as mean fluorescence intensity in the striations corresponding to the T-tubules. **Discussion** These results confirm previous rodent studies showing the subcellular localisation of GLUT4 in human skeletal muscle cells in basal conditions. The quantitation methods for immunofluorescence images introduced here will be used in future studies to investigate skeletal muscle GLUT4 translocation in response to feeding and exercise in insulin sensitive and insulin resistant humans.

#### **EFFECT OF ACUTE ECCENTRIC EXERCISE ON MUSCULAR MITOCHONDRIAL OXIDATIVE STRESS IN ELDERLY RATS**

TADANO, C., YONA, M., NAITO, Y., SEKI, H., SHIMOSE, R., SUGAWARA, H., TANAKA, M., MACDONALD, G., MURO, M.

TOHO UNIVERSITY

**[Introduction]** Loss of skeletal muscle function with age caused by a reduction of muscle activity via disuse triggers increase of tissue oxidative stress. The mitochondrion is a major site for generating reactive oxygen species (ROS) that facilitates oxidative stress in tissue. It has been pointed out that ROS might be reduced by mitochondrial uncoupling protein 3 (UCP3). Aging decreases UCP3 protein content in muscle. But, it is not clear whether such UCP3 depression with aging induces an oxidative stress in elderly muscle. The aim of this study was to examine the effect of aging on muscular oxidative stress during acute exercise. **[Methods]** Male wistar rats (Young: 12wk, Elderly: 89wk) rats performed downhill running on a treadmill: Young (incline: -16 degree, 10m/min for 3hr); Elderly (incline: -7 degree, 8m/min for 1.5hr). Quadriceps muscles were removed 4 hours after exercise. Superoxide dismutase (SOD) and glutathione peroxidase (GPX) activities were determined. Protein content of uncoupling protein 3 (UCP3) and manganese superoxide dismutase (MnSOD) was also determined with western blotting. Nuclear and mitochondrial DNA was extracted and 8-hydroxy-2'-deoxyguanosine (8-OHdG) was determined in both nuclear and mitochondrial DNA as indices of oxidative stress. **[Results]** SOD activity tended to increase with age but was not affected by exercise. GPX activity was higher in Elderly than in Young and was reduced by the exercise in Young but not in Elderly. UCP3 protein content decreased with age and was reduced by the exercise in Elderly. MnSOD protein, located in mitochondria, greatly increased with age and was elevated with the exercise in Elderly. There was a positive correlation between UCP3 and MnSOD in Young ( $r = 0.87$ ). Oppositely, in Elderly there was a negative correlation between UCP3 and MnSOD ( $r = 0.80$ ). Content of 8-OHdG (DNA damage) was higher in Elderly than in Young in both nuclei and mitochondria. The exercise enhanced mitochondrial DNA damage in Young and Elderly. But there was no effect of exercise on nuclear DNA damage in either group. Mitochondrial DNA damage positively correlated with MnSOD ( $r = 0.75$ ) and negatively correlated with UCP3 ( $r = 0.77$ ) in Elderly, but no correlation was observed in Young. **[Discussion & Conclusion]** In this study, low intensity eccentric endurance exercise enhanced oxidative DNA damage in muscular mitochondria and induced expression of MnSOD in Elderly. UCP3 tended to decrease with age. This data indicates that lower levels of UCP3 might be related to increases in mitochondrial oxidative stress. This UCP3 reduction might lead to a differential contribution of MnSOD to mitochondrial DNA damage during exercise. This result suggests the importance of maintaining UCP3 content to reduce mitochondrial oxidative stress in aged muscle.

#### **HEART BIOCHEMICAL ASPECTS IN OBESE RATS SUBJECTED TO PHYSICAL DETRAINING**

ROSTOM DE MELLO, M., MOURA, L.P., SILVA, A.C., ARAUJO, M.B., DALIA, R.A., JUNIO, M.C., VOLTARELLI, F.A.

SÃO PAULO STATE UNIVERSITY

**INTRODUCTION** The practice of regular physical exercise is highly recommended for the treatment of heart disease, but little is known about the effect of detraining associated with a high fat diet on heart metabolism. **OBJECTIVE** The aim of this study was to analyze the effect of exercise training, of detraining and of the administration of a high fat diet (HFD) on body weight and levels of triglycerides (TG), total protein and DNA of the left ventricle of rats. **METHODOLOGY** Forty weanling rats (28 days) were fed up to 90 days of age with a commercial rat chow. From there, they were divided into four groups: control (C), sedentary rats fed semipurified AIN-93M diet (Reeves et al., 1996) from 90 to 160 days of age; High-Fat Diet (HFD) sedentary rats fed a semipurified diet containing 35% fat from 90 to 160 days of

age; Trained High-Fat Diet (THFD) rats exercised from 28 to 160 days of age, fed a diet containing 35% fat from 90 to 160 days; Detrained High-fat Diet (DHFD) rats exercised from 28 to 90 days, whose exercise training was suspended, fed a diet containing 35% fat from 90 to 160 days. The exercised groups were trained by swimming 80% of anaerobic threshold (AT), determined by the lactate minimum test performed every 25 days (Mello et al., 2010). RESULTS DHFD and HFD groups had higher body weight (g) (C:  $527.13 \pm 71.39$ ; HFD:  $575.81 \pm 68.57$ ; DHFD:  $575.78 \pm 62.25$ ; THFD:  $487.62 \pm 62$ , 1990) and heart TG concentrations (mg / g) (C:  $3.58 \pm 0.37$ , HFD:  $4.39 \pm 1.93$ ; DHFD:  $4.39 \pm 1.99$ ; THFD:  $3.46 \pm 9.92$ ) compared to C and THFD. No difference was found between the groups for: protein (mg/100 mg) (C:  $1.04 \pm 0.18$ , HFD:  $1.15 \pm 0.20$ ; DHFD:  $1.22 \pm 0.26$ ; THFD:  $1.09 \pm 0.31$ ), DNA (mg / g) (C:  $0.079 \pm 0.026$ ; HFS:  $0.078 \pm 0.013$ ; DHFD:  $0.078 \pm 0.019$ ; THFD:  $0.086 \pm 0.018$ ) and Protein / DNA ratio (C:  $14.37 \pm 4.76$ ; HFD:  $15.40 \pm 4.98$ ; DHFD:  $16.46 \pm 5.11$ ; THFD:  $12.98 \pm 3.64$  in the left ventricle. DISCUSSION AND CONCLUSION It was possible to induce obesity in adult rats by HFD without leading to heart hypertrophy and hyperplasia. Exercise training at 80% of LA reduced the weight gain induced by the high consumption of fat, as well as attenuated the accumulation of TG in the heart. REFERENCES REEVES et al. ### INFLUENCE OF EXERCISE ON PLASMA HOMOCYSTEINE LEVELS.

MAROTO, B., GARCÍA-GONZÁLEZ, C., PEDRERO, R., BENITO, P.J., MELÉNDEZ, A., GONZÁLEZ-GROSS, M.

UNIVERSIDAD POLITÉCNICA DE MADRID

INFLUENCE OF EXERCISE ON PLASMA HOMOCYSTEINE LEVELS. Maroto B, García-González C, Pedrero R, Benito PJ, Meléndez A, González-Gross M. ImFINE research group. Department of Health and Human Performance. Universidad Politécnica de Madrid (Spain). Introduction High levels of Homocysteine (Hcy) in plasma have been identified as a cardiovascular risk factor (Boushey, et al., 1995), relating hyperhomocysteinemia with cardiovascular diseases, venous thrombosis and disruption of the central nervous system and stroke, among others. In relation to physical exercise, the results are contradictory (Gelecek, et al., 2007). Some studies show a decrease in Hcy concentrations induced by exercise, others that physical exercise increases the levels of Hcy, or that there has been no effect. The aim of this research is to determine the influence of maximal intensity exercise of short duration and submaximal exercise of moderate intensity on plasma Hcy levels. Methods We studied 10 physically active male subjects (mean age:  $23.51 \pm 1.84$ ), who performed two treadmill tests: a maximal test with an average time of 14'14"; and a stable submaximal test of 40 minutes with an intensity of 65% of VO<sub>2</sub>max. Blood samples were taken immediately before and after each test. Concentrations of Hcy, Folate, and B12 were analysed. Physiological parameters were monitored during both tests, as heart rate and VO<sub>2</sub>max using a Polar S810 and a gas analyzer Jaeger Oxicon Pro, respectively. Results We found statistically significant increases ( $p < 0.05$ ) in plasma Hcy levels after the maximal test. After the submaximal test plasma Hcy levels were significantly higher ( $p < 0.001$ ) than before. Levels of Folate and B12 also significantly increased after both tests ( $p < 0.05$ ). A statistically significant inverse relationship ( $p < 0.05$ ) was found between Folate and tHcy levels. Discussion A comparison with other studies showed similar results in relation to the increase in Hcy during the submaximal exercise test. Those findings support our results. Furthermore, our findings related with Folate levels are similar with those found in other studies. Investigations also indicate that Hcy levels increase according to exercise intensity and duration, although there are no conclusive data (Gelecek, et al., 2007). Nevertheless, it can be said that both high intensity and moderate aerobic exercise are enough to increase plasma tHcy levels immediately after exercise in young, healthy and physically active men. Since the rise of these levels could be identified as a cardiovascular risk factor, its impact on health should be carefully studied. References Boushey, C. J., Beresford, S. A., Omenn, G. S., & Motulsky, A. G. (1995). A quantitative assessment of plasma homocysteine as a risk factor for cardiovascular disease. JAMA, 274, 1049-1057. ### CHANGE IN LACTATE ACCUMULATION AFTER ISOMETRIC EXERCISE TRAINING AND ITS RELATIONSHIP WITH REDUCED RESTING BLOOD PRESSURE

SWAINE, I.

CANTERBURY CHRIST CHURCH UNIVERSITY

Change in lactate accumulation after isometric exercise training and its relationship with reduced resting blood pressure Swaine, I. 1, Devereux, G.2, Wiles, J.1, Coleman, D.1. 1: CCCU (Canterbury, UK), 2: UAD (Dundee, UK) Introduction The purpose of this study was (a) to assess lactate accumulation during incremental isometric exercise (b) to quantify the shifts in this lactate accumulation after isometric training and (c) to relate the training-induced changes in lactate accumulation to the reductions in resting blood pressure. Methods 11 male subjects participated in a 4 week isometric training study using double-leg exercise. Before and after the training resting blood pressure was determined (SBP, DBP and MAP). A discontinuous incremental isometric exercise test was also performed, during which finger-prick blood sampling was used to determine blood lactate (La) at each intensity of exercise. From this, peak lactate was identified (L<sub>peak</sub>) and from the pre- and post- training exponential curves it was possible to quantify shifts at 2, 3 and 4mmol.L<sup>-1</sup> blood lactate. Results There were reduction in mean SBP, DBP and MAP of ( $-4.9 \pm 6.3$  mmHg,  $p = 0.01$ ;  $-2.6 \pm 2.3$ ,  $p = 0.001$ ; and  $-2.6 \pm 3.0$  mmHg,  $p = 0.01$  respectively) and a mean shift in the lactate curve, from  $135.60 \pm 25.27$  to  $155.22 \pm 33.55$  mV and from  $114.43 \pm 21.70$  to  $131.03 \pm 27.07$  mV for 4 and 3 mmol.L<sup>-1</sup> respectively. There was no relationship between shifts in lactate curves and reductions in resting blood pressure. However, training intensity, when expressed relative to lactate peak (%L<sub>peak</sub>), was strongly correlated with reduction in resting SBP ( $r = 0.78$ ;  $p < 0.01$ ) and MAP ( $r = 0.75$ ;  $p < 0.01$ ) in individuals. Discussion These findings using double-leg isometric exercise showed that (a) lactate accumulates in an exponential fashion during incremental isometric exercise (b) 4 weeks of training caused significant shifts in the lactate accumulation curves and (c) reductions in resting blood pressure are not related to changes in lactate metabolism but they are strongly related to training intensity, when it is expressed relative to pre-training peak lactate. This raises the possibility that lactate, or some metabolite associated with it, might provide the stimulus for the reductions in resting blood pressure observed after isometric training.

## THE IMPORTANCE OF THE DETECTION OF BOTH MACROSCOPIC AND MICROSCOPIC CHARACTERISTICS OF SPONTANEOUS PHYSICAL ACTIVITY IN POST-MENOPAUSE

DI BLASIO, A., BUCCI, I., DI DONATO, F., IZZICUPO, P., D'ANGELO, E., RIPARI, P., NAPOLITANO, G.

CHIETI-PESCARA UNIVERSITY

**Introduction** The analysis of spontaneous physical activity is important to characterise the lifestyle and to promote behavioural modifications. Usually, the attention of the analysis is focused on macroscopic characteristics of daily movement, such as total energy expenditure (DEE m/die), daily steps (STEPS m/die), mean daily intensity of physical activities (METs m/die), and both time (TPA m/die) and energy spent (PAEE m/die) on physical activities at moderate intensity. Therefore, literature indicates that it is also important the way through which, for example, TPA is totalized. The aim of our study was to investigate the importance of the detection of microscopic characteristics of daily movements, during spontaneous physical activity analysis, in post-menopause. **Methods** Sixty-two post-menopausal women ( $55.71 \pm 4.94$  yrs) were enrolled in the study. Body composition was assessed by electrical bioimpedance technique, while the SenseWear Pro3 Armband (Bodymedia, Pittsburg, PA) measured daily physical activities characteristics. The device gives information about mean daily values of DEE, STEPS, METs, TPA and PAEE. By our software we calculated the numbers of total daily bouts of moderate intensity physical activities, and the number of those lasting almost 3 (B3), 5 (B5) and 10 (B10) consecutive minutes. Blood was collected to measure plasma lipoproteins, insulin and glucose. A dietitian estimated dietary habits and calories intake. **Results** Pearson's correlations showed METs m/die and TPA m/die inversely correlated with body composition and plasma triglycerides, while their correlations with fasting glucose to insulin ratio (G/I) were direct. Partial correlation, performed controlling for METs m/die, TPA m/die and daily energy intake, showed BMI, WC, fat mass and visceral fat inversely correlated with both B10 and mean duration of each bout. On the contrary, they were found directly correlated with the number of those bouts of moderate intensity physical activities lasting minus than 3 minutes. Plasma HDL-cholesterol has been found positively correlated with B10; the same was for G/I. **Discussion** Together with macroscopic characteristics of spontaneous physical activity (i.e. METs m/die and TPA m/die), microscopic characteristics (i.e. B10) are important for body composition, insulin sensitivity and plasma HDL-cholesterol of post-menopausal women that are not under controlled diet and physical exercise program. The analysis of microscopic characteristics of daily movement should be always carried out in order to better understand the physiological and pathological conditions of the persons concerned, and the effectiveness of their spontaneous physical activity.

## INFLUENCE OF A VITAMIN SUPPLEMENTATION ON MAXIMAL MUSCULAR PERFORMANCE DURING A STRENGTH-TRAINING PROGRAM IN MASTER ATHLETES

LOUIS, J., HAUSSWIRTH, C., BIEUZEN, F., BRISSWALTER, J.

UNIVERSITY NICE-SOPHIA ANTIPOLIS

**INFLUENCE OF A VITAMIN SUPPLEMENTATION ON MAXIMAL MUSCULAR PERFORMANCE DURING A STRENGTH -TRAINING PROGRAM IN MASTER ATHLETES** Louis J1,2, Hausswirth C1, Bieuzen F1, Brisswalter J2 **Laboratory of human motricity, education and health, University of Nice-Sophia Antipolis, France** 2Research department, National institute of sport, expertise, and performance (INSEP), Paris, France **Introduction:** Intensive physical training may lead to severe damages in muscles fibers, inducing fatigue and bad recovery capacities (Barnett, 2006). Micronutritional supplementations are one of the most used strategies to enhance muscular recovery in young athletes (Gauché et al. 2007). However, very few information is available for master athletes for whom the age could accentuate the effect of exercise in damaging muscles (Close et al. 2005). Within this framework, the purpose of this study was to analyze the efficacy of a vitamin supplementation in enhancing maximal muscular performance in master athletes during a strength-training program. **Methods:** Twenty well-trained master athletes took part in a 3 weeks strength-training program and in a same time in a micronutritional supplementation program. At first, master athletes were assigned in a double-blind process to one of the two treatment groups: vitamin supplementation (Isoxan Force®, Vit group) or placebo supplementation (Pl group). Three times a week, subjects had to perform 10x10 bilateral knee extensions at 70% 1RM, separated by 3min rest, on a leg extension device (Technogym, Gambettola, Italy). Before and after the training period, blood markers of muscle damages (creatine kinase, CK, and tumor necrosis factor- $\alpha$ , Tnf- $\alpha$ ) were assessed. Before each training sessions knee extensors' maximal voluntary isometric strength was recorded (Biodex S3, Shirley, NY, USA). **Results:** After the training period, knee extensor's maximal voluntary strength significantly increased (+9,7% in Vit group versus +6,3% in Pl group) in both groups. However, this increase was more pronounced in Vit group than in Pl group and strength recovery between training sessions was improved. Moreover, significant differences in blood markers of muscle damages were found between groups at the end of the training program. CK concentration increased in Pl group (+58,5%) whereas it decreased in Vit (-34%), and Tnf- $\alpha$  concentration increased in Pl group (+87%), whereas it was only a trend in Vit group (+14,3%). **Conclusion:** In all subjects, strength production capacity has significantly increased after the 3 weeks of training. Moreover, the micronutritional supplement is associated with a lower muscle inflammation suggesting an improvement of the beneficial effect of strength training with vitamin and mineral supplementation. **References:** Barnett A. ## LOWER-VOLUME EXERCISE TRAINING AND BRANCHED-CHAIN AMINO ACID INTAKE PREVENT MUSCLE DEGRADATION DURING IMMOBILIZATION

FUJIOKA, M.

TOKYO MEDICAL UNIVERSITY

**Lower-volume exercise training and branched-chain amino acid intake prevent muscle degradation during immobilization** Fujioka M1, Hamaoka T2, Osada T1, Murase N1, Kime R1, Kurosawa Y3, Ichimura S4, Homma T5, Ueda C6, Esaki K7, Ohmori F8, Yamaguchi K9, Katsumura T1 **1) Tokyo Medical University, 2) Ritsumeikan University, 3) University of Cincinnati, 4) Tokyo University of Science, 5) Japan Institute of Sports Sciences, 6) Meisei University, 7) Shiga University, 8) Kokugakuin University, 9) Yamanashi Gakuin Junior College** **Introduction** In our previous research, muscle functions declined without a decrease in muscle cross-sectional area after a 3-week forearm immobilization (3W-IMM) (Kitahara et al., 2003) and the low-volume endurance training twice weekly was effective in preventing IMM-

induced declines in muscle endurance (Homma et al., 2009). In a previous study, branched-chain amino acids (BCAA) supplementation has beneficial effects on decreasing exercise-induced muscle damage. The purpose of this study was to investigate the effect of a lower-volume training once weekly with BCAA intake on muscle functions and protein turnover during 3W-IMM. Methods Twelve healthy male subjects with the 3W-IMM were designated into BCAA (100mg/kg/day) or placebo daily-intake group in a double blind manner. Both groups performed strength (70% of maximum voluntary contraction: MVC, 10 repetitions) and endurance (30% MVC, 1 contraction every seconds until exhaustion) grip exercise training once weekly during the 3W-IMM period. Blood BCAAs and aromatic amino acids (tyrosine and phenylalanine) were evaluated before and 3 hours after the acute supplementation test both pre- and post-3W-IMM. Moreover, MVC, and forearm circumference were measured. Muscle endurance and oxidative capacity were evaluated using 31-phosphorus magnetic resonance spectroscopy and near-infrared continuous wave spectroscopy, respectively. Results MVC significantly decreased (-9.9% for BCAA group and -9.7% for placebo group) and muscle endurance and oxidative capacity did not change in both groups after 3W-IMM. Blood BCAAs were significantly elevated and aromatic amino acids, significantly lowered after acute supplementation test both pre- and post-3W-IMM in the BCAA group. Discussion BCAA intake during 3W-IMM did not show the functional and morphological effect on muscle, but it seems that the lower-volume training itself was effective on functional deterioration. It is reported that BCAA intake decreased the efflux of the aromatic amino acids from the leg, indicating a decreased net rate of protein degradation during exercise (MacLean et al., 1994). Therefore, it is suggested that acute BCAA intake may have prevented muscle degradation pre- as well as post-immobilization. References Kitahara et al. (2003). *Med Sci Sports Exerc*, 35, 1697-702. ### LEUCINE-RICH DIET AND EXERCISE CHANGED GENE EXPRESSION OF MUSCLE GLYCOLITIC ENZYMES IN TUMOUR-BEARING RATS.

SALOMÃO, E.M., TONETO, A.T., SILVA, G.O., GOMES-MARCONDES, M.C.

UNICAMP

LEUCINE-RICH DIET AND EXERCISE CHANGED GENE EXPRESSION OF MUSCLE GLYCOLITIC ENZYMES IN TUMOUR-BEARING RATS. Salomão E.M., Toneto A.T., Silva G.O., Gomes-Marcondes M.C. Laboratory of Nutrition and Cancer, Department of Physiology and Biophysics, IB, UNICAMP, Campinas, SP, Brazil. Introduction Cancer-cachexia state promotes intense involuntary weight loss resulting mainly in muscle protein depletion due to increase in proteolysis and/or decreased protein synthesis. Leucine can be used as energy source by skeletal muscle or acts as a cell signaling. Physical exercise promotes an increased glucose uptake, reducing the glucose and insulin levels, which supplies less substrate to tumour cells (Inui, 1999). Methods We evaluate muscle glycolytic enzymes gene expression and muscle glucose and lactate receptors in rats submitted to aerobic exercise and leucine-rich diet and distributed into 8 groups: C-control rats; TC-trained, W- Walker 256 tumor-bearing; TW-trained tumor-bearing, L-rats fed leucine diet, TL-trained rats fed leucine diet; LW-tumor-bearing fed leucine diet; TLW-trained tumor-bearing fed leucine diet (Salomão et al., 2010). The results are expressed as optical density (arbitrary unit). Results The gene expression of glucose transporter Glut-4 in the gastrocnemius muscle reduced significantly only in tumour groups (W=44.0+11.0; TW=47.7+5.7) compared to leucine-rich diet groups (LW=76.0+20.1; TWL=62.2+11.2). Hexokinase phosphorylates the glucose uptake into glucose-6-phosphate and has its gene expression increased significantly in trained groups and in all tumour groups (TC=69.6+8.3; W=63.6+4.3; TW=51.3+19.7; LW=93.9+7.8), except in TWL(39.0+12.4) vs C(31.8+2.8) group. The pyruvate dehydrogenase converts pyruvate into acetyl-CoA, and this enzyme gene decreased in TWL(47.2+14.9) compared to TC(134.6+17.7) and L(140.7+0.9) and slightly increased in W(116.7+7.6) and LW(102.9+8.4). The conversion of L-lactate and NAD<sup>+</sup> to pyruvate and NADH in the final step of anaerobic glycolysis in the gastrocnemius muscle is catalyzed by lactate dehydrogenase, which gene expression increased in W(67.9+12.9) vs C(21.3+5.2) group. The MCT1 and 4 (monocarboxylate transporter) transport lactate in and out of muscle cells. The gene expression of MCT1, related oxidative muscle fibers, in the gastrocnemius muscle reduced significantly in tumour-trained group (TW=33.0+5.6; TWL=29.8+6.3) compared to W(67.2+4.3). Discussion Tumour growth produced deleterious effects in host leading to the cachectic state, since reduced the muscle glucose transporter diverting this substrate to neoplastic cell metabolism. Leucine supplementation combined with exercise benefited host tissues, as shown in metabolism of glucose by enzyme gene expression, improving host tissue in detriment of tumour growth. PHYSICAL EXERCISE AND LEUCINE-RICH DIET IMPROVES THE GLUCOSE METABOLISM IN TUMOR-BEARING RATS. Salomão E.M., Toneto A.T., Silva G.O., Gomes-Marcondes M.C.C. Nutrition and Cancer, Department of Physiology and Biophysics, IB, UNICAMP, Campinas, SP, Brazil. Introduction Cancer patients often have hypoglycaemia associated to reduced host-tissue glucose metabolism. However, the anaerobic glycolysis that occurs in neoplastic cells, due to high glucose oxidation, leads to energy waste and catabolism of store depots from host, converting lactate, alanine and glycerol into glucose, by Cori cycle, increasing energy deficit in cachectic state. Methods We analyzed serum and gastrocnemius muscle in Wistar rats submitted to aerobic exercise and leucine-rich diet and distributed into 8 groups: C-control rats; TC-trained, W- Walker tumor-bearing; TW-trained tumor-bearing, L-rats fed leucine diet, TL-trained rats fed leucine diet; LW-tumor-bearing fed leucine diet; TLW-trained tumor-bearing fed leucine diet. Results The serum glucose content reduced in tumor-bearing groups (W=102.2+15.3mg/dL, LW=90.9+17.3, TWL=97.7+21.6) when compared to control groups (C=133.0+6.8; TC=181.3+13.7; L=151.6+17.8; TL=156.1+16.8). Despite having cancer, the TW(128.6+20.8) had similar glycaemia as the control group. Insulin levels decreased in all tumor-bearing groups (W=60.29+2.9pg/mL; TW=46.90+3.8; LW=42.50+7.0 TWL=55.48+6.3) compared to control (C=147.6+48.6; TC=173.8+43.6; L=126.7+61.6; TL=54.53+7.3) and serum glucagon levels increased in tumor groups (W=7.3+3.6pg/mL; TW=10.5+5.7; LW=6.0+1.1; WL=6.5+2.5; control groups: C=0.8+0.2; TC=0.8+0.2; L=0.6+0.2; TL=0.8+0.2); although, this increase was lower in LW and TLW groups. Muscle cell glycogen content reduced in tumor-bearing group (W=1.3+0.1 arbitrary unit from histological analyses, LW=1.8+0.3) when compared to other groups (C=2.8+0.1; TC=3.1+0.4; TW=3.1+0.1; L=6.3+0.3; TL=7.1+0.4; TWL=2.8+0.6). Discussion We observed decrease in serum glucose in tumor-bearing groups, justifying the high glucose utilization preferentially by neoplastic cells. In experimental animals, hypoglycaemia is common since glucose is the main energy substrate used by tumor growth (Tisdale, 1997). Several studies with experimental tumors have shown a decreased insulin secretion in response of tumor effects, providing glucose supply to cancer cells, as well as increasing peripheral resistance to insulin (El Razi et al., 1996). The hormonal changes due to tumor growth showed a compensatory balance between anabolic and catabolic hormones, since the glycaemia and muscle glycogen in TW and TLW was maintained under normal values, despite being leucine-rich diet treated. The exercise diverted the

substrate from tumor cells toward to skeletal muscle, decreasing the neoplastic energy supply in order to prevent muscle energy storage. References Tistale JM. (1997) Nutrition 13: 1-7, 1997. El Razi Neto S, Zorn TM, Curi R, Carpinelli A.R. (1996) Am. J Physiol. 271: 804-809.

### **EFFECT OF SUPPLEMENTATION OF CRUDE MAGNOLIA AND ENDURANCE TRAINING ON LIVER IL-6, TAC AND GLYCOGEN CONCENTRATIONS IN MALE RATS.**

FARZANEGI ARKHAZLO, P.1, GAFARIAN, F.2, GHANBARI-NIAKI, A.3, FATHI, R.4

ISLAMIC AZAD UNIVERSITY, SARI BRANCH

**Introduction:** Study on Effect of supplementation of crude magnolia and endurance training on liver IL-6, TAC and glycogen concentrations in male rats. **Methods:** Twenty one adult Wistar male rats (6–8 weeks old, 142.19±12.733 g) were used for this study. Animals were divided into three groups including: control (placebo), experimental-1(placebo+training) and experimental-2 (magnolia+training). Training group was given exercise for 6 weeks (at 25 m/min, 0% grade, for 60 min/day, 5 days/week). Rats were sacrificed 72 h after the last session of exercise and 4 h fasting. **Results:** IL-6 concentrations was significantly increased in experimental-1 group and decreased in experimental-2 group when compared with control group that this decrease not significant. Liver TAC and glycogen concentrations were significantly increased in experimental-2 group and decreased in experimental-1 group when compared with control group that also this decrease not significant. **Discussion:** findings of Present study indicated that supplementation of crude magnolia and endurance training can play protective role against oxidative and inflammatory agents by increase of liver TAC and glycogen stores. **Keywords:** IL-6, TAC, Glycogen, extraction of magnolia, Endurance training **References** 1. ### **EFFECT OF 8-WEEKS OF EICOSAPENTAENOIC AND DOCOSAHEXAENOIC ACID SUPPLEMENTATION ON IMPROVEMENT OF EXERCISE ECONOMY DURING AEROBIC EXERCISE**

NEYA, M.1, KAWABATA, F.2, HAMAZAKI, K.3

1: THE UNIVERSITY OF TOKYO, 2: HUMAN LIFE SCIENCE R&D CENTER, NIPPON SUISAN KAISHA, LTD., 3:FACULTY OF MEDICINE, UNIVERSITY OF TOYAMA

**Introduction** Based on the effects of omega-3 fatty acid such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) on reduction of blood viscosity, it could improve aerobic performance by increasing oxygen supply to tissue (Woodcock et al., 1985). However, the effects of ingestion of omega-3 fatty acid on oxygen uptake (VO<sub>2</sub>) during exercise has not yet confirmed (Brilla et al., 1990; Raastad et al., 1997). Therefore, the purpose of this study is to investigate the effects of continuous supplementation of EPA and DHA on energy supply during aerobic exercise. **Methods** Twenty healthy physically active college male were divided into two groups (n=10 in each group, Active and Placebo groups). Before 8-weeks of ingestion of either EPA/DHA capsules containing 3.6 g/day of fish oil (Active group; ACT) or capsules containing 3.6 g/day of medium-chain triglyceride (Placebo group; PLA), they measured maximal oxygen uptake (VO<sub>2</sub>max) and relationship between blood lactate concentration (BLA) and submaximal exercise intensity using cycle ergometer. They also measured oxygen uptake during submaximal exercise (two sessions of 30-min exercise at intensity levels equivalent to 2 mM and 3 mM of BLA based on the relationship). After 8-weeks ingestion, they measured again VO<sub>2</sub>max and submaximal VO<sub>2</sub> at two sessions of 30-min same absolute intensity levels. Before and after 8-weeks ingestion, blood samples were used for the determination of EPA, DHA and hematocrit. **Results** After 8-weeks ingestion, EPA (148%, p<0.001) and DHA (13%, p<0.001) in the red blood cell membrane of ACT was significantly increased compared to pre-ingestion, but these of PLA did not change. In ACT, the negative linear correlation (r=0.750, p<0.05) was detected between the differences of EPA in RBC versus whole VO<sub>2</sub> during submaximal exercise between before and after 8-weeks ingestion. **Discussion** These results suggest that increased EPA in RBC after 8-weeks ingestion could influence the energy supply during steady state submaximal exercise and induce improved exercise economy. The major factor seems to be a more efficient oxygen supply to exercise muscle due to reduced blood viscosity. The influence of DHA on VO<sub>2</sub> was not detected in this study. Therefore, EPA is the important determinant of exercise economy during steady state submaximal exercise. **References** Woodcock BE., Smith E., Lambert WH. et al. (1984). Br Med J, 288, 592-4. ### **SUPPLEMENTATION WITH VITAMIN C ATTENUATES OVERLOAD-INDUCED SKELETAL MUSCLE HYPERTROPHY**

MAKANAE, Y., KAWADA, S., SASAKI, K., ISHI, N.

THE UNIVERSITY OF TOKYO

**Introduction** Physical exercise generally provides beneficial effects on human health. On the other hand, it generates reactive oxygen species (ROS) in skeletal muscle and other organs, which gives rise to undesirable reactions with biological substances, i.e., DNA oxidation, fat peroxidation and protein carbonyl. Although supplementation with antioxidants is recommended for individuals regularly performing exercise, it has recently been shown that ROS acts not only as a harmful substance but also as an important signal mediator. In fact, antioxidants supplementation has been shown to attenuate endurance training-induced muscle adaptation and gene expression (Gomez-Cabrera et al., 2008; Ristow et al., 2009). However, it remains unclear whether antioxidants such as vitamin C attenuate the hypertrophic response of skeletal muscle to overload. Thus we investigated the effect of vitamin C supplementation on overload-induced skeletal muscle hypertrophy in the rat. **Methods** Male Wistar rats were randomly assigned into 3 groups: sham operated (SHA group; n = 8), placebo (PLA group; n = 8) and vitamin C (VC group; n = 9). For PLA and VC groups, surgical removal of the gastrocnemius and soleus muscles was performed on the right hindlimb with sham surgery on the contralateral limb, inducing chronic overload on the plantaris muscle for 14 days. SHA group was subjected to sham surgery for both hindlimbs. VC group was orally administered with a large amount of vitamin C (500 mg/kg) once a day for 14 days. **Results** There was no significant difference in body weight between PLA and VC groups. In PLA and VC groups, the plantaris muscle of overloaded limb showed a significant increase (P < 0.05) in wet weight when

compared with those in SHA group. However, the increase in muscle wet weight in VC group was significantly smaller ( $P < 0.05$ ) than that in PLA group. Discussion The results indicated that supplementation of vitamin C attenuated overload-induced skeletal muscle hypertrophy. Since vitamin C is a non-specific antioxidant, we believe that this result is due mainly to suppression of ROS generation. Although the mechanisms underlying vitamin C-mediated attenuation of skeletal muscle hypertrophy remain unclear, ROS would play an important role in overload-induced skeletal muscle hypertrophy. ### THE EFFECT OF A VITAMIN C+E SUPPLEMENT AND A COMBINED OMEGA-3 AND PROTEIN SUPPLEMENT ON RECOVERY FROM A BOUT OF RESISTANCE EXERCISE

HAMARSLAND, H., PAULSEN, G., RAASTAD, T.

NORWEGIAN SCHOOL OF SPORT SCIENCES

The effect of a vitamin C+E supplement and a combined omega-3 and protein supplement on recovery from a bout of resistance exercise Hamarstrand, H.1, Paulsen, G.1, Raastad, T.1 1: NSSS (Oslo, Norway) The generation of free radicals (RONS) in the working muscles during resistance exercise seems to be important for cell signalling and the concomitant increase in rate of protein synthesis. Consequently, intake of high dosages of antioxidants may inhibit muscle growth by reducing the oxidative stress during exercise. On the other hand, increased intake of antioxidants may reduce some of the negative stress on muscle structures and thereby increase the rate of recovery. In this study we aim to investigate some of the acute effects of vitamin C and E on recovery from a bout of resistance exercise. Eleven subjects (8 men and 3 women;  $27 \pm 7$  years) were recruited from an ongoing 12 week strength training intervention with vitamin C and E, combined omega-3 and protein (Smartfish® recovery drink) or placebo supplementation (more subjects are currently being enrolled). The subjects performed a maximal voluntary isometric contraction (MVIC, knee-extension) before (-15min) and after (10 min and 24 h) a bout of 4x10RM of leg press and knee-extension (1 min between sets). 500 mg vitamin C and 117.5 mg vitamin E, Smartfish® (7 g of protein) or placebo supplements were taken 3 h before exercise and again half way into the exercise bout. Biopsies were collected before exercise and 80 and 130 min after exercise. Protein measurements of p70, RPS6 and eEF2 phosphorylation are currently being conducted. MVIC was decreased by  $24 \pm 9\%$  in the vitamin C+E group 10 min after exercise and recovered to  $11 \pm 2\%$  below baseline 24 h after exercise. For the Smartfish group the decreases were:  $23 \pm 11\%$  and  $2 \pm 8\%$ , and for the placebo group:  $15 \pm 8\%$  and  $4 \pm 5\%$ , 10 min and 24 h after exercise, respectively. The preliminary data indicate that recovery after a bout of resistance exercise is somewhat slower in subjects receiving vitamin C and E, compared to the combined omega-3 and protein supplement and placebo. The addition of more subjects in these analysis and the ongoing measurements of the phosphorylation of kinases related to protein synthesis might explain the apparent differences in recovery of muscle function between groups.

### VITAMIN C AND E SUPPLEMENTATION DOES NOT INHIBIT IMPROVEMENTS IN CARDIOPULMONARY FITNESS INDUCED BY ENDURANCE TRAINING

PAULSEN, G., HANSEN, J., SVEEN, O., RØNNESTAD, B.R., SKAUG, A., HALLÉN, J., RAASTAD, T.

NORWEGIAN SCHOOL OF SPORT SCIENCE

Vitamin C and E supplementation does not inhibit improvements in cardiopulmonary fitness induced by endurance training Paulsen, G.1, Hansen, J.2, Sveen, O.3, Rønnestad, B. R.2, Skaug, A.3, Hallén, J.1, Raastad, T.1 1: NSSS (Oslo, Norway), 2: LUC (Lillehammer, Norway), 3: ØUC (Halden, Norway) Vitamin C and E supplementation has recently been found to inhibit adaptations to endurance training in some studies (Gomez-Cabrera et al., 2008; Ristow et al., 2009), but not in others (Yfanti et al., 2010). We aimed to test the hypothesis that high dosages of exogenous antioxidants eliminate some of the oxidative stress necessary to initiate adaptation processes after endurance exercise training. Twenty-three, young, endurance trained subjects (10 females and 13 males;  $23 \pm 4$  years,  $VO_{2max} = 52 \pm 9$  ml/(kgxmin)) were randomized to receive vitamin C and E (1000 mg + 235 mg pr. day;  $n=12$ ) or placebo supplementation ( $n=11$ ) in a double-blinded fashion. All subjects followed the same training program for 11 weeks with 3-4 sessions per week. The exercise consisted of 30 and 60 minutes continuous running sessions at 80-90% and 70-85% of HRmax, respectively, as well as sessions with 4 and 6 minutes intervals (x4-6) at  $>90$  of HRmax.  $VO_{2max}$  was measured and the beep-test was conducted before and after the 11 weeks of training. Biopsies from m. vastus lateralis were collected before and after the training period.  $VO_{2max}$  increased by  $5.1 \pm 3.9\%$  in the C+E vitamin group and  $5.5 \pm 4.1\%$  in the placebo group ( $p < 0.001$ ). The performance in the beep-test was improved by  $9.2 \pm 10.4\%$  and  $11.6 \pm 15.3\%$  in the C+E vitamin group and the placebo group, respectively ( $p < 0.05$ ). No group differences were found in these parameters. We are currently analyzing the biopsies for changes in endogenous antioxidant systems and markers for mitochondrial biogenesis, as well as capillarization. A mixed running endurance training program increased cardiopulmonary fitness in already trained individuals, and there were no detectable effect of vitamin C and E supplementation. Thus, intake of large dosages of vitamin C and E seem not to hamper increases in  $VO_{2max}$  or the beep-test. Potential effects in the exercised muscles are under examination. ### PHYSICAL ACTIVITY, BODY COMPOSITION AND ENERGY CONSUMPTION IN UNIVERSITY STUDENTS

ARABACI, R., ERDEN, S., KORKMAZ, N.H., CANKAYA, C., KORKMAZ, F., YILDIZ, H.

ULUDAG UNIVERSITY, FACULTY OF EDUCATION

Introduction Today, in many countries around the world dramatic increase obesity, bone disorders, cardiovascular (CVD) and some cancer diseases. Physical activity and dietary intake have preventive role on these diseases. Therefore, the aim of this study was to determine ambulatory activity, body composition and energy consumption in university students and investigate relationship between these components. Methods A total of 914 Turkish university female ( $n=441$ , age  $21.1 \pm 1.6$  years) and male students ( $n=473$ , age  $22 \pm 1.9$  years) participated in present study. Pedometer determined number of daily step method used to assessment physical activity of subjects. One week number of daily steps was measured by YAMAX PW 610 pedometer. Body composition was analyzed by Bio-electrical Impedance method (Tanita BC-418MA). The subjects recorded a weekly food intake. Mean energy consumption was determined by nutrition and diet

computer program (BEBIS 6). Results Mean  $\pm$  SS of daily step number, BMI, energy intake, BMR, percentage body fat, fat mass, free fat mass and total body water in female and male students were  $7981 \pm 3048$  steps $\cdot$ day $^{-1}$  and  $8509 \pm 3139$  steps $\cdot$ day $^{-1}$  ( $p > 0.05$ ),  $20.6 \pm 2.9$  kg $\cdot$ m $^{-2}$  and  $22.7 \pm 2.6$  kg $\cdot$ m $^{-2}$  ( $p > 0.05$ ),  $1548 \pm 661$  kcal $\cdot$ day $^{-1}$  and  $1559 \pm 715$  kcal $\cdot$ day $^{-1}$  ( $p > 0.05$ ),  $1445 \pm 317$  kcal $\cdot$ day $^{-1}$  and  $1859 \pm 328$  kcal $\cdot$ day $^{-1}$  ( $p < 0.05$ ),  $19.2 \pm 6.6$  % and  $10.5 \pm 5.7$  %,  $11.4 \pm 5.1$  kg and  $7.7 \pm 4.9$  kg ( $p < 0.05$ ),  $46.8 \pm 6.6$  kg and  $63.2 \pm 7.1$  kg ( $p < 0.05$ ),  $34.4 \pm 5.3$  kg and  $46.1 \pm 6.3$  kg ( $p < 0.05$ ), respectively. Daily step number was not significantly correlated with BMI, fat % and energy consumption ( $r = .080$ ,  $r = -.072$ ,  $r = .024$ , respectively,  $p > 0.01$ ). Daily step number was inversely correlated with right leg and left leg fat percentage ( $r = -.110$  and  $r = -.104$ , respectively,  $p < 0.05$ ). Discussion From 1960s in Japan achieving 10000 steps $\cdot$ day $^{-1}$  gaining popularity with the media and practice. Tudor Locke and Bassett classify 'somewhat active' healthy adults that pedometer-determined ambulatory activity 7500-9999 steps $\cdot$ day $^{-1}$ . According this classify subjects of present study were somewhat active. Information about associations between daily step number and body composition variables is more limited. In some studies was stressed that daily step number was inversely correlated with body composition parameters such BMI and body fat percentage. In present study daily step number was not significantly correlated with BMI and body fat percentage, however there was inversely significant correlation between daily step number and leg (both) fat percentage. In female subjects energy intake and BMR was similar, but in male subjects BMR was high than energy intake. As a result, we say that both female and male university students should increase physical activity and male university student intake more energy. References 1. Arabacı R. (2010). ## MARGINAL VITAMIN D INTAKE IN ELITE ATHLETES

SILLERO QUINTANA, M.1, GARCÍA APARICIO, A.1, LAZAR, E.A.2, GARRIDO PASTOR, G.2

1: UNIVERSIDAD POLITÉCNICA DE MADRID. 2: FRANCISCO DE VITORIA UNIVERSITY

Introduction Diet intake in athletes must ensure optimal health and athletic performance. Protein (P), carbohydrate (CH) and energy intake have been related to physical performance. Moreover, vitamin D intake may influence athletic performance, and it has been associated with bone and muscle health. In recent years, the number of diseases associated with vitamin D deficiency has been growing (Holick, 2007). The aim of this work was to analyze diet composition and describe vitamin D and calcium intake in elite athletes competing in three different events: fast events (FE), middle distance (MD) and long distance (LD) runners. Methods Participants were 81 Spanish elite athletes (45 females, 36 males; 22 FE, 30 MD, 29 LD). Group characteristics were similar for age ( $23.8 \pm 4.9$ ) and height ( $1.73 \pm 0.09$ ), but weight ( $70.0 \pm 13.1$ ;  $60.4 \pm 8.3$ ;  $57.8 \pm 6.3$ ) and BMI were higher ( $p \leq 0.01$ ) in FE athletes. Diet composition was estimated by a retrospective method over a 3-day period and compared to Dietary Reference Intake (FNB, 2006). Additionally, during the same period the participants completed a 24h activity questionnaire to determine different training patterns in each group. Results Energy intake ( $2672 \pm 640$  Kcal/day) was similar in all groups, however we found differences ( $p \leq 0.01$ ) in energy intake related to body weight (Kcal/Kg) in FE ( $39 \pm 9$ ) compared to LD ( $47 \pm 11$ ). Energy distribution was similar by groups (%P =  $17 \pm 3$ ; %CH =  $49 \pm 7$ ; and %lipid =  $34 \pm 6$ ). P ( $1.6 \pm 0.4$ ;  $1.8 \pm 0.3$ ;  $2.0 \pm 0.4$ ) and CH ( $4.4 \pm 1.4$ ;  $5.1 \pm 1.4$ ;  $5.7 \pm 1.3$ ) relative to weight (g/Kg) were significantly lower ( $p \leq 0.01$ ) in FE vs. LD. Additionally, FE group fibre intake ( $24.1 \pm 7.9$ ) was lower than LD ( $36.2 \pm 18.8$ ;  $p \leq 0.05$ ) and MD ( $31.2 \pm 18.5$ ). Marginal intake for vitamin D was found in more than half of the athletes: 59% of FE, 63% of MD and 55% of LD. Moreover calcium intake was also suboptimal and affected 50% of FE, 40% of MD and 31% of LD. Discussion/Conclusion We found low CH intake in all groups. However, P intake was adequate in MD and in LD, but FE athletes achieved only the minimum recommendation level for power training. Athletes competing in FE and MD had a higher incidence of low vitamin D and Ca intake than those competing in LD. LD athletes usually train more often outdoors, while MD and FE groups spend more training time indoors, so the latter groups may be at greater risk for vitamin D deficiency. In order to ensure bone health and athletic performance, vitamin D status must be monitored throughout the year in order to ensure bone health and athletic performance in athletes with different training patterns. Food and Nutrition Board (2006). National Academies Press, Washington (DC). Holick MF (2007). N. Engl. J. Med. 357: 266-81.

## HIGH-INTENSITY INTERMITTENT SWIMMING TRAINING REDUCED IN DMH-INDUCED ABERRANT CRUPT FOCI IN RAT COLON

MATSUO, K., TSUJI, K., LIU, X., TABATA, I.

RITSUMEIKAN UNIVERSITY

Introduction: The incidence of colon cancer is increasing at a faster rate than that of rectal cancer in recent years in advanced countries. Epidemiological evidence has suggested that physical activity has a protective effect on colon cancer incidence (1, 2). Some animal studies found that both voluntary and treadmill running training reduced tumor incidence after the administration of 1,2-dimethylhydrazine (DMH) or azoxymethane (3). Low-intensity running training inhibits the initiation of aberrant crypt foci (ACF) in rat colon induced by DMH (4). However, the effect of high-intensity exercise or training is unknown. Therefore, we examined the effects of high-intensity intermittent swimming training on the number of DMH-induced ACF, because previous studies suggested that physical training of this type has a protective effect on colon tumor incidence in rats. Methods: Four-week-old F344 rats ( $n = 16$ ) were randomly assigned to training (8 rats) and control (8 rats) groups. After a week, all rats were given DMH (20 mg/kg-1 body weight) once a week for 2 wk. High-intensity intermittent swimming training was started at age 7 wk (repeated a 20-sec swimming bout 12 times while bearing weight equivalent to 16%). After 4 wk of training, the rats were sacrificed and the colon was removed, opened, and counted for ACF with 0.2% methylene blue staining. Results: High-intensity intermittent swimming training resulted in lower body weight (Control:  $263.75 \pm 15.02$  g, Swimming:  $246.50 \pm 10.62$  g) ( $p < 0.05$ ) and perirenal adipose tissue weight (Control:  $1.84 \pm 1.10$  mg/g-1 body weight, Swimming:  $1.23 \pm 0.65$  mg/g-1 body weight). The numbers of ACF were significantly lower in the swimming training group ( $122.4 \pm 47.4$ ) than in the control group ( $47.4 \pm 21.6$ ) ( $p < 0.05$ ). Conclusion: Our result suggests that high-intensity intermittent swimming training inhibits DMH-induced initiation of colon ACF development. However, our experimental study has not been conducted to elucidate the mechanisms of exercise-related effects on colon cancer. In future, the clinical implications and pathophysiological mechanisms of these findings warrant further investigation. References: 1) Wolin, KY., Colditz. (2011). **PLASMA ADENOSINE TRIPHOSPHATE IS A TRIGGER OF HEAT SHOCK PROTEIN 72 RELEASE AFTER EXERCISE.**

OGAWA, K., SETA, R., SHIMIZU, T., SHINKAI, S., NAKAZATO, K., TAKAHASHI, K.

TOKYO METROPOLITAN INSTITUTE OF GERONTOLOGY

**Introduction** Extracellularly localized and surface-bound Heat Shock Protein (eHsp) plays a major role in the activation of the immune system and may also be of importance for the immune response to exercise. Recently, the endolysosome pathway has been proposed for secretion of Hsp72 with a regulatory role for extracellular adenosine triphosphate (ATP). We tested the hypothesis that extracellular ATP mediates the increase in plasma Hsp72 during and after exercise. **Methods** All subjects cycled for 60 min at 70% VO<sub>2</sub> max (mean±SE: 157.4±6.9 W) in warm conditions and performed 7 sets of 10 eccentric actions with a set interval of 60 sec. Blood samples were obtained immediately after the exercise (post) and at 10, 30, and 60 min after exercise. **Results** Compared with the levels of Hsp72 and ATP in plasma after bicycle exercise, those after eccentric exercise did not change. A significant group x time interaction was not observed for Hsp72 or ATP in plasma. A significant correlation was found between Hsp72 and ATP in plasma ( $r=0.79$ ,  $P<0.05$ ), but not between Hsp72 and norepinephrine ( $r=0.64$ ,  $P=0.09$ ) after bicycle exercise. We used stepwise multiple-regression analysis to determine independent predictors of exercise-induced elevation of eHsp72. Candidate predictor variables for the stepwise multiple-regression analysis were time (Pre, Post, Post10, Post30, Post60), exercise type (aerobic, eccentric), ATP, cathepsin D, norepinephrine, epinephrine, glucose, and FFA. In the regression model for Hsp72 in plasma, increased ATP and glucose were the strongest predictors of increased Hsp72 (ATP:  $R^2=0.213$ ,  $B=0.473$ ,  $P=0.000$ ; ATP and glucose:  $R^2=0.263$ ,  $B=0.534$ ,  $P=0.000$ ). **Discussion** The present study demonstrated that circulating levels of ATP are associated with plasma levels of Hsp72. It has been proposed that lysosome exocytosis is a possible mechanism of Hsp release from cells; a schematic model involves the activity of ABC-family transmembrane transporters and the participation of purinergic receptors. Extracellular ATP binding causes the opening of purinergic receptor channels, and the entry of Hsp72 into the secretory compartment of lysosomes through ABC-family transporters. The lysosomes are then transported to the cell surface. Subsequent fusion of Hsp72 containing lysosomes with the cell surface results in release of Hsp72. We postulated that circulating levels of ATP stimulated during exercise lead to lysosome exocytosis with the release of Hsp72. In the present study, the plasma levels of ATP were associated with the elevation of eHsp72 after bicycle exercise, which, at least in part, supports our hypothesis on the mechanism of Hsp release—that circulating ATP is a necessary factor to induce secretion of Hsp72 during aerobic exercise.

**OREXIN-A REGULATES THE AMPK ACTIVITY IN VARIOUS TISSUES**

MOLNÁR, A.H.1,2, KIS, G.K.2, RÁKOSI, K.3, SCERIF, M.4, LÁSZLÓ, F.A.2, LÁSZLÓ, F.1,2, KORBONITS, M.4

**Introduction** The hypothalamic hormone orexin-A (OXA) increases food and water intake, regulates the sleep-wake cycle, muscle tone and energy balance (Heinonen et al., 2008; Mileykovskiy et al., 2002). AMP-activated protein kinase (AMPK) is an important metabolic regulator with direct hypothalamic orexigenic and diverse peripheral effects including fat tissue and muscle (Kola et al., 2006). We aimed to study the influence of OXA on the activity of AMPK in the hypothalamus, subcutaneous and visceral adipose tissues, and skeletal muscle. **Methods** Thirty minutes after intraperitoneal (i.p.) or intracerebroventricular (i.c.v.) administration of OXA to male Wistar rats, tissues were rapidly dissected and protein extracts were immunoprecipitated and the AMPK activity was determined by an in vitro kinase assay. **Results** AMPK activity significantly increased in the hypothalamus after i.c.v. OXA administration [ $172\pm15.8$  pmol ATP/min/mg protein (control, mean±SEM),  $236\pm11.5$  (OXA)  $P=0.0022$ ,  $n=6-8$ ]. The AMPK activity decreased in white adipose tissues after i.p. OXA administration [subcutaneous fat:  $52\pm14.3$  (control),  $14\pm2.9$  (OXA),  $P=0.0121$ ; visceral fat:  $76\pm6.8$  (control),  $41\pm6.3$  (OXA),  $P=0.0173$ ]. In the skeletal muscle neither types of OXA administration had effect on AMPK activity. **Conclusion** Central administration of OXA increases appetite by the elevation of the AMPK activity in the hypothalamus. Peripheral administration of OXA reduces the AMPK activity in both subcutaneous and visceral white adipose tissues, which could lead to increased fat stores. **References** Heinonen MV, Purhonen AK, Mäkelä KA, Herzig KH. **EXPRESSION OF SIGNALING PROTEIN MOLECULES DURING RECOVERY AFTER ENDURANCE EXERCISE IN RATS**

SON, H.J., HAN, G.H., KWON, H.T., YOON, J.R., KIM, H.J.

KOREA NATIONAL SPORT UNIVERSITY, SEOUL, KOREA

**Introduction** Skeletal muscle is a plastic tissue with the ability to respond to a variety of external stimuli, such as exercise. Muscle contractile activity associated with physical exercise stimulates multiple signaling pathways and induces transient changes in gene transcription. The present study was to investigate protein synthesis immediately after exercise and during recovery after endurance exercise in rats, using an endurance exercise protocol consisting of one session separated by 6h recovery (VO<sub>2</sub>max 75-80% treadmill exercise). **Methods** The samples were obtained before, immediately after, 30 min, 1h, 2h, 3h and 6h after exercise for the determination of mammalian target of rapamycin (mTOR), p70S6 kinase (p70S6k) and eukaryotic initiation factor (eIF) 4E-binding protein (4E-BP1) phosphorylation. **Results** Endurance exercise generated a significant increase in mTOR phosphorylation immediately after exercise occurred and maintained to 6h recovery (~90%,  $p=.024$ ). In addition, 4EBP1 phosphorylation was significantly increased at the immediately after exercise and decreased in an hour recovery. However, 4EBP1 was resumed to increase for 2-3 hours during recovery (~48%,  $p=.05$ ). Phosphorylation of p70S6K during recovery was continuously elevated above rest level and reached to peak at 6h recovery (303%,  $p=.001$ ). **Discussion** The present study demonstrates that endurance exercise increases mTOR signaling activity and protein synthesis in rodent skeletal muscle, and one session of high intensity endurance exercise activates rather p70S6k in muscle via an MAPK - independent pathway as reported in the previous studies. **References** Bodine SC, Stitt TN, Gonzalez M, Kline WO, Stover GL, Bauerlein R, Zlotchenko E, Scrimgeour A, Lawrence JC, Glass DJ, Yancopoulos GD (2001) Akt/mTOR pathway is a crucial regulator of skeletal muscle hypertrophy and can prevent muscle atrophy in vivo. *Nat Cell Biol* 3: 1014-1049 Coffey VG, Reeder DW, Lancaster GI, Yeo WK, Febbraio MA, Yaspelkis BB 3rd, Hawley JA (2007) Effect of high-frequency resistance exercise on adaptive responses in skeletal muscle. *Med Sci Sports Exerc* 39:2135-2144 Mascher H, Andersson H, Nilsson PA, Ekblom B, and Blomstrand E (2007) Changes in signalling pathways regulating protein synthesis in human muscle in the recovery period after endurance exercise. *Acta Physiol* 191:67-75

**NF- $\kappa$ B SIGNALING RESPONSE TO ACUTE ENDURANCE EXERCISE OF SKELETAL MUSCLE IN AGED RATS**

SON, H.J., KIM, H.J., YOON, J.R., KIM, H.J., KIM, C.K.

KOREA NATIONAL SPORT UNIV. SEOUL, KOREA

**Introduction** Nuclear factor kappa B (NF- $\kappa$ B) is a important transcription factor of skeletal muscle atrophy. Several studies have been explored the possible pathways which may be modulated with exercise and age. The purpose of this study was to examine the effect of one single bout of endurance exercise on nuclear factor kappa B (NF- $\kappa$ B) activation and MuRF1 expression in old rat. **Methods** 32 rats were used and divided into two groups by age; 20 weeks (n=16), 72 weeks (n=16). Each experimental group was further divided into two subgroups; Before exercise (n=8) and after exercise (n=8). All animals in exercise groups performed one bout of 3 hr swimming exercise (30min x 6 bouts). **Results** Following the one single bout of endurance exercise, the protein level of NF- $\kappa$ B (p65) subunit was increased in both old and young group (p< .05). The protein level of NF- $\kappa$ B (p65) was higher in old than young group before exercise (p< .05). However, the expression of MuRF1 was increased in only old group after exercise (p< .05), whereas phospho-IkBa was unchanged (p> .05). **Discussion** Accordingly, these results represent the possibility of increasing the expression of nuclear factor kappa B (NF- $\kappa$ B) inducing muscle atrophy during endurance exercise by age. **References** Ji LL, Gomez-Cabrera MC, Steinhafel N, Vina J (2004) Acute exercise activates nuclear factor (NF)- $\kappa$ B signaling pathway in rat skeletal muscle. *FASEB J* 18:1499-1506 Cai D, Frantz JD, Tawa NE, Jr, et al. **EFFECT OF ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE ON MGF AND MTOR GENE EXPRESSION**

TRICOLI, V.1, BLAZEVICH, A.2, UGRINOWITSCH, C.1, AOKI, M.S.3, NOSAKA, K.

1: EEEF-USP (SÃO PAULO-BRAZIL) 2: ECU (JOONDALUP-AUSTRALIA), 3: EACH-USP (SÃO PAULO-BRAZIL)

**EFFECT OF ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE ON MGF AND mTOR GENE EXPRESSION** Tricoli, V.1, Blazeovich, A.2, Ugrinowitsch, C. 1, Aoki, M.S.3, Nosaka, K.2 1: EEEF-USP (São Paulo-Brazil), 2: ECU (Joondalup-Australia), 3: EACH-USP (São Paulo-Brazil) **Introduction** It has been shown that exercise-induced damage is associated with the release of growth factors (i.e. MGF) by the skeletal muscle (Morgan & Partridge 2003). These growth factors may modulate signaling events in Akt/mTOR hypertrophy pathway which has been attributed as one of the key regulators of cell growth (Nader et al. 2005). It is well known that the magnitude of eccentric exercise-induced muscle damage is attenuated in the successive bouts of exercise (Nosaka et al. 2001). Thus, it is plausible to assume that a repeated bout of eccentric exercise will cause less muscle damage, thereby inducing a smaller MGF release and consequently smaller Akt/mTOR pathway activation. Thus, the aim of this study was to investigate the effect of two eccentric exercise bouts on muscle damage indirect markers and the MGF and mTOR gene expression. **Methods** Eight male subjects (33.9 yrs) participated in the study. They were submitted to two bouts of eccentric exercise (10 x 10 maximum reps, knee extension at 60deg/sec) 15 days apart. Muscle samples were obtained from the vastus lateralis before, 15 min and 2h after each bout. Indirect markers of exercise-induced muscle damage (maximum voluntary isometric contraction [MVIC], muscle soreness, serum creatine kinase [CK] activity) were assessed before, 2, 24, 48 and 72 h after each exercise bout. In addition, changes in MGF and mTOR gene expression were measured before, 15 min and 2h after each bout. **Results** Total work performed and changes in MVIC, muscle soreness and CK activity were not significantly different between bouts (p>0.05). Changes in mTOR gene expression were similar between bouts 1 and 2. On the other hand, after the second bout, MGF gene expression showed an early increase at 15 min (~2.4-fold induction, p<0.05), reaching the highest value 2h after exercise (~3.8-fold induction, different from bout 1, p<0.05). **Discussion** Despite similar alterations in muscle damage indirect markers after the two exercise bouts, we found a greater change in MGF gene expression 2h after the second exercise bout. However, it should be mentioned that there was non-significant trend toward smaller changes in MVIC and muscle soreness after the second bout. Interestingly, there was no difference in mTOR gene expression between bouts. Therefore, we concluded that the magnitude of exercise-induced muscle damage seems to have no effect on MGF release and Akt/mTOR pathway activation. **References** Morgan JE, Partridge TA (2003) *Int J Bioch Cell Biol*, 8, 1151-6. **HEAT SHOCK PROTEIN RESPONSE TO TRAINING IN VASTUS LATERALIS MUSCLE OF YOUNG AND ELDERLY SUBJECTS**

SCHAAD, L.1, KVAMME, N.H.2, UGELSTAD, I.2, HOPPELER, H.1, RAASTAD, T.2

1: UNIVERSITY OF BERN (BERN, SWITZERLAND), 2: NORWEGIAN SCHOOL OF SPORT SCIENCES (OSLO, NORWAY)

**Introduction** Ageing is associated with a progressive decrease in muscle mass, strength and regeneration capacity. Although the underlying mechanisms have not been comprehensively elucidated, the loss of an adequate stress response has been suggested to play an important role in the development of age-related muscular dysfunctions. Hitherto the exercise-induced heat shock protein (Hsp) response in ageing muscle is fairly uncharacterized. Consequently, the aims of the present study were to determine the effect of different training modalities on the Hsp response in elderly subjects and to identify whether the Hsp responses differ between elderly and young subjects. **Methods** 37 elderly subjects (> 70 years) performed traditional strength training (STG), functional strength training (FTG) or endurance training (ETG) 3 days/week for 13 weeks. A control group continued their daily activities (CON), whereas the 13 young subjects (YOUNG, 20-40 years) performed traditional strength training 3 days/week for 11 weeks. Biopsies were collected from the m. vastus lateralis before and after the training period.  $\alpha$ B-crystallin and Hsp70 levels were quantified by western blot, whereas Hsp27 levels were measured by ELISA. **Results** Elderly subjects displayed significantly higher baseline levels of Hsp27. After the training period, the Hsp27 and  $\alpha$ B-crystallin expression levels were not altered in any of the elderly groups in the cytosolic or membrane fraction. In contrast, in the YOUNG, Hsp27 and  $\alpha$ B-crystallin expression significantly increased after training in both the cytosolic and membrane fractions. Moreover, the Hsp70 expression in response to training was not changed in the YOUNG, the elderly ETG or CON, whereas it was significantly decreased in the cytosolic fractions of STG and FTG. **Discussion** Neither long-term strength training nor endurance training changed the expression of sHsps (Hsp27 and  $\alpha$ B-crystallin) in human ageing skeletal muscle. Furthermore, long-term strength training caused a downregulation of Hsp70 in elderly individuals, which inversely correlated with age. Taken together, the Hsp response in ageing muscle is severely impaired and this lack of adaptation might be contributing to the development of age-related muscular dysfunctions.

**EFFECT OF EXERCISE ON FIBROBLAST GROWTH FACTOR 21 OF MUSCLE IN MICE.**

**INTRODUCTION:** Fibroblast growth factor 21 (FGF21) is a novel metabolic regulator and improve glucose and lipid metabolism. FGF21 is produced and secreted by liver, adipose, and skeletal muscle. Recently, it was shown that FGF21 secreted from skeletal muscle is elevated upon activation of the PI3k/Akt signaling pathway in mice. Akt is activated by insulin and cellular stress (i.e. muscle contraction). Therefore, we hypothesize serum FGF21 is increased through elevation of the expression of muscle in response to acute exercise. We reported serum FGF21 increase after exercise in human (ECSS 2010 in Antalya). This time, we examined whatever FGF21 of muscle increase after exercise. **METHODS:** ICR mice (8 weeks old) were divided into two groups: sedentary (SED), running exercise (EX). EX group performed treadmill running (30m/min, 60min), then taking blood and gastrocnemius was rapidly removed and analysed for FGF21 mRNA, and blood. The expression of FGF21, and glucose in mice was assessed by real-time polymerase chain reaction, ELISA and enzyme assay. The alteration of FGF21 expression was compared with SED. **RESULTS:** The level of serum FGF21 in EX significantly increased compared with the level in SED ( $P < 0.05$ ). mFGF21 of muscle in EX tended to increase compared with SED ( $P = 0.1$ , effect size  $d = 0.7$ ). Blood glucose in EX tended to decrease compared with SED ( $P = 0.05$ , Effect size  $d = 0.99$ ). **DISCUSSION:** Serum FGF21 of EX in this study was significantly increased compared with SED as well as our previous study. FGF21 mRNA was elevated in EX in comparison to SED mice. Thereby, serum FGF21 may be secreted through the elevation of the expression of FGF21 in muscle in response to muscle contraction. These result may be suggest exercise including muscle contraction induced FGF21. Further study needs to examine the improvement of lipid by exercised-induced FGF21. **CONCLUSION:** FGF21-derived muscled may be increase after exercise.

**COMPLEX DNA TEST METHOD WITH A DNA CHIP AMONG HUNGARIAN ATHLETES**

*SEMMELEI UNIVERSITY (SEMMELEI UNIVERSITY FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES)*

**Introduction** We have been studying the genetic background of sport and exercise physiology on several genes and their polymorphisms. We wanted to broaden the number of measured genes and examine not only the specific sport genes but the area of sudden cardiac death (SCD) and metabolic syndrome (MetS) as well. SCD can strike both professional and amateur, young and old. When it happens to an athlete it makes us re-evaluate exercising for health. The reason of SCD in athletes is mostly unclear, therefore it is essential to understand the genetic background. The MetS is a cluster of risk factors including central obesity, hypertension, hyperglycaemia and dyslipidaemia. There is evidence already of a complex interplay between genetic determinants and environmental factors. These factors are lesser-known, therefore it can be informative to study athlete population, who live a healthy lifestyle (nutrition, exercise, non-smoking) to associate the genetic variants with measurable phenotypes (blood pressure, lipid levels etc.) **Method** DNA is extracted from blood samples using a DNA isolating kit. 64 genes are studied from each DNA sample. DNA detection is done with a DNA chip at Avidin Ltd. TaqMan OpenArray plate is divided into 48 subarrays; each subarray consists of 64 through-holes, which means that 3072 nanocapillary quick reaction time (QRT) PCR can be run at one time. To measure the polymorphisms fluorescently signaled Taqman probes are used. The isolated DNA (150ng) is mixed with OpenArray MasterMix and loaded into the nanocapillary reaction chamber. The OpenArray plates are put into Perkin Elmer 1000 Plate PCR device for 50 cycles and afterwards are put into the BioTrove OpenArray™ NT Cycler where 3 plates can be analyzed at the same time which means that more than 9000 individual reactions can be run. The intensity of fluorescence is detected automatically in every point and can be analyzed afterwards. **Results, Targeted genes** The system has been validated with previously genotyped DNA samples. From the studied 64 genes the first part is in connection with physical performance. They are put together based on international studies. I emphasise the ADRB2 ARG16Gly SNP, which is associated with elite endurance performance and SCD and other genes (ACTN3, Myostatin etc.) The second group of genes includes genes in connection with SCD, Heart Failure and Cardiovascular Disease. (AMPD1, NOS1 AP, AMPD-1 etc.). The third group contains genes in connection with MetS. For example the LIPG gene which is associated with interindividual variability in HDL-C and its subfractions and their response to exercise training, and many others (ADIPOQ, FABP2, Ghrelin). **Discussion** The results of the study could be used as a tool to filter out individuals who have risk factors.

**ANALYSIS OF 'HEALTH' GENE POLYMORPHISMS IN ELITE PROFESSIONAL ICE-HOCKEY PLAYERS**

*OTT'S INSTITUTE OF OBSTETRICS AND GYNECOLOGY RAMS, CENTER OF SPORT MEDICINE*

**Introduction** Association of genes polymorphisms with physical performance is well-known. The most valuable association was shown for ACE, ACNT3, AMPD gene polymorphisms (Myerson et al., 1999; Papadimitriou et al., 2007; Rubio et al., 2005). Our aim was to study as sport skills are caused by different genetic factors involved in the regulation of many metabolic processes with physical performance in professional ice-hockey players. **Methods** The polymorphisms of NOS3 (5/4), AGT (Met235Thr), ACE (I/D), AGTR1 (1166A>C), AGTR2 (3123C>A), BDKRB2 (-58T>C), REN (-83G>A), F5 (1691G>A), PAI1(5G>4G), ITGB3 (1565 T>C), F2 (20210G>A), F1 (455G>A), MTHFR (677C>T), ADRB2 (48A>G, 81C>G), PPARA (2528G>C), PPARG (294T>C), PPARG (Pro12Ala), UCP2 (Ala55Val), UCP3 (-55C>T), PPP3R1 (51/5D), AR (ICAGIn), DRD2 (A1/A2), HTR2A (SR) (102 T>C), PPARGC1A (Gly482Ser) were studied in high ice-hockey professional (N=20, men, several world cup champions) and population controls (N=196, men without sport success). DNA was extracted from the blood cells. Then the polymorphisms of 28 genes were determined by PCR-RFLP and PCR-biochip methods. **Results** Only distribution of genotypes frequencies of five genes were different in both groups ( $p < 0.036$ ). Four from these genes are regulators of arterial pressure. Genotypes A/A of AGTR1, C/C of AGTR2, A/G of ADRB2, 5/5 of NOS3 were prevalence in ice-hockey men compared to controls (A/A - 100%, C/C - 80%, A/G - 75%, 5/5 - 90% for athletes and 61%, 55%, 53%, 37% for controls respectively;  $p < 0.01$ ). Also we have determined prevalence of C/C genotypes of ACNT3 in controls compared to athletes (49% and 20%, respectively;  $p < 0.02$ ). **Discussion** Important to note that differences were determined for genotypes which associated with «normal» arterial pressure that is not consistent with the hypothesis about prevalence of the «genotype of hypertension» in athletes involved in short and intense physical training (Ying et al., 2010). But it might be speculated that determined genotypes of those genes has provided some inherited advantages for physical performance in ice-hockey sportsmen. **References** Myerson S, Hemingway H, Budget R, Martin J, Humphries S, Montgomery H. Material and Methods: We conducted a cross sectional study (the HELENA-CSS) which comprised 1053 (499 males; 12.5-17.5 years) adolescents from ten European cities. Weight, height, waist circumference and skinfold thickness were measured, and body mass index (BMI) was calculated. Markers of insulin resistance included fasting insulin glucose and homeostasis model assessment (HOMA). Physical activity (PA) was assessed by accelerometry and the follow intensities were calculated; inactive, low PA, moderate PA, vigorous PA, moderate to vigorous physical activity (MVPA) and average physical PA. Results: In females, MVPA and average physical activity were negatively associated (all  $P < 0.05$ ) with insulin resistance after controlling for pubertal status, center and markers of body fat (BMI, skinfold thickness and waist circumference). In males, vigorous physical activity was negatively associated (all  $P < 0.05$ ) with insulin resistance after controlling for pubertal status, center and BMI or waist circumference, but not when using skinfold thickness. Conclusions: Our results suggest that PA, especially those with high intensities, could positively influence markers of insulin resistance after controlling for several confounders including total and central body fat. Preventive strategies should not only focus on increasing PA, but also to increase the intensity of PA.

#### DEVELOPMENT OF SIMPLE LEG/TRUNK TRAINING METHODS SAFELY ACHIEVABLE EVEN BY THE FRAIL ELDERLY

MURATA, S.

*NISHIKYUSHU UNIVERSITY*

**PURPOSE** This study evaluated the effects of leg training to improve the load-bearing capacity, easily practicable using a commercially available resistance-training machine, on physical functions of the frail elderly. **SUBJECTS** The subjects were 60 elderly persons, 30 men and 30 women, who were either frail or certified as in need of low levels of care with an average age of 78.4 (SD=4.1) years. **METHODS** Twenty-nine elderly people who successfully continued 15-minute daily training three times weekly for 12 weeks (intervention group) were compared regarding their physical functions (lower limb loading force, grip strength, walking speed, muscular strength of the quadriceps femoris, Timed up & go test(TUG), and the frequency of standing up) with 28 who did not practice any specific exercise (control group). **RESULTS** The results showed no significant differences between the groups in grip strength, TUG, and the frequency of standing up. However, in the elderly in the intervention group, the lower limb loading force ( $p < 0.01$ ), muscular strength of the quadriceps femoris ( $p < 0.01$ ), and walking speed ( $p < 0.01$ ) significantly increased after the training, with the former two significantly higher than those in the control group. The elderly in the control group, on the other hand, showed no significant changes in any items measured before and after the training. **CONCLUSION** These findings suggest that leg training to improve the load-bearing capacity effectively promotes the muscle strength as well as ambulatory ability of the frail elderly.

#### PREVALENCE OF THE FRAILTY SYNDROME IN THE ACTIVE AND SEDENTARY ELDERLY

CRUZ, F.A.S.1, CAIXETA, G.M.1, COSTA-FARIA, F.A.1.2, NEIVA, C.M.2.3

*1:UNIPAN (PATOS DE MINAS-MG), 2: UNIFRAN (FRANCA-SP), 3 - UNESP (BAURU-SP)*

**Introduction** In recent years, geriatricians and gerontologists have used the term frailty syndrome to characterize elderly more vulnerable and weak, although there is still no agreement about the definition of frailty syndrome. Today, there are about 14 million elderly in Brazil, with over 75 years age and susceptible to frailty. This study aimed to determine the prevalence of frailty syndrome in active and sedentary elderly in the community. **Methods** This is a transversal (cohort) study, not controlled, in order to compare the prevalence of frailty syndrome in elderly. The sample, included 38 elderly, was divided into Group I (sedentary,  $n = 19$ ) and Group II (active,  $n = 19$ ), members of the continuing education program, 'UNIPAM-Senior'. The Mini-Mental, used as a cognitive screening was applied to the participants as an exclusion criterion. The modified evaluation protocol prepared by Fiber Network was used to assess the phenotype of frailty, and checked the five criteria proposed by the study of Fried (2004): 1- unintentional weight loss; 2- fatigue index; 3- test of grip strength; 4- caloric expenditure; 5- walk test. The independence test chi-square was used to verify the equivalence using SPSS version 15.0. **Results** There was a positive association ( $P = 0.05$ ) between groups I and II and the categories of frailty. In group I, 15.8% were classified as fragile, 73.7% pre-frail and 10.5% not-fragile. In group II none was classified as fragile, 63.2% were classified in stage pre-frail and 36.8% non-fragile. Positive correlations were also found in the occurrence of falls ( $P < 0.05$ ) and the presence of disease ( $P > 0.05$ ) with the classification of frailty. Still, among those who have suffered falls, 75% were pre-frail, and had two or more diseases. No significance was found between the presence of depression and the phenotype of frailty. **Discussion** For Petersen et al (2005), the association between regular physical activity and reduction of some inflammatory markers and reducing the sarcopenia in elderly are the most important

factors. The diversity of criteria for defining the frail elderly, hinders consensus on the necessary interventions. Sarcopenia is identified as the most important cause of frailty. Regular physical exercise can reduce the incidence of the frailty syndrome probably by a diminution of inflammatory markers, and a consequent reduction in sarcopenia. Physiotherapy has an important role in prevention and intervention in patients with the syndrome. References FRIED L. P. ### COMPARISON BETWEEN TOWEL-GATHERING EXERCISE AND TOE-PAD FOR THE ANKLE SPRAIN

SHIROSHITA, T.1, KIMURA, A.1, FUKUBAYASHI, T.2

1:GUMMA PAZ COLLEGE 2:WASEDA UNIVERSITY

【Introduction】 This study examines physiotherapy for the ankle sprain from clinical data. Towel-gathering exercise (scrunching a towel lying on the floor with the toes) is commonly chosen in the treatment of ankle sprain in Japan. However, the towel-gathering exercise is unclear which toe exercises. Hence, author developed Toe-Pads (Size of each pad is 10×10mm, thickness is 2mm) which pasted on each toe. Therefore, we compared the pain-release effect of the towel-gathering with these Toe-Pads we developed. We welcomed 17 subjects (males 12, females 5) suffering from ankle sprain as subjects. The mean age was 21.7±12.2 years old. The subjects were chosen only cases to complain for pain when a therapist did supination. All subjects were given enough explanations about this experiment and obtained its consent. 【Methods】 Toe-Pads we developed have three conditions, which were pasted under First-toe, 2nd-to-5th and 3rd-to-5th. All subjects performed the towel-gathering exercise (about 3min), and were pasted each Toe-Pad condition randomly. Before and after each condition we assessed the pain scale by provocative tests such as stepping, hopping, running and others with Visual Analog Scale (VAS). We compared each condition to before, which each experiment condition was analyzed by statistics (Wilcoxon, Friedman test).

【Results】 The towel gathering and first Toe-Pad ( $p_T=0.001$ ,  $p_F=0.001$ ,  $N=17$ ) and were showed significant difference. On the other hand, both the 2nd-to-5th and 3rd-to-5th Toe-Pad were not shown significant difference ( $p_{2-5}=0.736$ ,  $p_{3-5}=0.234$ ,  $N=17$ ). 【Discussion】 As for the treatment and the prevention of the ankle sprain report, there are the exercise of the peroneal muscle (Monaghan, K. et al 2006), the balance exercise (Mohammadi, F. M. 2007) and mobilization or taping. In this study, it was aimed to consider an ankle sprain to be from the viewpoint that was slightly different from these, which it's a toe function. The towel gathering and First Toe-Pad were showed overtly significant the pain-release effect, which more than 70% of subject showed. However, the 2nd-to-5th and 3rd-to-5th Toe Pads were not showed overtly significant the pain-release effect. A result of the towel gathering was similar to first Toe-Pad greatly. Therefore, the towel gathering might be an exercise of the hallux mainly. Additionally, the result of this study seemed to present that this disease was bought by a dysfunction of the hallux. In our opinion, if a clinician chooses Toe-Pads as an assessment in clinical setting, it might be one of effective assessment for this disease. However, several attentions were necessary that all Toe-Pads didn't have pain releasing. For example, the towel gathering exercise might not be effective when First Toe-Pad didn't show pain releasing. References Monaghan, K. et al, *A. Clin. Biomech* 21, 168-174 (2006) Mohammadi, F. M., *s, Am J Sports Med*, 35(6): 922-926 (2007)

### SPINAL SHAPE AND LOW BACK PAIN – NON-INVASIVE MEASUREMENTS AND MULTIVARIATE ANALYSES FOR FEMALE LOW BACK PAIN PATIENTS

SCHROEDER, J., MATTES, K.

HAMBURG UNIVERSITY

Introduction In manipulative therapy concepts, spinal shape is well known to be associated with functional disorders of the locomotor system (4). But x-ray based diagnostic procedures are not suitable for screening surveys, and there is still a lack of evidence in the management of exercise programs based on spine shape findings. Subjects 129 female patients with chronic LBP (age: 50.5±14.2 y; body mass index: 24.2±1.6 kg/m<sup>2</sup>) and 79 pain free female volunteers with no back pain history (age: 24.5±4.7 y; body mass index: 22.8±1.4 kg/m<sup>2</sup>) participated in this controlled cross-sectional study. Spinal shape was measured by means of Formetric®-System, an optical high resolution (10 pts/cm<sup>2</sup>, 0.2-0.5 mm reconstruction error) device for three-dimensional back surface reconstruction (3). Statistics: Multivariate discriminant analyses were calculated to reveal predictive spine shape variables to identify low back pain patients. Univariate tests for mean differences followed multivariate findings (Student's t-test). Results Discriminant analyses lead to moderate estimation models (canonical correlation: 0.448; Wilks' Lambda: 0.799;  $p<0.000$ ) and pointed out the role of trunk imbalance (tr-imb), trunk inclination (tr-inc), and pelvis torsion (p-tors) to discriminate LBP patients from pain free controls: tr-imb ( $t=-3.993$ ;  $p<0.000$ ), tr-inc ( $t=-4.959$   $p<0.000$ ), p-tors ( $t=-3.811$ ;  $p<0.000$ ). Discussion and conclusions Using a non-invasive back surface reconstruction system, our results confirmed x-ray findings, where frontal plane spinal asymmetries and pelvis position parameters were associated with low back pain and judged to be risk factors for its development (1, 2, 4). Differences in the trunk inclination should be considered to be due to the higher age of LBP patients (5). The findings provide applications for screening surveys in junior elite sports or medical school examinations. References: 1. Adams, M.A., Mannon, A.F. & Dolan, P. (1999). ### POSTURAL STABILITY IN WOMEN WITH JOINT HYPERMOBILITY SYNDROME

IATRIDOU, K., MANDALIDIS, D., CHRONOPOULOS, E., VAGENAS, G., ATHANASOPOULOS, S.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

POSTURAL STABILITY IN WOMEN WITH JOINT HYPERMOBILITY SYNDROME Iatridou, K.1, Mandalidis, D.2, Chronopoulos E.1, Vagenas, G.1, Athanasopoulos, S.1 1: NKUA (Athens, Greece) 2: PhD, PT (Athens, Greece) Introduction Joint hypermobility syndrome (JHS) is a heritable disorder of the connective tissue and especially of type I collagen (Grahame, 2003). Type I collagen is proposed to be a key structural component of load-bearing tissues such as tendons, ligaments and fascia. These tissues contribute to joint stabilization via passive and active mechanisms. Active joint stabilization is mainly based on proprioceptive input from ligaments, joint capsule, tendons and muscles. The combination of proprioceptive, visual, and vestibular sensory information is utilized by the central nervous system for conscious

appreciation of the position and movement of the body and limbs. Although, deficiencies in proprioceptive sense have been described in subjects with JHS, there is a limited amount of literature studied the role of proprioception deficits in postural control. The aim of the present study was to assess static balance in female persons diagnosed with JHS. Methods Static balance was assessed in 21 women with JHS and in 20 age matched women without JHS. For the assessment, it was recorded the distribution of foot pressure (CoP) during a 20-second single-leg stand on a platform under three different conditions; opened eyes, closed eyes, opened eyes with head extension. Results Non parametric statistical analysis showed that during the single-leg stand with opened eyes the JHS group demonstrated significantly greater sway path length ( $p=0.009$ ), mediolateral sway ( $p=0.003$ ) and ellipse area of CoP ( $p=0.003$ ) than that of controls. During single leg stance with opened eyes and head extension all the indices that characterize the sway path were significantly greater for the JHS group ( $p<0.05$ ). In the condition of closed eyes the group with JHS demonstrated significantly greater values for sway path length ( $p=0.05$ ). Discussion Physically active hypermobile women without acute symptoms demonstrated impaired postural control based on the distribution of CoP during single-leg stance. A possible explanation of the results could be that the proprioceptive deficit that has been detected in hypermobile subjects may have affected the feedback and feedforward mechanisms (Ferrell et al., 2007; Gatev et al., 1998). The interaction of these mechanisms is responsible for the modulation of spine and lower limbs muscle activity in order to maintain balance during stance. Further study of these mechanisms could lead to a design of rehabilitation protocols specific to the impairment, for the improvement of static balance in females with JHS. ## EVALUATION OF FUNCTIONAL CAPACITY IN MYOTONIC DYSTROPHY TYPE 1 PATIENTS

DESJARDINS, P.1, GAGNON, C.2, CHOUINARD, M.C.1, MATHIEU, J.2, COMTOIS, A.S.3, LEONE, M.1

1UNIVERSITÉ DU QUÉBEC À CHICOUTIMI, 2UNIVERSITÉ DE SHERBROOKE, 3UNIVERSITÉ DU QUÉBEC À MONTRÉAL

Introduction Myotonic dystrophy type 1 (DM1) is one of the most frequent neuromuscular disorder in adults. Although this disease affects primarily muscle function, DM1 causes multisystemic impairments. Thus, DM1 is often presented as an accelerated aging model. In clinical setting, most of the physical evaluations are based on subjective factors, which can cause a lack of precision in the rehabilitation strategy. Recently, a new functional test battery (UQAM-YMCA) has been developed for elder persons. The nature of this test battery seems to be an interesting tool to help clinicians to improve their assessment of the physical limitation in DM1 patients. Thus, the aim of this research is to assess the validity and reliability of the UQAM-YMCA functional test battery with DM1 patients. Methods A total of 28 participants (14 men, 14 women, mean age  $45.8 \pm 11.7$  years old), fifteen diagnosed with DM1 stage 3 to 4 according to the Muscular Impairment Rating Scale (MIRS) and a control group composed of 13 healthy individuals, were assessed with the UQAM-YMCA functional test battery. The test battery allows measuring 17 variables regrouping in 6 main factors: reaction time, balance, and flexibility, speed of limbs, muscular strength and walking capacity. Results The test-retest procedure (t-test paired sample) showed a high reliability with correlation coefficients greater than 0.80 for most of the tests. Comparison of the groups by an independent sample t-test procedure (DM1 vs Healthy) showed significant differences ( $p \leq 0.05$ ) for all the tests but one (shoulder flexion). Discriminant analysis showed that the model predicts correctly more than 92% of the participants in the right group. Finally, when the DM1 group was compared with Canadian normative data for aging population, the average test results indicated that DM1 patients have a functional capacity similar to women aged 72 years old. Discussion The UQAM-YMCA test battery showed excellent test-retest reliability with DM1 patients, which is an important step to determine the usefulness of this test battery for this population. When compared with healthy participants (age and gender match), DM1 patients in this study showed impairments in all of the 6 factors assessed. In fact, even if the mean age of the DM1 group was approximately 46 years old, their functional capacity was comparable to women over 70 years old. DM1 phenotype was extremely distinctive as showed by the stepwise discriminant analysis. Hand grip and balance eyes opened contribute the most to classify correctly 92.9% of the participants in the right group. Conclusion The UQAM-YMCA test battery appears to be an excellent tool to determine, globally or specifically, the degree of impairment for DM1 patients.

## THERMOGRAPHIC PROFILE FOR THE REHABILITATION OF THE TOTAL OF ACL RUPTURE

PIÑONOSA, S., GARCÍA, M.A., SILLERO, M., GÓMEZ, P.M., FERNÁNDEZ, I., SZENDREI, B., GRANJA, A.

UNIVERSIDAD POLITÉCNICA DE MADRID

Introduction Infrared thermography is a noninvasive technique that allows, quickly, and without any contact, display and record temperatures of different areas of the body by a Infrared sensor (Ring & Ammer, 2000). When the muscles or joints of a body area are overloaded or injured there is an acute increase in temperature (Santilli, 1981). On the other hand, the rupture of anterior cruciate ligament (ACL) is an injury very common in the field of sport (Codesido, 2009). The time needed from the operation to a total recovery is about 2 months (Paus, 1999). Methods The study was carried out for six months. Patients of ACL injuries ( $N = 30$ ) were followed throughout their stay in a room specially prepared for them with the same hospital rehabilitation protocol. Data was taken once a week: Anterior and posterior thermogramme of the lower extremities, leg, thigh and knee (above the patella) anthropometric measurements, BORG subjective pain scale CR10 (Borg, 1998) and manual goniometer to measure degrees of flexion and extension. The thermograms from our FLIR T335 were analyzed establishing areas in each leg, obtaining averages and maximum points temperature. The results were analyzed with SPSS v.15.0. Results The thermograms shows an increase in temperature of the inner zone of the affected knee in the anterior view ( $1.4^\circ \text{C}$ ) and an acute increase in temperature throughout the posterior view of the uninjured leg ( $0.92^\circ \text{C}$ ). Both leg and thigh circumferences decreased in the injured leg ( $\bar{x} = 0.83 \text{ cm}$ ,  $\bar{x} = 1.42 \text{ cm}$ , respectively). Otherwise, the measures taken in the upper perimeter of the affected knee patella is significantly higher ( $\bar{x} = 2.3 \text{ cm}$ ) than the healthy knee. Discussion We can describe a thermographic profile of ACL rupture and its evolution during rehabilitation: In the beginning we found big temperature descompensation between knees in the anterior view, being much higher in the injured one. In contrast, in the posterior view the temperature rise up in the area of the hamstring of the uninjured leg, possibly due to result of overload of lameness. As rehabilitation progresses, the thermal values of both legs should match. The greatest differences in the areas are found in the leg and patella measurements. At the start of the treatment, the perimeter of the injured leg has lower muscle mass due to non-exercise. Referring to the patella we see a significant perimeter increase, in this case, because of inflammation. References Borg, G. (1998). Borg's perceived exertion and pain scales. ### PHYSICAL PERFORMANCE OF SUBJECTS WITH OR WITHOUT OSTEOARTHRITIS. A LONGITUDINAL STUDY WITH A 10-YEAR FOLLOW-UP

VAN LEEUWEN, D., DE RUITER, C., DEEG, D., PEETERS, G., TWISK, J., LIPS, P., DE HAAN, A.

RESEARCH INSTITUTE MOVE, VU UNIVERSITY AMSTERDAM, THE NETHERLANDS

Physical performance of subjects with or without osteoarthritis. A longitudinal study with a 10-year follow-up D.M. van Leeuwen 1,2, C.J. de Ruiter 1, D.J.H. Deeg 3, G.M.E.E. Peeters 4, J.W.R. Twisk 3, P. Lips 1,3, A. de Haan 1,2 1 Research Institute MOVE, VU University Amsterdam, The Netherlands 2 Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University, Manchester, UK 3 EMGO+ Institute, VU University medical center, Amsterdam, The Netherlands 4 The University of Queensland, School of Human Movement Studies, Brisbane, Australia Osteoarthritis (OA) is a joint disease which is characterized by pain, loss of strength and problems with activities of daily life, especially when the hip or knee joint is affected. Longitudinal studies can bring insight in the change of function over time to distinguish between loss of function due to OA and aging. There are indications that detrimental effects of OA on physical performance occur on the long term, but there is a lack of studies with long follow up periods. In addition there are very few longitudinal studies with physical performance as the primary outcome measure (as opposed to self-report). The present study aimed to compare physical performance between older people with and without knee or hip OA during a follow-up period of 10 years. Subjects from the Longitudinal Aging Study Amsterdam (LASA) with OA (N=158) and without OA (N=822), age between 58 and 90, were followed-up during 10 years on 4 occasions. OA was assessed by self report. Physical performance was defined by the sum of the scores (0-4) of a chair stand, walking, and balance test (range 0-12). Generalized estimating equations were used on a model with physical performance as the primary outcome variable, time as categorical variable, OA and the interaction between OA and time as independent variables. A significant interaction was found for gender, and therefore, analyses were performed separately for men and women. For men with OA, performance was significantly lower ( $p < 0.05$ ) on all 4 occasions. Performance was 1.0 point lower on the first occasion, and this deficit increased to 3.3 points on the fourth occasion after 10 years. For women with OA, only the performance on the third (-1.0) and fourth occasion (-1.8) was significantly lower. Adjustment for confounders (BMI, age, physical activity and number of chronic diseases) marginally influenced the results for men, but only the performance after 10 years was lower for women with OA. Additional analyses of the individual performance tests showed that balance was impaired in both men and women with OA on occasions 3 and 4. Chair rise and walking ability were already impaired in men with OA from the first occasion on, and from occasion 3 (chair) and 4 (walk) for women with OA. The results suggest that physical performance is affected in older people with OA. The difference in performance between OA and non OA is greater in men than in women.

### ELECTRICAL STIMULATION IN PATIENTS WITH A PERONEAL NERVE LESION: ANALYSIS OF STIMULATION PARAMETERS

SCHULZ, A.1, LINDNER, T.2, CREUZNACHER, U.1,4, LUDEWIG, H.1, HAUENSTEIN, K.3, BADER, R.2,4, ZSCHORLICH, V.1,4

UNIVERSITY OF ROSTOCK

[1] Institute of Sport Science [2] Department of Orthopaedics, Biomechanics and Implant Technology Research Laboratory [3] Institute for Diagnostic and Interventional Radiology [4] Department Aging Science and Humanities Introduction Functional electrical stimulation is a treatment for both training in healthy subjects and therapy of disease. Even in patients with lesion of the peroneal nerve it is used to improve strength and function of foot raising muscles during walking. The purpose of the present study is to determine the effect of different stimulation parameters on strength of dorsal extensor muscles and sensation of pain. Methods Nine patients aged 34-77 ( $58.2 \pm 13.7$  years) with a drop foot resulting from an incomplete lesion of the peroneal nerve participated in the study. An electrical stimulator (DKI, Dresden and MTR, Berlin) generated nine different programs with variations in envelope (rectangle, triangle, trapezium) and single pulses (short: 0.25 ms, medium: 7.5 ms, long: 15 ms). All currents were bipolar with same frequencies. Patients were placed with the leg in horizontal position and the foot in neutral zero position. Contraction strength of dorsal extensors was recorded by a piezoelectric force sensor (Kistler, Winterthur) and interpreted in relation to the maximal voluntary contraction (MVC) forces. Stimulation intensities were chosen by the patients and differed between subjects related to their experience of pain. Results High muscle forces were noticed in programs with rectangular envelopes (up to 26 % of MVC). Triangular and trapezoid envelopes produced lower values (up to 17 % of MVC and up to 22 % of MVC). Long and medium single pulses induced similar forces between 14 and 26 % of MVC whereas short single pulses reached 8 to 19 % of MVC. Intensities of current remained small in programs with long and medium single pulses (15-21 mA). Discussion The results suggest that rectangular envelopes with long or medium single pulses offer the best variety for producing strength of the dorsal extensors with electrical stimulation. Low current intensities in such programs indicate small pain tolerance. Both contraction strength of dorsal extensors and current intensities have an influence on the effectiveness and tolerance of functional electrical stimulation as a therapy for patients with lesion of the peroneal nerve.

### INJURY RATE AND RISK FACTORS IN YOUNG AND ADULT FEMALE NATIONAL BASKETBALL TEAM ATHLETES: A TWO-YEAR FOLLOW-UP STUDY

PATSIKA, G., KOFOTOLIS, N., FETLIS, A., KELLIS, E.

NEUROMECHANICS LAB, ARISTOTLE UNIVERSITY OF THESSALONIKI

Introduction Many studies have investigated injury risk factors at lower level of competition levels (Arendt & Dick 1995, Messina et al., 1999, McKay et al., 2001, Anderson et al., 2003, Agel et al., 2007). In contrast, a few studies have focused in women basketball players competing at professional level (Deitch et al., 2006, Junge et al., 2006, Kofotolis & Kellis 2007), but it is clear that more longitudinal studies at elite level athletes are necessary. The purpose of this study was to determine injury rate and risk in female national basketball Greek athletes. Methods Eighty-two female athletes (Senior n=14, U20 n=23, U18 n= 22, U16 n=23) were followed during a two-year period. Injury data were retrospectively reviewed for two-year period. The frequency of all injuries and the rate of game and practice related injuries were calculated. Results Among 82 players, there were 61 injuries ( $S=27.8\%$ ,  $U20=24.6\%$ ,  $U18=24.6\%$ ,  $U16=23\%$ ) with an injury rate of 4.24 per 1000 hours of exposure ( $S=3.72/1000$ ,  $U20=4.1/1000$ ,  $U18=4.4/1000$ ,  $U16=5.5/1000$ )  $p=0.024$ . Ankle and knee sprains represented the most commonly injured region (36.2%) while a considerable number of participants (29.5%) displayed low back pain. Game injury rates were significantly higher compared with those occurring in practice ( $p=0.030$ ). Most injuries were contact injuries with another player  $p<0.001$ , occurring inside the key area of the basketball court  $p<0.001$ . Discussion The results of this study showed that young basketball players display a high injury rate, at all participation levels. It was also very interesting that almost 1/3 of the sample had severe incidents of back pain which prevented them from participation. Given the young age of these players, the provision of safety guidelines regarding prevention of trunk and ankle injuries is absolutely necessary. References Arendt E, Dick R. Am J Sports Med.

#### UNDERSTANDING AND QUANTIFYING THE CORNER KICK IN FOOTBALL

VICENTE, A., LOPES, H., FERNANDO, C.

UNIVERSITY OF BEIRA INTERIOR, UNIVERSITY OF MADEIRA, CIDESD

**INTRODUCTION** In the FIFA World Cup 2010 there was an average of 28.28 shots per game (14.14 per team), but only 10.67 shots on goal (5.34 per team). There was an average of 9.80 corner kicks per game (4.9 per team). The corner kick is a very important opportunity to score. However, knowledge of the corner kick is essentially empirical and there is not enough data to try to understand how we can improve practice and how to take decisions in competitions. **METHODS** Starting from the model of football corners (Almada et al., 2010) we've defined limits for  $t$  (being  $t$  - the time the ball takes to reach the goal area) and the intermediate times in that we can decompose this  $t$  and what actions can be made in those times by the attacking team. We compared all these times with the times that concomitantly were used by the defending team,  $t'$ , and the parcel times that compose this  $t'$ . We've compared the reached conclusions with what we have analyzed in all the 14 corner kicks from the FIFA World Cup 2010 Final (Netherlands-6 vs. Spain-8), trying to see if our definitions where coherent. To do it, we've calculate the time the ball can take to reach the goal area utilizing the ballistic trajectory formula. Simultaneously, we've defined the different conditions that were possible in acceptable limits. We've measured the time the ball took until being touched by any player. The time the attacking team took to prepare their action and their consequences was also taken into account, as well as the time the defending team had to intercept the ball and what the player could do/did. **RESULTS** The ball took a minimum of 960 up to a maximum of 1720 milliseconds to reach the goal or being touched/shot by a player. The attacking players always started their movement before the defending players and 280 milliseconds before the ball being kicked from the corner. No goal was scored from this situation. **DISCUSSION** The definition of possible strategies for the attacking team with the knowledge of the limits of the variables and the limits of their values is feasible and could improve the performance even for a top level team. However, the attacking team could be in advantage if they prepare the right strategy. We can conclude that there are limits that can be reached and are useful, but depending on the objectives aimed there are others that are neither reachable nor useful. Their definitions are interesting to define practice and improving player's performances. **REFERENCES** 1. Almada, F., Fernando, C., Lopes, H. & Vicente, A. (2010). V.M.L., 1

#### DETECTION OF COUNTER-ATTACK INTERACTION PATTERNS IN FOOTBALL

SARMENTO, H.1,2,4, MARTINS, N.1,2, MARTINS, J.3, MARQUES, A.3, BARBOSA, A.1,2, ANGUERA, T.2,3, CAMPANIÇO, J.1,2, LEITÃO, J.1,2

1-UTAD, VILA REAL, PORTUGAL 2-CIDESD, PORTUGAL 3-FMH, LISBOA, PORTUGAL 4-UB, BARCELONA, ESPANHA

**Introduction** The purpose of this study was to observe and to characterize the tactical performance in the counter-attack (CA) of three football teams (F.C. Internazionale Milano (IM), FC Barcelona (FCB) and Manchester United (MU)) with different philosophies of the game in the 2009/2010 sporting season. **Methods** Thirty-six games (12 per team) were encoded by using the observational instrument developed by Sarmento et al. (2010). The study of the data reliability was calculated by the intra-observer agreement, and values above 0.95 for all criteria were achieved. For the detection of temporal patterns, we used the software THÈME 5.0, and the following criteria were used: the minimum number of events was set at 3 and the level of significance was set at 0.005. **Results and discussion** We detected 788 T-patterns in the CA developed by the FCB team. One of those is a complete t-pattern, and represents an offensive sequence that occurs three times in different situations and ends in a goal. The CA starts by an interception of the ball in the defensive midfield (lateral right corridor) in a context of relative superiority (i.e., the observed team has one or two more players in the center of the game). The development of the CA was done in a context of numeric equality and the ball moves, by conduction, from the central to the left corridor. The CA ends with a goal, resulting by a shot in the offensive third (central corridor), in a context of relative inferiority (the observed team has one or two players less in the center of the game). The analysis of the CA actions of MU team showed 87 t-patterns (3 completed t-patterns). In relation to the team of the IM, we found only 3 incomplete t-patterns. The analysis of the detected incomplete patterns provided important information about how the teams start, develop and end the CA. The more significant T-patterns will be later explained in a detailed way. **Conclusion** The results show a high variability of environmental situations that are expected at this competitive level. The study of the incomplete patterns made it possible, in a phased way, to characterize the observed offensive actions, and we consider that it is relevant for the understanding of the game. The difference in the number of t-patterns detected in the different teams can explain different philosophies of the game, and suggest that the CA of FCB team has more consistency in their temporal structure than those of other teams. The preliminary data highlights the potential for t-pattern analysis to make a significant contribution to sport performance analysis. Sarmento, H., Anguera, T., Campaniço, J. & Leitão, J. (2010). Development and Validation of a Notational System to Study the Offensive Process in Football. Medicina (Kaunas), 46(6), 401-407.

#### OFFSIDE DECISION MAKING SKILLS OF ASSISTANT REFEREES IN FOOTBALL IMPROVE AFTER 12-WEEK TRAINING USING VIDEO FEEDBACK

ISHIHARA, I., NAITO, H., AOBA, Y., YOSHIMURA, M.

JUNTENDO UNIVERSITY

**Introduction** An ability to make accurate offside decisions is highly required for assistant referees in football. Helsen et al. (2006) revealed the accuracy of offside decision during 2002 FIFA World-Cup, and reported that the error rate was 26.2%. There have been several attempts to reduce the error rate in offside decisions such as "on-the-field offside test" that evaluates the current decision skills (Gillis et al., 2009). The training effect of the field offside test (offside decision making training, ODMT) is however yet to be investigated. This study therefore aimed to investigate whether 12-wk training using ODMT would improve the offside decision making skills of assistant referees.

**Methods** Eight male assistant referees ( $21 \pm 1$  y-o) having a beginner class licence accredited by Japan Football Association participated in this study. The ODMT was designed based on Helsen et al. (2006) to improve referees' decision makings in a situation difficult to judge offside or inside. Subjects were assigned five complicated situations (varying positions of the ball and players) randomly, with each situation repeated for three times (15 trials, one session/week for 12-wk). All trials were recorded by a video camera. A correct or incorrect decision was respectively assigned 1 or 0 point, determined by the video film. The correctness of the decision and the recorded scene were fed back to the subjects prior to the commencement of next session. The assigned scores in the 1st week were compared to those after 12th week to evaluate the training effect. **Results** The decision score significantly increased from  $9.0 \pm 2.6$  to  $13.0 \pm 1.5$  following the 12-wk training ( $p = 0.0078$ ). **Discussion** To our knowledge, this is the first to have demonstrated the effect of offside decision making training for assistant referees using video feedback. For assistant referees, it is important not only to keep up with the offside line but to keep the most appropriate visual field (Gilis et al., 2006). Catteeuw et al. (2010) suggested that the ideal positions of assistant referees from the field players could be determined by using video feedback. In this study, the subjects indeed received feedback before commencing each training session using the video scene on both the correctness of offside decision and the actual positioning from the field players of the previous session, allowing them to adjust their moves for a better visual field in the subsequent test. The present finding suggests that decision making training can be recommended to improve overall performance of assistant referees. **References** Catteeuw P, Gilis B, et al. ## THE INFLUENCE OF DELIBERATE PRACTICE ON THE OFFENSIVE PERFORMANCE IN YOUTH SOCCER

ALMEIDA, C.H., FERREIRA, A.P., VOLOSSOVITCH, A., DUARTE, R.

*FACULTY OF HUMAN KINETICS, TECHNICAL UNIVERSITY OF LISBON*

**Introduction** The influence of deliberate practice on skill acquisition in sports remains an actual and debatable issue among researchers and coaches (Ericsson, 2006; Williams & Ford, 2008). The autonomous playing experiences seem to influence skill acquisition in different way, when compared with the activities specifically designed to improve performance. The present study aimed to analyze the influence of deliberate practice on the offensive sequences performed by different experienced level groups of young soccer players. **Methods** Thirty under-15 males were distributed per two groups according to their deliberate practice experience in soccer game: the Non-Experienced group (N-Exp) and the Experienced (Exp) group ( $3.87 \pm 0.99$  years of experience). The experimental protocol consisted of three independent sessions separated by one week intervals. In each session both groups participated in two small-sided games (Gk+3v3+Gk and Gk+6v6+Gk) during 10 minutes interspersed with 5 minutes of passive recovery. Two types of performance indicators were used to characterize the observed Offensive Sequences (OS): the simple parameters (SP) and the composite parameters (CP). The SP were simple counts of the game performance: Duration of Ball Possession, Number of Players Involved, Ball Touches, Number of Passes, Number of Shots. The CP were defined as "ratios" obtained by dividing two SP: Number of Players/Duration of Ball Possession, Ball Touches/Duration of Ball Possession, Number of Passes/Duration of Ball Possession, Ball Touches/Number of Players, Number of Passes/Number of Players, Number of Passes/Ball Touches and Goal/Shots. A non-parametric MANOVA was used to analyze the effect of "experience level" on the OS characteristics. **Results** The factor 'experience level' revealed a significant effect on SP and CP that characterize the OS in four-a-side ( $\chi^2(5) = 20.604$ ;  $p = 0.001$  and  $\chi^2(6) = 24.072$ ;  $p = 0.001$ , respectively) and seven-a-side games ( $\chi^2(5) = 14.592$ ;  $p = 0.012$  and  $\chi^2(6) = 14.592$ ;  $p = 0.024$ , respectively). **Discussion** Results demonstrate that deliberate practice experience can be a relevant factor for improving sport-specific game skills of young soccer players. While the Exp group adopted a more positional style of play, with a larger ball circulation between players, the N-Exp group performed faster OS where the individual actions were predominant. **References** Ericsson KA (2006). ## SEASONAL BIRTH EFFECT AND HEIGHT, WEIGHT AND GIRTHS MEASURES OF YOUNG SOCCER PLAYERS

FERREIRA, J.I., FRAGOSO, I.I., MASSUÇA, L.I.2

*1: FMH-UTL (LISBON, PORTUGAL); 2: ICPOL-ISCPSI / FEFD-ULHT (LISBON, PORTUGAL)*

**Introduction** The morphologic characteristics of athletes can determine in several ways the success they will achieve in a few particular sports (Matkovic et al., 2003). So, the purpose of this study was to show how the seasonal birth influences the anthropometric variables and the performance level of elite young soccer players, disregarding the effect of bone age. **Methods** A total of 133 under-15 young soccer players were studied. Each participant was measured in some anthropometric variables, namely height, weight and calf, thigh and upper arm girth (see Marfell-Jones et al., 2006). The athletes were divided in four trimesters: first trimester with a  $n=60$  (45.1%); second trimester with a  $n=43$  (32.3%), third trimester with a  $n=22$  (16.6%) and; fourth trimester with a  $n=8$  (6.0%). Soccer-specific performance was obtained according to the success level achieved by each soccer player: Level 1, representing those who were dismissed from the club (27.8%); Level 2, player that stayed on the club but was never called to a youth selection (28.6%); Level 3, player that is called to the district selection (23.3%) and; Level 4, player of youth international level (20.3%). Maturity (bone age) was evaluated through Tanner-Whitehouse III Method (TW III). The 4 groups were compared with ANCOVA using the SPSS for windows (v.18.0). Permissions from parents and from the boys (self assent) were obtained before data collection. **Results** The athletes that achieve a higher degree of success in this sport were the ones that obtained better scores in the physical anthropometric's tests, and it should also be noted that most of them were born during the first semester of the year (77.4%). However the results showed that in general the studied groups were very similar in what respect anthropometric variables. The only exceptions were height (1-3;  $p=.034$ ) and arm girth (2-3;  $p=.043$ ) when comparing the four trimesters and arm girth (2-3;  $p=.044$  and 3-4;  $p=.022$ ) when comparing the four performance levels. **Discussion** Although the present results enable the conclusion that the young soccer players born in the first two trimesters (77.4%) of the year are, in general, taller, heavier and have larger calf, thigh and upper arm girth, only the height and arm girth presented significant differences. Besides that, the four groups of performance had very similar anthropometric results, which mean that after removing the bone age effect they seem to show a very identical robustness. **References** Marfell-Jones M, Olds T, Stewart A, Carter JEL (2006). *International Standards for Anthropometric Assessment* (revised 2006). ## THE TIME-COURSE OF CHANGES IN SKILL PERFORMANCE OF ELITE FOOTBALL PLAYERS FOLLOWING RESISTANCE EXERCISE IS INTENSITY-DEPENDENT

DRAGANIDIS, D., CHATZINIKOLAOU, A.1, ERMEIDIS, G.1, JAMURTAS, A.Z.2, KAMBAS, A.1, TSOUKAS, D.3, DOUROUDOS, I.1, MICHAELIDIS, Y.1, KATRABASAS, I.3, MARGONIS, K.1, THEODOROU, A.2, FATOUROS, I.1

DEMOCRITUS UNIVERSITY OF THRACE

**Introduction** Resistance exercise-induced muscle damage is associated with an acute-phase inflammatory response characterized by phagocyte infiltration into muscle, free radical production, and performance deterioration (Margonis et al., 2007). Resistance training is essential for the physical preparation of elite football players. However, little is known regarding the effects of resistance training on skill performance of football players. Therefore, the present investigation aimed to determine whether the time-course of changes in skill performance of elite football players following resistance training is intensity-dependent. **Methods** Following familiarization, 16 elite football players (20.1±0.7 yrs) participated in three different trials in a counterbalanced fashion: a) controlled trial (C, subjects participated only in the measurement procedures but they abstained from exercise), b) low-intensity resistance exercise protocol (LIR, 4 sets of 8-10 reps/set at 65% 1RM), and c) high-intensity resistance exercise protocol (HIR, 4 sets of ≤ 6 reps/set at 85-90% 1RM). Squat, side lunges with a barbell, leg curls, leg extension, calf raises were the exercises used in HIR and LIR. In each exercise trial, blood sampling and measurement of muscle damage markers (delayed onset of muscle soreness-DOMS, knee joint range of motion-KJRM, thigh girths) and football performance (short passing, dribbling, long passing, shooting, heading) were measured before exercise, 12 hours post-exercise as well as daily for six consecutive days. Blood samples were analyzed for creatine kinase activity (CK), white blood cell count (WBC), and CRP concentration. **Results** The control trial demonstrated no changes in all dependent variables measured. Both HIR and LIR induced a moderate DOMS and inflammatory response that peaked 24h post-exercise and subsided thereafter. Short passing was improved 48h following exercise in both groups. Furthermore, dribbling, heading, and long passing remained unaffected throughout recovery in both groups. However, shooting deteriorated for 12h post-exercise and recovered thereafter. **Discussion** In agreement with previous reports (Jamurtas et al., 2000), the results of the present study indicate that resistance training elicits only a moderate muscle damage response for as long as 24h. Besides shooting, football skill performance appears to remain unaffected by resistance training. These results suggest that resistance exercise is not a critical factor for skill performance within a training microcycle. **References** Jamurtas AZ, Fatouros IG, Buckenmeyer PJ, Kokkinidis E, Taxildaris K, Kambas A, Kyriazis G. ## REPORTING THE DEVELOPMENT OF A TACTICAL ASSESSMENT SYSTEM IN SOCCER

COSTA, I.T., GARGANTA, J., GRECO, P.J., MESQUITA, I., MAIA, J.

UNIVERSIDADE FEDERAL DE VIÇOSA

**Introduction** Assessment tools commonly used in the analysis of tactical behaviour have often been criticized because of their limitations in evaluating specific game characteristics, as well as there being little connection with the different structure and elements developed in training sessions. Accordingly, several researchers have recommended the development of tactical assessment tools should take into account specific aspects of the game as well as its training settings. The purpose of this study is to report the development and preliminary validation of a tactical assessment system in Soccer (FUT-SAT). **Methods** The system was designed to assess player's tactical actions (with and without the ball) according to ten core tactical game principles. Furthermore the evaluation took into account the location of the action and its outcome. The field test was designed in a space of 36 meters long by 27 meters wide and required the player to perform during four minutes (3 vs. 3 with goalkeepers). The validation process followed the main suggestions of Cronbach (1988): i) the players accept the fairness and accuracy of the test; ii) the analysis is carried out by a panel of experts; iii) the ability of the panel to assess the quality of the player's performance; iv) observer reliability. **Results** The players who carried out the field test agreed with its fairness and accuracy. It was found values higher than 0.63 for correlations between coaches' assessments and the system, showing the potential of FUT-SAT to distinguish the performances of players on the basis of the coaches' evaluations. All experts endorsed the categories and variables of this system. Reliability estimates were higher than 0.79 for intra and inter-observers. **Discussion** This system presents some improvement in the evaluation of players' behaviour related to the objective measures of players' movements on the field. This critical point has been mentioned by the literature as being a necessity in the construction of reliable assessment tools in match and training contexts (Olsen & Larsen, 1997). Additionally, the evaluation of the tactical actions performed by the players (with and without the ball), according to ten core tactical principles of the Soccer also provide advantages in evaluations carried out throughout the training process (Gréhaigne & Godbout, 1998). Therefore, it is possible to conclude that the system is valid and reliable for the assessment of the tactical behavior of soccer players. **References** Cronbach, L. J. (1988). ## COMPARISON OF SPECIAL EXERCISE AND SOCCER ORIENTED EXERCISE IN AMATEURS SOCCER PLAYERS

BOCCOLINI, G., SINUELLI, N., BONFANTI, L., ALBERTI, G.

DEPARTMENT OF SPORTS, NUTRITION AND HEALTH SCIENCES, FACULTY OF EXERCISE AND SPORTS SCIENCES, UNIVERSITA' DEGLI STUDI DI MILANO, ITALY

Sprint and vertical jumping abilities are usually improved by jumping exercises [2], and can be classified in general, special and specific. The general exercises are divided into analytical and global, the special in general and oriented, and the specific in pure and analytical [1]. The aim of this work is to evaluate the vertical jumping ability related to special-general exercises and special-soccer oriented exercises. **METHODS** 46 amateur soccer players (19.1±4.8 yr; height 176.8±5.8; weight 69.6±7.8) were tested with the Optojump (Microgate, Bolzano, Italy) [3], measuring the vertical jump height in two different jumping exercises. Every jumping session was made up of 3 trials, and the average jump height value has been computed for every one. Special-general exercises squat jumps (SJ) and counter movement jumps (CMJ), both with arms swing, have been performed. In the SJ the subjects started to jump from a standard position (sitting on a bench top 50 cm). The special-oriented exercises have been performed in the same way but with one variation: the ball has been launched by the coach from a distance of about 3 m, giving a task to hit the ball as high as possible (SJball - CMJball). Every trial has been executed after a rest of 30 seconds, while the recovery period between every session was one minute. The data were analyzed using paired T-test using SPSS software v. 17 (SPSS Inc, Chicago, IL). The significant level was set up to p<.05. **RESULTS** The mean value of

SJ, SJball, CMJ and CMJball, were respectively,  $40.9 \pm 5.7$ ,  $36.9 \pm 6.2$ ,  $41.9 \pm 5.9$  and  $37.5 \pm 6.6$  cm. There is a significant difference between SJ and SJball ( $p < .001$ ) and between CMJ and CMJball ( $p < .001$ ). **DISCUSSION** The mean jump height reached without ball during a SJ is significantly higher compared with the mean jump height reached when the ball is launched by the coach (SJball). The mean jump height reached without ball during a CMJ is significantly higher compared with the mean jump height reached when the ball is launched by the coach (CMJball). This data suggest that, during special-soccer oriented exercises, the expression of lower limb muscular strength is less than during special-general exercises. A player must be trained to perform a specific task in order to be able to execute the specific-exercise expressing his maximum potential. **REFERENCES** [1]Cometti G. ## HEAT STRESS AND DECISION MAKING IN ELITE SOCCER REFEREES

CLARKE, N.D., GREGSON, W., DRUST, B., REILLY, T., Helsen, W., WESTON, M.

LONDON METROPOLITAN UNIVERSITY

**HEAT STRESS AND DECISION MAKING IN ELITE SOCCER REFEREES** Clarke, N.D.1, Gregson, W.2, Drust, B.2, Reilly, T. 2, Helsen, W.3 and Weston, M.4 1: London Metropolitan University (UK), 2: Liverpool John Moores University (UK), 3: K.U.Leuven (Belgium) 4: Teesside University (UK) Introduction Soccer refereeing represents a significant physical and mental challenge (Castagna et al., 2007). Heat stress and dehydration have been shown to decrease performance of cognitive abilities such as decisional and perceptual tasks (Hancock, 1986). However, no previous study has determined the effect of heat stress on elite referees' ability to make match-specific decisions. The aim of this study was to examine the effect of heat stress on the physiological and cognitive responses of elite soccer referees during an exercise protocol simulating the demands of match-play. Methods Eight professional male soccer referees (age:  $37 \pm 5$  years) performed a 90-min referee-specific intermittent exercise protocol under laboratory ambient temperatures of  $33^\circ\text{C}$  (HEAT) and  $12^\circ\text{C}$  (COOL) (RH 70%). Rectal and skin temperatures and heart rate (HR) were recorded continuously. The accuracy and speed of the referees' decision making was assessed via digital video clips of match incidents every 3 min, on which the referees had to award the appropriate sanction. The appropriate sanction for each clip was previously determined by an independent panel of FIFA referees. Non-specific simple (SRT) and choice reaction times (CRT) were also recorded on 30 and 12 occasions, respectively. Results Rectal temperature was similar during HEAT compared with COOL after 45-min (HEAT:  $38.6 \pm 0.2^\circ\text{C}$ , COOL:  $38.4 \pm 0.4^\circ\text{C}$ ;  $P=0.08$ ) and was greater at exercise cessation (HEAT:  $39.6 \pm 0.3^\circ\text{C}$ , COOL:  $38.4 \pm 0.4^\circ\text{C}$ ;  $P<0.001$ ). Mean skin temperature and HR were also higher throughout HEAT ( $P<0.001$ ). There were no between-trial differences in the referees' accuracy (HEAT:  $62 \pm 15\%$  COOL:  $52 \pm 8\%$ ;  $P=0.07$ ) or speed (HEAT:  $757 \pm 455$  ms COOL:  $752 \pm 243$  ms;  $P=0.69$ ) of decision making during the match-specific incidents or SRT (HEAT:  $445 \pm 77$  ms COOL:  $412 \pm 72$  ms;  $P=0.73$ ). However, CRT was slower in the HEAT trial (HEAT:  $685 \pm 70$  ms COOL:  $661 \pm 63$  ms;  $P=0.03$ ). Discussion Performing a referee-specific exercise protocol in the heat does not impair the speed or accuracy of making match-specific decisions in elite soccer referees. In contrast, non-specific tasks may be impaired in the heat. These observations may reflect the use of elite referees in the current study. Expert performers are better able to cope with changing conditions such as physiological stress (McMorris & Graydon, 1996), possibly due to developing automatic processes in task performance. Consequently, in highly learned tasks, stress does not have the opportunity to disrupt the link between stimulus and response (Hancock, 1986). References Castagna et al. (2007). Sports Med, 37, 625-646. Hancock (1986). Psychol Bull, 99, 263-281. McMorris & Graydon (1996). J Hum Movement Stud, 30, 177-193.

## IMPROVEMENTS IN FUNCTIONAL MOVEMENT SCREEN SCORES ACROSS 6 MONTHS OF IN-SEASON STRENGTH AND CONDITIONING TRAINING IN ELITE ACADEMY FOOTBALL PLAYERS

KEENAN, J.1, FRUER, S.1, NOON, M.2, THAKE, C.D.1

COVENTRY UNIVERSITY (1), COVENTRY CITY FOOTBALL CLUB (2)

**Introduction** In elite academy football injuries occur at a rate of 37.2 and 4.1 per 1000 game/training hours respectively (Hawkins and Fuller, 1999). Players are injured on average 0.4 times per season with each injury prohibiting normal activity for an average of 21.9 days, equating to the player missing about 6% of the season and consequently a large portion of his development (Price et al., 2004). Epidemiological data indicate the most prominent risk factor associated with injury is previous injury and thus it is prudent to use methods of movement screening to predict functional specific weaknesses, with a view to intervening and reducing injury incidence (Kiesel et al. 2009). One method easily administered is the functional movement screen (FMS) that manipulates extremes of mobility and stability to uncover limitations and asymmetries in movement (Cook et al. 2006). This particular screening tool indicates that players scoring lower than 14 within the FMS are more likely to be injured (Kiesel et al. 2009). **Aim** To evaluate changes in FMS scores within elite academy players through a 6 month in-season strength and conditioning programme. **Methods** 6 elite football academy players ( $17.4 \pm 0.1$  yrs;  $1.75 \pm 6.6$  m;  $66.2 \pm 5$  kg) undertook a 6 month (once or twice a week in season) strength and conditioning programme consisting of developing technique (1st month) followed by a periodised programme consisting of strength and power phases. This programme incorporated the following exercises, snatch, clean and jerk, squat, overhead squat, deadlift, prone row, bench press, stiff leg deadlift and nordic hamstring curl. FMS was assessed pre and post. Data were analysed using Wilcoxon Signed Ranks Test. **Results** Mean total scores increased from pre ( $13.8 \pm 1.2$ ) to post ( $17.5 \pm 0.9$ ,  $P=0.03$ ). Significant differences pre and post were observed in overhead squat, in-line lunge and trunk stability ( $P=0.03$ ). In season there were 2 incidences of non-contact lower limb injury resulting in 3 lost training days. **Discussion** Positive changes were apparent in FMS scores over the 6 month intervention. Players improved in two of the three tests relating to the lower body function (overhead squat, in-line lunge), where the majority of football injuries occur (Hawkins and Fuller, 1999). Furthermore players maintained scores in the active straight leg raise demonstrating that hamstring length was maintained throughout the competitive season through use of eccentric hamstring exercises. This is despite football training and match play reducing hamstring range of motion, reducing function score and increasing lower limb injury risk (Engebretsen et al. 2010). **References** Cook G, et al. ## MONITORING OF BODY LOADING FOR RUGBY PLAYERS DURING TRAINING SESSION BASED ON "SMALL SIDED GAMES" METHOD.

GRANATELLI, G.I, BRIOTTI, G.I, PADULO, J.I, RUSCELLO, B.I, D'OTTAVIO, S.I.

UNIVERSITY "TOR VERGATA" (ROME ITALY)

**INTRODUCTION** The purpose of this study is to investigate the relation between the external and internal body load on rugby players, in order to verify the efficacy of control method to be used in action on field. In team sports, as rugby game, it is very complex to obtain reliable measurements because there are a lot of factors impacting the performance. Moreover it has to be pointed out that the instruments in use are often poor, the high costs and the reduced ecological validity where these experiences are carried out in laboratory (Bakatash). **METHODS** The research has been carried out on 24 subjects, divided in 4 player groups having a different qualification: (G1) six elite junior players; (G2) six senior amateur players; (G3) six senior professional players; (G4) six non-professional women players. In order to investigate on this relation, 8 different "small sided games" (SSG) have been identified, which are often used in high level rugby training, and then three have been chosen randomly and proposed to the four different player groups, in one only training session. In the body load evaluation it has been decided to use the Heart Rate (HR) survey, by calculating the % of highest HR of such player during the whole training session including three exercises, and then to proceed to the calculation for the SSG individuals, by using 6 "Polar team system®". In order to evaluate the individual perceived exertion after each SSG and after the training session, the players have been submitted to the RPE-Borg (CR10) test, according the following timing conditions: within 2' at the end of SSG, within 10' at the end of training session. The internal body load has been determined according the procedure proposed by Coutts and Impellizzeri (2003). **RESULTS** In order to verify the correlation between the HR and the obtained score in RPE, the Pearson test has been used. The following significant correlations have been found: (G1)  $r=0.66$ ; (G2)  $r=0.53$ ; (G3)  $r=0.85$ ; (G4)  $r=0.57$ . **DISCUSSION** At the end of this research we can state that the higher qualification level of players corresponds to the higher correlation between RPE/HR session. There are no difference among the different training typologies, that is to say an high match action "in the defence" or fixing training "in front of the defence" and so we can say that the use of RPE-Session through the "training body load" calculation as perception of body load in rugby activity, is a reliable, simple and inexpensive methodology. **REFERENCES** G.Borg (1998). ## TIME-MOTION ANALYSIS IN RUGBY SEVENS

GRANATELLI, G.I, BRIOTTI, G.I, RUSCELLO B.I, PADULO, J.I, D'OTTAVIO, S.I

UNIVERSITY "TOR VERGATA" (ROME ITALY)

**Introduction** The purpose of this study was to perform a Time Motion Analysis in "Rugby Seven", in high level players, involved in a real competitive event under the kinematics and dynamics points of view. "Rugby Seven", that will be an Olympic Sport in 2016, is still poorly investigated, particularly regarding to the performance model. **Methods** Three Italian elite players men (age  $26.6 \pm 4.5$  yrs; body mass  $80 \pm 4.3$  kg; height  $175.3 \pm 1.5$  cm; years of experience  $15 \pm 4.5$  yrs) were monitored during four matches at the "Rome Seven's" international tournament through the SPI ELITE GPSport Systems®, 3 cardio-frequency meters Polar team system® and the software GPSport Team AMS v1.2.1.0. These parameters were analyzed: the Total Distance Covered (TDC; m); the Distances covered in each different speed zones (DSZ; m); the percentage of the Distance Covered (DCSZ%) and the Time Spent (TSSZ%) in the different speed zones, the amount of repeated Sprints (S), the amount and the intensity of Impacts (nl; gl) and the Heart Rates (HR). **Results** (TDC) of  $1260.5 \pm 196.1$  m, (match time 14'). On the first half was  $629.35 \pm 52.4$  m while on the second half a mean value of  $630.9 \pm 149.87$  m. (DCSZ%): (0-6 km/h):  $41.3 \pm 0.24\%$ ; (6-12 km/h):  $25.8 \pm 1.76\%$ ; (12-14 km/h):  $9.7 \pm 2.68\%$ ; (14-18 km/h):  $12.7 \pm 3.57\%$ ; (18-20 km/h):  $2.9 \pm 0.40\%$ ; (20 km/h-Upper):  $7.8 \pm 3.83\%$ . (S) : [1.50-1.99 m/s-s]:  $n=12.5 \pm 3.42$ ; TD =  $15 \pm 10.12$  m; mean acceleration (Ma)  $1.7 \pm 0.14$  m/s-s. [2.00-2.49 m/s-s]:  $n=12 \pm 1.49$ ; TD =  $22.4 \pm 17.50$  m; (Ma)  $2.2 \pm 0.12$  m/s-s. [2.50-2.74 m/s-s]:  $n=20 \pm 3.47$ ; TD =  $17.9 \pm 10.83$  m; (Ma)  $2.6 \pm 0.06$  m/s-s. [ $a > 2.50$  m/s-s]:  $n=1.3 \pm 1.80$ ; TD =  $21.1 \pm 9.66$  m; (Ma)  $3.2 \pm 0.57$  m/s-s. (nl; gl): Zone (Z) 1 (5-6 gl):  $37.9 \pm 9.8\%$ ; (Z) 2 (6-6.65 gl):  $34.6 \pm 16.8\%$ ; (Z) 3 (6.5-7 gl):  $12.3 \pm 4.9\%$ ; (Z) 4 (7-8 gl):  $9.2 \pm 4.6\%$ ; (Z) 5 (8-10 gl):  $5.3 \pm 1.1\%$ ; (Z) 6 (10-12 gl):  $0.8 \pm 0.3\%$ . Heart Rates were recorded throughout all the matches and expressed as Percentages of the maximal theoretical Heart Rate (HR), computed according to Tanaka's equation (Tanaka, 2001). We observed a mean HRmax% of  $93.13 \pm 3.25\%$ . **Discussion** There are no significant differences between the total distance covered in each half of the match, maybe due to the reduced game time. We found worth mentioning the amount of the recorded sprints at high acceleration rate [2.50-2.74 m/s-s:  $n=20 \pm 3.47$ ; TD =  $17.9 \pm 10.83$ m; mean acceleration  $2.6 \pm 0.06$  m/s-s] whereas in Rugby Union only 10 sprints of this class were found over 83' of game (Cunniffe, 2009). The observed mean HRmax% throughout all the matches witnessed the high physical demands imposed by this sport discipline. **Reference** Cunniffe B, Proctor W, Baker JS, Davies B.(2009). ## RELATIONSHIP BETWEEN HAEMOGLOBIN MASS, BLOOD VOLUME, VO2MAX AND PEAK CARDIAC OUTPUT IN ROWERS

TREFF, G., KIRSTEN J., STEINACKER, J.M.

ULM UNIVERSITY

**Introduction** VO2max is a strong predictor of rowing performance [1]. It has been shown that rowers possess a high VO2max, which is correlated to total haemoglobin mass (tHb) and blood volume (BV) [2]. Since rowers work at high intensities with large muscle groups, O2-delivery is likely to limit VO2max in this group of athletes. O2-delivery is determined by O2-transport capacity - explaining the importance of tHb - and by cardiac output (Q). Up to now, there are no data that describe the relationship between tHb, VO2max and especially BV and Qpeak in rowers. Therefore, this was the focus of our study. **Material and Methods** 9 trained rowers (age =  $21 \pm 3$  y (19 - 37); height =  $187 \pm 17$  cm (177 - 193); body mass =  $84 \pm 10$  kg (72 - 107); VO2max =  $53 \pm 10$  ml/kg/min (47 - 66)) performed a VO2max-test on a rowing

ergometer (Concept 2, Morrisville, USA). tHb was measured and BV was calculated according to [3]. Q was measured on a cycle-ergometer with an inert-gas rebreathing technique (Innocor, Innovision, Odense, DK). For attaining near maximal conditions, Qpeak was measured at a work load equal or higher than 90 % of VO2max, which was determined in a preceding test. All data are Median (Min - Max). Correlations were calculated by Spearman's coefficient (rSP). Results The inert gas rebreathing maneuver for determination of Qpeak was performed at 93 % (90 - 100) of VO2max. Qpeak amounted to 23.6 l/min (18.8 - 30.7). tHb was 1039 g (930 - 1358), BV was 7390 ml (6679 - 9096). Analysis of correlation revealed rSP(VO2max:tHb) = .69; rSP(VO2max:BV) = .67; rSP(Qpeak:tHb) = .78, rSP(Qpeak:BV) = .80, rSP(Qpeak:VO2max) = .83. The ratio Qpeak:BV in the whole group was 3/min. Discussion We measured Q in rowers in near maximal or maximal work conditions. The strong correlation of BV:Qpeak explains the correlation of BV and VO2max in rowers, that has been shown in previous studies [2]. A large BV increases cardiovascular preload and consequently enhances stroke volume (and Q) via the Frank-Starling-mechanism in a compliant heart. Q is a key variable of the Fick principle and therefore strongly correlated to VO2max. The relationship between tHb and VO2max is obvious, since tHb determines O2-transport capacity and consequently affects avDO2. Finally, the ratio of Q:BV indicates, that the blood passes the cardio-respiratory system 3 times per minute at high intensive rowing. Conclusion The study illustrates the relationship between BV and Qpeak and underlines the importance of blood volume and oxygen delivery for VO2max in rowers. ## UP-HILL TREADMILL TESTING PREDICTS CROSS-COUNTRY RUNNING PERFORMANCE IN YOUNG ELITE ORIENTEERS

FRANCH, J.1,4, JOHANSEN, L.2, LARSSON, B.2, LINDSTROM, L.3

1: AAU (AALBORG, DENMARK), 2: TEAM DK (BRØNDBY, DENMARK), 3: DOF (BRØNDBY, DENMARK), 4: ACTIVE INSTITUTE (AARHUS, DENMARK)

**Introduction** Cross-country running performance in elite orienteers has most often been evaluated through level treadmill testing. More recently, Zürcher et al., 2005, evaluated Swiss elite orienteers' ability to perform extreme uphill treadmill running at 22% inclination (INC) in preparation for the WOC in Japan, but the relationship to field performance was not investigated. The aim of the present study is to test the hypothesis that uphill treadmill testing may be a better test indicator for cross country running performance compared to level testing. **Methods** Thirteen young Danish elite orienteers (7 women, 6 men) participated in the project (Age: 18.7±2.3 years), including several medal winners at the JWOC 2010 and EOC 2010. Level, 0% INC, as well as up-hill submaximal treadmill runs (15% INC) were performed at succeeding days in the lab. Maximal oxygen uptake (VO2max) was measured during semi-level (2-8% INC) and uphill conditions (15% INC). Within 3 weeks of lab testing, a 4.5 km cross country course was raced individually by the participants (short dist. orienteering course previously raced by the participants). Finishing time served as indicator for cross-country field performance. Results Men performed faster than women in the field performance test (25:32 min vs. 31:46 min, p < 0.001). During uphill running, the velocity triggering 4 mmol lactate conc. in the blood showed higher correlation values with cross-country performance compared to the equivalent level velocity in both men and women (Men: r = -0.88, p < 0.05 vs. r = -0.53, ns; Women: r = -0.85, p < 0.05 vs. r = -0.71, ns). Overall comparison: r = -0.95, p < 0.0001 vs. r = -0.88, p < 0.0001 for uphill and level respectively. VO2max was higher during up-hill treadmill testing compared to semi-level testing (P < 0.05). **Discussion** In competitive orienteers tested at level conditions (0-2% INC.), it has been shown that VO2max and running velocity at the onset of blood lactate accumulation are predictors of cross-country running performance (Jensen et al., 1994, 1999; Moser et al., 1997). Here we show that uphill testing leads to higher VO2max in some, but not in all orienteers, and that uphill testing further contributes to prediction of cross country field performance with strong correlation within gender groups. We suggest to use uphill testing for prediction of cross-country running performance in elite orienteers. References Jensen K, Franch J, Kärkainen O-P, Madsen K. (1994). *Scand. J. Med. Sci. ## DIFFERENT TREADMILL-PROTOCOLS TO ASSESS VO2MAX IN WELL-TRAINED RUNNERS

KRUEGER, M.1,2, SPERLICH, P.2, SPERLICH, B.1, ZINNER, C.1,2, MESTER, J.1,2

GERMAN SPORT UNIVERSITY COLOGNE

**INTRODUCTION:** Several different test protocols exist to estimate VO2max on the treadmill. They usually differ in speed, treadmill gradient and the increments of both as well as the duration per step. Some ramp test protocols are not challenging enough for trained athletes to reach exhaustion within target time of 8 to 12 min. Therefore we chose four demanding ramp test-designs and one incremental step test as control protocol to measure VO2max in trained athletes. We hypothesized that above mentioned differences effect the maximal oxygen consumption. **METHODS:** 14 male well-trained athletes (26.1 ± 4.2 yrs; 184.0 ± 6.2 cm; 78.0 ± 6.2 kg) participated in the study. They performed five different treadmill protocols in randomized order: 1. Incremental step test (ST) (2.8 m/s; increase 0.4 m/s every 5 min). 2. Velocity-dependent ramp test (VR) (12 km/h; increase 0.5 km/h every 30 sec.). 3. Ramp test designed by Costill/Fox (Kang et al. 2001) (CF) (4.0 m/s constant speed; increase 2% in treadmill gradient every 2 min). 4. Velocity and gradient- dependent ramp test (VGR) (2.4 m/s for 2 min; increase 0.2 m/s every 30 sec. till 4 m/s; then 0.5% in treadmill gradient every 30 sec.). 5. Individual Protocol (IP) (increases in velocity and treadmill gradient at will). Oxygen uptake was measured with a portable Spirometry-system (Metamax 3b, Cortex, Germany). ACSM-criteria for exertion were met in all tests. **RESULTS:** Time to exhaustion (test duration until subjects voluntary stopped the protocol due to individual exertion) for each test protocol was: ST 25.5 ± 3.0; VGR 10.9 ± 1.5; IP 9.8 ± 0.9; CF 7.5 ± 1.2; VR 7.3 ± 1.1 min. Despite CF vs. VR (p=0.58) other differences are significant (VGR vs. IP p<0.03, all other combinations p<0.01). The highest oxygen uptakes measured during the five tests were: CF 63.1 ± 3.2; VGR 62.6 ± 5.0; VR 61.8 ± 4.1; IP 61.5 ± 4.3; ST 59.5 ± 4.1 ml/min/kg. These differences were only significant between ST and all ramp test protocols (ST vs. VR/CF/VGR: p<0.01; ST vs. IP: p<0.02). Between the ramp test protocols there were no statistical differences in VO2max, RQ, max. heart rate and blood lactate concentration. **DISCUSSION:** Although the test durations were significantly different in most protocols no significant differences in VO2max, RQ, max. blood lactate or max. heart rate could be measured. Thus, in contrast to our hypothesis, the exercise protocol (variations in velocity and treadmill gradient) of a ramp test seems to have no effect on VO2max, as long as cardio-respiratory exhaustion is reached within target time, that might be even shorter than 8 - 12 minutes. Therefore all ramp test protocols used in this study can be recommended for well-trained athletes.

**REPRODUCIBILITY OF TREADMILL TESTS TO EXHAUSTION IN RATS: IS THERE A SLOPE EFFECT?**

DUFOUR, S.P., RASSENEUR, L., LONSDORFER-WOLF, E., DOUTRELEAU, S., ISNER, M.E., FAVRET, F., PIQUARD, F., GENY, B.  
UNIVERSITY OF STRASBOURG

**Introduction** Accurate exercise tests with animal models are of paramount importance in the evaluation of exercise capacity and aerobic function (Booth et al, 2010). Previous studies have shown a good reproducibility (CV typically ~5%) of maximal oxygen uptake measurement (Wisloff et al, 2001; Copp et al, 2009). However, the reproducibility of peak treadmill velocity (Vpeak), time to exhaustion at Vpeak (Tlim@Vpeak) and the effect of incline treadmill on these parameters are not known. The aim of this study was to determine the reproducibility of Vpeak and Tlim@Vpeak in level vs. 25° grade treadmill running in rats. **Methods** Twelve young male Wistar rats (317±3g) performed a total of 8 treadmill tests to exhaustion separated by 48h rest: 2 level incremental tests, 2 incremental tests with 25° grade, 2 level constant- and 2 constant-speed tests with 25° grade. The incremental tests to determine Vpeak involved 2min stages with 8 or 5 cm/s speed increments at 0° or 25° grade respectively. The constant-speed tests were performed at Vpeak to determine Tlim@Vpeak. Blood samples were obtained at the tip of the tail during each test after 3min of recovery for maximal blood lactate determination. Results Vpeak during level treadmill running was 73±2 cm/s and decreased to 45±2 cm/s with 25° grade with similar CV (22±3 and 20±4% respectively). Tlim@Vpeak during level running was 446±95s and remained unchanged at 451±85s with 25° grade with equivalent CV (30±9 and 44±11% respectively). CVs were significantly higher for Tlim@Vpeak than for Vpeak (P<0.05). Maximal blood lactate was 8.4±0.7 and 8.6±0.9 mmol/L after level vs. 25° grade incremental tests and was not different after Tlim@Vpeak (7.0±0.6 vs. 7.7±0.9mmol/L at level or 25° grade respectively). CVs for maximal blood lactate were similar whatever the type of test or the slope of the treadmill (ranging from 19 to 26%). **Discussion** These data demonstrate that duplicate Vpeak and Tlim@Vpeak tests give similar group mean results with intra-rats CV being unaffected by the treadmill slope. However, intra-rat CVs for Tlim@Vpeak are greater than for Vpeak. Both Vpeak and Tlim@Vpeak tests lead to similar maximal blood lactate with equivalent CVs with no effect of the treadmill slope. It is concluded that 25° grade vs. level treadmill running does not allow for a better reproducibility of usual exercise performance parameters in rats. **Bibliography** Booth FW, Laye MJ, Spangenberg EE (2010) J Appl Physiol, 108, 219–221 Wisloff U, Helgerud J, Kemi OJ, Ellingsen Ø (2001) Am J Physiol Heart Circ Physiol, 280, H1301–H1310 Copp SW, Davis RT, Poole DC, Musch TI (2009) J Appl Physiol, 106, 1072–1078

**DETERMINING EXERCISE INTENSITY AT MAXIMAL OXYGEN UPTAKE: METHODOLOGICAL ISSUES AND REPEATABILITY**

MERRY, K.L.1, GLAISTER, M.2, HOWATSON, G.3, VAN SOMEREN, K.4

1: LOUGHBOROUGH COLLEGE (LOUGHBOROUGH,UK), 2: ST MARY'S UNIVERSITY COLLEGE, (TWICKENHAM,UK), 3: NORTHUMBRIA UNIVERSITY, (NEWCASTLE UPON TYNE, UK), 4: ENGLISH INSTITUTE OF SPORT, (TWICKENHAM, UK)

**DETERMINING EXERCISE INTENSITY AT MAXIMAL OXYGEN UPTAKE: METHODOLOGICAL ISSUES AND REPEATABILITY** **Introduction** The minimum exercise intensity that elicits 2max (2max) is one of the most pertinent factors associated with endurance exercise performance (Jones and Doust, 2000; Berthon and Fellmann, 2002). A direct method of determining 2max from a single incremental test utilising 1 minute stages is favoured in research (Billat et al., 1996); however, this approach is limited by the size and duration of the increments used. The aims of this study were to address those limitations to develop a method that more accurately determines minimum 2max from a single trial and then assess the repeatability of the modified method (MM). A secondary aim was to compare the 2max value produced by a single trial of MM with a refined 2max value (RV) derived from repeated trials of MM. **Methods** Seventeen male cyclists (age 33.9 ± 7.7 years, body mass 80.9 ± 10.2 kg, height 1.82 ± 0.05 m; 2max 4.27 ± 0.62 litres.min<sup>-1</sup>) performed 4 separate incremental cycle ergometer tests (3 min stages; 20 W increments). Trials 1 and 2 were identical and used for assessing the repeatability of MM using an intraclass correlation coefficient (ICC) and coefficient of variation (CV). Trials 3 and 4 had different starting intensities in comparison to trials 1 and 2 and were used for determination of RV. MM and RV were then compared using a paired samples t-test. Results MM showed good test-retest repeatability for 2max (CV = 4.1%; ICC = 0.93), 2max (CV% = 6.3; ICC = 0.90), and test duration (CV% = 6.7; ICC = 0.89). 2max values for MM (309 ± 44 W) were significantly greater than those for RV (301 ± 42 W) (P < 0.05). 2max values were 52.6 ± 9.1 and 52.7 ± 8.6 ml.kg<sup>-1</sup>.min<sup>-1</sup> for MM and RV respectively and were not significantly different (P > 0.05). Test duration was not significantly different between MM (20.9 ± 2.9 min) and RV (20.4 ± 2.9 min) (P > 0.05). **Discussion** The present results suggest that MM is a repeatable method of single trial 2max determination. However, identification of the minimal 2max during a single incremental test appears to be dependent upon the starting intensity of the test. Therefore, determination of the minimal 2max may not be a realistic criterion to assign to single trial approaches to determining 2max. **References** Berthon P, Fellmann N. (2002). **VENTILATORY EQUIVALENT RATIO FOR VCO2-VO2 DIFFERENCE LINKED TO THE MAXIMAL BLOOD LACTATE LEVELS**

EMESE, T., BOSNYAK, E., KOMKA, ZS., UDVARDY, A., SZENDREI, B., PROTZNER, A., GYÖRE, I., TÓTH, M.

SEMMELEWIS UNIVERSITY FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES

**Introduction** Exercise represents one of the greatest stresses that an organism can encounter. There are many variables that influence endurance performance. VO2max is thought to be the best indicator of aerobic capacity and also is a relatively good predictor of endurance performance. Carbon dioxide is a by-product of cellular metabolic processes. VCO2 can be used as an indicator of the metabolic changes during incremental exercise. In our investigation we measured elite hungarian canoeists' performance. We used the ventilatory equivalent ratio for VCO2-VO2 difference (VCO2-VO2/VE) to analyze the important changes during an incremental test such as the anaerobic threshold (AT). **Methods** Elite men kayakers and canoeists participated in this study (n=48, 31 kayakers, 17 canoeist). Age: 23.3±5.1 years; height: 184±0.1 cm; weight: 85±8.3 kg; BMI: 25.2±1.7. The examination consisted of a vita maxima test. The athletes completed the test to exhaustion on treadmill with a constant velocity (10 km/h) and starting from a 1,5 % gradient, which ascended with 1,5 % every other minute. During the examination we registered heart rate (HR), maximal oxygen uptake (VO2max), ventilation (VE), respiration quotient (RQ), lactate concentration in rest (Lar), at peak of maximal load (Lamax), and 5 minutes after the maximal load (Lar5). Basic statistics and for comparison of the measured data linear correlation was used (significance level: p<0.05). Results After the vita maxima test the following peak values of the maximal respiratory parameters were registered: VO2max: 4722±522 (ml/min); VCO2max: 6034±668 (ml/min); VEmax: 163±16.3 (l/min); (VCO2-VO2)/VE: 8.1±1.9; HRmax: 188±10; watt:427±36; Lamax 12.7±2.8 mmol/l; Lar5:13.8±3.3 mmol/l. We have found a significant correlation (p<0.05) between the (VCO2-VO2)/VE to the maximal lactate values (Lamax) with a higher coefficient correlation (r=0.72). We have not found any correlations between the (VCO2-VO2)/VE to the Lar5. **Discussion** These not usual calculated indexes can be more informative for the athletes and can help to determine important changes during physical exercise.

## TEST-RETEST REPEATABILITY OF DIFFERENT MODELS TO ASSESS HR RECOVERY AFTER SUBMAXIMAL EXERCISE AT THE BICYCLE ERGOMETER

ROMAGNOLI, M.1, ARDUINI, A.2, GOMEZ-CABRERA, M.C.3

1CATHOLIC UNIVERSITY OF VALENCIA, PHYSICAL EDUCATION AND SPORTS, 2DEPARTMENT OF PHYSIOLOGY, FACULTY OF PHARMACY, UNIVERSITY OF VALENCIA, SPAIN. 3DEPARTMENT OF PHYSIOLOGY, UNIVERSITY OF VALENCIA, SPAIN.

**Introduction.** Measurement of HR recovery after exercise is used in healthcare and sport settings to assess adaptation to training, and it has also been proposed as independent predictor of all-cause mortality. Different models to assess HR recovery have been developed but knowledge of their reliability is poor at different submaximal exercise intensities and recovery durations. Submaximal exercise is more reproducible than maximal one and allows a better standardization of the test(1). **Objective.** Our aim was to determine the reliability of 11 indices of HR recovery after a test on a cycle ergometer, at two intensities of submaximal exercise (65% and 80% HRmax). **Results.** We found that: 1) assessment of HR recovery after 80% HRmax exercise leads to more reliable values than after 65% HRmax exercise (mean ICC: 0.827 vs. 0.747); 2) a longer recovery time increases the absolute consistency of the measurement (%SEM: 26.7 at 60 s, 19.5 at 120 s and 16.3 at 180 s, irrespective of model or exercise intensity); 3) T30min is more reliable than T30 (ICC: 0.691 vs. 0.528; %SEM: 28.5 vs. 70.8) for the calculation of the fast component of HR recovery (HR kinetics calculated over  $\leq 60$  s) after exercise. **Conclusion.** A good sensitivity of measurement - large ICC and small SEM - is obtained for analysis of HR recovery after submaximal exercises on the cycle ergometer, especially for internal workloads of 80% HRmax. At this workload, consistency of results increases for recoveries of longer duration. **References** 1.Cole CR, Foody JM, Blackstone EH et al. Heart rate recovery after submaximal exercise testing as a predictor of mortality in a cardiovascularly healthy cohort. *Ann Intern Med.* 2000; 132:552-555

## DOUBLE BOUT NON-EXHAUSTIVE TETHERED SWIM TO EVALUATE THE AEROBIC CAPACITY IN SPEED SWIMMERS

GOBATO, C.A.1, SANTHIAGO, V.2, PAPOTI, M.3, MANCHADO-GOBATO, F.B.4

1: UNICAMP (LIMEIRA, SP), 2: UNIP (SÃO PAULO, SP), 3: UNESP (IP. PRUDENTE, SP), 4: UNIMEP (PIRACICABA, SP). BRAZIL.

**Introduction** The gold standard test to aerobic capacity evaluation in crawl swimming is the maximal lactate steady state (MLSS) but it requires direction changes at each pool turn, adding at this moment an underwater dolphin kick, altering the style. Besides of this, the MLSS test can promote exhaustion and athlete injury depending of training phase. However, a method used to training is the tethered swim (TS), which shows an advantage on prescription training by continuous swimming style. So, the aim of study was propose a non-exhaustive method to determine the aerobic capacity in a TS test applied to male swimmers. **Methods** Twelve subjects ( $23 \pm 1$ yr) were submitted to 2 TS tests: TS double bouts and TS-MLSS. The double bouts test consisted of four loads at different intensities (68, 70, 72 and 74N) accomplished at random with almost 24-h pause among them. The athletes swam twice for 3-min each time, at same intensity, with a 1.5-min rest between the efforts. Heart rate (HR) and blood lactate concentration (BL) were determined after the first and second bout exercise. These swimming intensities were got from a load cell coupled by the pool and integrated to the data acquisition system with signs collection at 1000Hz (Papoti et al., 2007). The non-exhaustive aerobic parameter was determined by two linear regressions of deltas (HR and BL) of the four loads, considering the y-intercept as critical force (CF - null delta HR and BL)(Chassain, 1986). So, two CFs were determined from HR and BL parameters. These tests were retested to verify the reproducibility and reliability. To validate this non-exhaustive tethered method, TS-MLSS was accomplished using five 30-min constant loads varying of 50 to 90N. The TS-MLSS was considered the load in which the increase of BL between 10 and 30-min was not superior to 1mM (Beneke, 2003). **Results** The CF test-retest from HR parameter was  $69.3 \pm 1.9$  and  $68.9 \pm 1.9$ N, respectively. To BL, the CF was  $69.0 \pm 1.8$ N (test) and  $69.1 \pm 1.9$ N (retest). The TS-MLSS load was obtained at  $70.8 \pm 1.9$ N. ANOVA two-way did not reveal differences among CF results (HR and BL, test and retest) and the Pearson's coefficients showed high significant correlations among parameters (mean  $r$  0.89, mean  $P$  0.001). Bland-Altman test verified reliability among CF (HR and BL) and MLSS. **Discussion** The non-exhaustive method to determine the aerobic capacity parameter (CF), using HR or BL is valid, reproducible and reliable in speed swimmers evaluated by double bouts tethered method. ## EFFECT OF TRAINING FREQUENCY ON ABDOMINAL MUSCLE ENDURANCE

JUAN-RECIO, C., LÓPEZ-VIVANCOS, A., MOYA, M., PELÁEZ, M., VERA-GARCÍA, F.J.

UNIVERSIDAD MIGUEL HERNÁNDEZ DE ELCHE

**Introduction** The frequency of training sessions is one of the factors that determine the effectiveness of a training program (Kraemer and Ratamess, 2004). However, we have only found two studies examining the influence of this variable on the results of abdominal exercise programs (DeMichelle et al., 1997; Vera-García, 2003). The aim of this study was to evaluate the effects of different training frequencies on the abdominal muscle endurance. **Methods** One hundred and eighteen high school students (59 men and 59 women; mean age: 17.0 years) without experience in trunk exercise programs, volunteered to take part in this study. The participants were randomly divided into four groups: G1 ( $n = 21$ ), which trained 1 d/w; G2 ( $n = 27$ ), which trained 2 d/w; G3 ( $n = 23$ ), which trained 3 d/w; and Control Group (CG;  $n = 47$ ), which did not train. The abdominal training program lasted 8 weeks. In each session, 2 sets of each of the following trunk flexion exercises were executed: crunches (or curl-ups) and cross-crunches (or cross-curl-ups). Before and after training the participants performed the bench trunk-curl test (Knudson and Johnston, 1995) to assess the dynamic abdominal endurance. During the first two weeks of training the number of repetitions for each set was 30% of the maximum number of repetitions reached at the first assessment, increasing 5% every two weeks. **Results** Statistical analysis of covariance revealed that exercise training significantly improved the abdominal endurance for G1, G2 and G3 ( $p < 0.001$ ). There were no significant gender differences for these improvements. In addition, results from inter-group comparisons showed no significant differences in abdominal endurance after training, either between G1, G2 and G3, or between GC and G1. However, the differences were significant between G2 and GC ( $p = 0.023$ ) and between G3 and GC ( $p = 0.006$ ). **Discussion** Although there is no optimal training frequency for all people and programs, training frequencies of 2-3 d/w appear to be appropriate for most of the abdominal endurance programs (DeMichelle et al., 1997; Vera-García, 2003). However, based on our results, a frequency of 1 d/w may be sufficient to produce improvements in non previously trained people, which may promote adherence to abdominal training programs. **References** DeMichele PL, Pollock ML, Graves JE, Foster DN, Carpenter D, Garzarella L, Brechue W, Fulton M. **EFFECT OF SPECIFIC RESISTANCE TRAINING ON READINESS TO CHANGE AND SELF-RATED HEALTH IN THE WORKING LIFE**

BREDAHL, T., JÖNSSON, C., ANDERSEN, L., SJØGAARD, G.

UNIVERSITY OF SOUTHERN DENMARK, \*NATIONAL RESEARCH CENTRE FOR THE WORKING ENVIRONMENT

**Introduction** The objective of this study was to investigate the effect of 20 weeks of strengths training on readiness to change and self-rated health, amongst laboratory technicians with industrial repetitive work. **Methods** A cluster randomised controlled trial was performed with an intervention group (IG)(n=282) and a control group (CG)(n=255). The IG performed five specific strengthening exercises for the neck-shoulder region, three times a week for approximately 20 minutes, during working hours. Participants replied to a questionnaire at baseline and follow-up. The main objectives were changes in readiness to change, self-rated health, strengths and fitness. **Results** The IG had a statistically significant higher readiness to change after 20 weeks of training compared to baseline, whereas no statistical significance was found for the CG, with mean values of intervention ( $3.72 \pm 1.53$  vs.  $3.89 \pm 1.44$ ) and control ( $3.79 \pm 1.42$  vs.  $3.82 \pm 1.48$ ). However, the increase in readiness to change in the IG was not statistically significant compared to the CG ( $p=0.238$ ), with delta values of ( $0.17 \pm 1.16$  vs.  $0.03 \pm 1.20$ ). The IG had a statistically significant increase in self-rated health after 20 weeks of training compared to baseline, while no increase was found for the CG, with mean values of ( $3.63 \pm 0.72$  vs.  $3.79 \pm 0.75$ ) and ( $3.65 \pm 0.82$  vs.  $3.65 \pm 0.85$ ). Increase in self-rated health in the IG was statistically significant higher compared to the CG, with delta values of ( $0.16 \pm 0.69$  vs.  $0.01 \pm 0.63$ ,  $p=0.019$ ). The IG had a statistically significant increase in self-rated strength after 20 weeks of training compared to baseline, while no statistically significant increase could be found in the CG, with mean values of ( $5.82 \pm 1.80$  vs.  $6.25 \pm 1.81$ ) and ( $5.75 \pm 2.12$  vs.  $5.84 \pm 2.01$ ). The increase in the IG was statistically significant compared to the CG with delta values ( $0.42 \pm 1.33$  vs.  $0.09 \pm 1.41$ ,  $p=0.013$ ). Both the intervention and the CG had a statistically significant increase in self-rated fitness after 20 weeks of training compared to baseline, with mean values of ( $5.72 \pm 2.05$  vs.  $6.02 \pm 2.06$ ) and ( $5.59 \pm 2.31$  vs.  $5.76 \pm 2.29$ ). The increase in self-rated fitness was not statistically significantly larger in the IG compared to the CG ( $0.29 \pm 1.41$  vs.  $0.18 \pm 1.26$ ,  $p=0.364$ ). **Discussion** The study has shown that specific resistance training has a positive effect on self-rated health, self-rated strength and self-rated fitness. However, the study did not show any significant effect of specific resistance training on readiness to change, perhaps because the participants entering the study were already selected on a high preference for exercising.

**Poster presentations****PP-PM58 Training and Testing: Sports Performance 2****A STUDY ON SPATIAL DISTANCE IN BUDO**

FUJIWARA, T.

TOKYO UNIVERSITY OF SCIENCE

**Introduction** In confronting opponents one-on-one in Budo, 'Ma'ai' is the spatial distance from your opponent. It is imperative that you keep Ma'ai advantageous to you and disadvantageous to your opponent. For this, you must set Ma'ai by not only taking into account your skills and tactics, predicting necessary skills and tactics to respond to your opponent's moves, but also by surveying your surroundings. Ma'ai is not constant; it varies according to the conditions at the time, and the techniques to be used vary in limitless ways accordingly. In this study, we conducted experiments to determine what Ma'ai actually means in Budo and the types of Ma'ai that invites the use of certain techniques, 'Waza'. **Study Method** For the experiments, a total of seven male black-belt Shorinji Kempo practitioners engaged in one-minute matches under three different rules respectively; one using assault arts only, another using grappling arts only, and the other for using both arts in combination. The confrontations were recorded using digital video cameras and the corresponding images were transferred to a personal computer. A three-dimensional DLT(Direct Linear Transformation) method was then used to plot three-dimensional position coordinates and thus determine Ma'ai, namely, the distance between the opponents. And, to study Ma'ai that provides chances opportune for initiating attacks on the opponent, the subjects were surveyed before the matches for subjective Ma'ai at which they would be tempted to make an attack on the opponent. **Results and Discussion** The average Ma'ai during the one minute matches in this study was  $1.63 \pm 0.09$ m for G ('hard' techniques, used to fell an opponent at a distance with a strike),  $1.05 \pm 0.32$ m for J ('soft' techniques, used to control and fell an opponent at close range while in constant contact), and  $1.58 \pm 0.11$ m for G+J. In G+J, the G Ma'ai was used as the standard, with the J Ma'ai being adopted in response to the opponent's moves, and the nature of the attack. The rate of attacks at subjective Ma'ai during the matches was 14.7% for G, 5.3% for J, and 11.9% for G+J, suggesting that the subjective Ma'ai is merely one factor affecting attack chances. It is possible that factors like gaps in opponent's stance, breaks in posture, physical attributes, and circumstances such as rules of the match might weigh on Ma'ai. We intend to further our study on these aspects in the future.

**MEASURING KAYAK PADDLE PERFORMANCE WITH WIRELESS STRAIN SENSORS ON THE SHAFT – A VALIDATION STUDY**

STURM, D., YOUSAF, K., HALVORSEN, K., ERIKSSON, M., HÅKANSSON, P., SEGERSTRÖM, Å.

KTH ROYAL INSTITUTE OF TECHNOLOGY

**Introduction** In flatwater kayaking the boat is propelled by a combination of forces, which the athlete exerts on the seat, the foot stretcher and the paddle - to be more specific: on the paddle shaft. Due to this force the paddle shaft bends, because the immersed blade causes a friction in the water. We have designed a mobile, wireless force measurement and feedback system for measuring the two most prominent forces on-water: the paddle and for the foot stretcher force (Sturm et al., 2010). The aim of this study was to validate the paddle force data of this system against a laboratory system consisting of commercial force sensors. **Methods** A Labview programme (Labview 2010; National Instruments, USA) and data acquisition system (NI 9205, NI 9237; National Instruments, USA) was used to record data from the customised force transducers (Segeström et al.) on the ergometer (Dansprint, Denmark) and from the wireless system (Sturm et al., 2010) under evaluation. An experienced adult kayak athlete performed three sets of exercises at four work levels. After collection the data from the PC and the mobile phone was aggregated and analysed with Matlab (Matlab R2010a; Mathworks, USA). **Results** Force recordings during three trials each at the exercise levels of 80W/60s/72 strokes per minute (spm), 160W/60s/88spm, 240W/60s/100spm and 300W/30s/116spm revealed a mean absolute difference of 5.4N (12.7N), 12.4N (23.2N), 15.7N (29.0N) and 8.6N (20.6N) respectively with average force peaks at 110.0N, 162.8N, 205.3N and 174.2N. **Discussion** Although the two paddle transducers were calibrated simul-

taneously with the force sensors on the ergometer there is a slight difference in the recorded force value between the systems, which grows with an increase of applied force. Discrepancy between the force measured in the ergometer ropes and that of the paddle transducers is likely due to a varying angle between the rope and the paddle. In water – the design scenario for the paddle system, the wing paddle blade requires a specified orientation (Kendal et al., 1992); an ergometer's pole is a circular rod unaffected by rotation. Further differing characteristics between ergometer and on-water paddling have been discussed (Begon et al., 2007) and may have played a role. Our next investigations will look further into the agreement of both methods and are aiming at deeper insights into the biomechanical scenario. References Begon, M., Colloud, F. (2007). ### MULTIVARIATE RELATIONSHIP BETWEEN MORPHOLOGY, FUNCTIONAL CAPACITIES AND SPORT-SPECIFIC SKILLS IN ADOLESCENT MALE BASKETBALL PLAYERS

VALENTE-DOS-SANTOS, J.I, PIMENTA, R.I, RÊGO, I.I, GONÇALVES, C.E.I, FIGUEIREDO, A.J.I, PHILIPPAERTS, R.M.2, MALINA, R.M.3, COELHO-E-SILVA, M.J.I

1 FCDEF (UNIVERSITY OF COIMBRA, PORTUGAL), 2 DMSS (UNIVERSITY OF GHENT, BELGIUM), 3 FACSM (FELLOW OF THE AMERICAN COLLEGE OF SPORTS MEDICINE)

**INTRODUCTION** The influence of maturity status on body size, functional capacities and basketball-specific skills was already evaluated in late adolescent basketball players (Coelho e Silva et al., 2008). However, previous analysis ignored the multivariate nature of morphology, physical fitness and basketball skills. The present study examined the relationships between domains of variables in 80 male basketball players aged 12.0-13.9 years. **METHODS** Height, body mass and two skinfolds (triceps and subscapular) were measured. Functional capacity was assessed with the countermovement jump, 2-kg medicine ball throw, hand grip strength, 60-second sit-ups and endurance shuttle run (Coelho e Silva et al., 2010). Performances on four basketball skills were tested: shooting, passing, dribbling and defensive movements (Kirkendall et al., 1987). Associations among body size, adiposity, functional capacities and skills were evaluated with canonical correlation analysis. **RESULTS** The canonical correlation between morphological indicators and functional capacities was 0.84 ( $rc^2=0.70$ , Eigenvalue = 2.34, Wilks' Lambda = 0.13,  $F=14.31$ ,  $p<0.01$ ). The correlations between variables and the respective first pair of canonical variates suggested that players who were heavier (+0.92) and taller (+0.90) attained better scores in strength and tasks that did not require displacement of the body through space (hand grip: +0.86; 2-kg ball throw: +0.84). The canonical correlation between morphology and sport-specific skills was 0.53 ( $rc^2=0.28$ , Eigenvalue = 0.38, Wilks' Lambda = 0.69,  $F=2.46$ ,  $p<0.01$ ). The pattern of loadings suggested that dribbling (+0.66) and defensive movement (+0.56) were associated with lower levels of adiposity (-0.91). The first linear combination obtained to maximize the correlation between basketball skills and functional capacities showed substantial shared variance ( $rc=0.70$ ,  $rc^2=0.50$ , Eigenvalue = 0.98, Wilks' Lambda = 0.39,  $F=3.89$ ,  $p<0.01$ ). Endurance items, 20-meter shuttle run (+0.88) and sit-ups (+0.71), were the primary contributors to performance on the four basketball skills. **DISCUSSION** Manipulative skills are important components of success in basketball and appeared to be independent of pubertal status (Coelho e Silva et al., 2008). A positive relationship of abdominal muscular strength and aerobic endurance with skills was noted in the present study. Since the tallest basketball players were not more skilled than other players in explosive tasks, the selection of biologically advanced subjects can be myopic. **ACKNOWLEDGMENTS** Partially supported by FCT (SFRH/BD/64648/2009; PTDC/DES/2011) **REFERENCES** Coelho-e-Silva MJ, et al. ### EFFECT OF IBUPROFEN ON PERFORMANCE IN RUNNERS WITH EXERCISE-INDUCED MUSCLE DAMAGE

DA SILVA, E., PINTO, R.S., RIBEIRO, J.P., METZ, V.R., GIAZZON, I.W., RICARDO, Y., LUZ, C., LAITANO, O., KRUEL, L.F.M.

LABORATORY OF HUMAN MOVEMENT (LMH), UNIVERSITY OF CAXIAS DO SUL (UCS), CAXIAS DO SUL - RS, BRAZIL; FEDERAL UNIVERSITY OF RIO GRANDE DO SUL, PORTO ALEGRE, BRAZIL

**Objective:** This double-blind, randomized clinical trial was designed to investigate the effect of prophylactic administration of Non-steroidal anti-inflammatory (NSAID) on the time until reporting fatigue (tlim) in runners with exercise-induced muscle damage. **Methods:** Twenty healthy, young long-distance runners (age  $19 \pm 0.5$  years;  $VO_{2peak}$   $55.5 \pm 5.9$  ml.kg<sup>-1</sup>.min<sup>-1</sup>), participated in this study. They were assigned into two groups (n=10) to perform two time limit to exhaustion trials (tlim), 48h before and after a protocol of exercise-induced muscle damage (isokinetic dynamometry). The ibuprofen group received 1.2g of NSAID ibuprofen orally while the control group received a placebo (microcrystalline cellulose). Immediately before, 24h and 48h after the protocol of exercise-induced muscle damage, participants were asked to report local pain (CR10). **Results:** Participants of both groups reported a significant increase in pain of knee extensor and flexors 48h after the muscle damage protocol. There was a reduction in performance in both groups in terms of time ( $p<0.01$ ), yet without significant interaction ( $p=0.55$ ), indicating the failure of the drug to reduce the impact of pain on performance. **Conclusion:** No evidence of an ergogenic effect of NSAID ibuprofen on the performance of runners with exercise-induced muscle damage was found. This disproves the possibility of improving performance of runners with induced muscle pain by the prophylactic analgesic strategy. **Da Silva ER, De Rose EH, Ribeiro JP, et al. ### MONITORING INTERVAL TRAINING IN MASTER ENDURANCE ATHLETES

MINGANTI, C., FERRAGINA, A., CAPRANICA, L., MEEUSEN, R., PIACENTINI, M.F.

UNIVERSITY OF MAGNA GRAECIA

Monitoring interval training in master endurance athletes Carlo Minganti <sup>1,2</sup>, Andrea Ferragina <sup>1</sup>, Laura Capranica <sup>2</sup>, Romain Meeusen <sup>3</sup>, Maria Francesca Piacentini <sup>2,1</sup> Experimental and Clinical Medicine Department, University of Magna Graecia, Catanzaro, Italy <sup>2</sup> Department of Human Movement and Sport Sciences, University of Foro Italico, Rome, Italy <sup>3</sup> Department of Human Physiology and Sports Medicine, Vrije Universiteit Brussel, Belgium **Introduction** In recent years there has been an increased interest in issues related to the enhancement of the performance of master endurance runners (MER). MER adopt different training strategies commonly used by elite athletes such as high intensity interval training (HIT). For these athletes the session-RPE method may provide valuable information to avoid

the maladaptive responses such as overreaching or overtraining phenomena (Foster, 1998) however, recovery time during HIT is a substantial portion of training. Therefore the aim of the present study was to evaluate the effectiveness of the session RPE method as a tool to quantify internal training load during HIT in MER. In addition, we investigated whether it is appropriate to take into account rest periods when calculating the session-RPE (Shannon & Meeusen, 2005). Methods Eight male MER (age:  $45.3 \pm 7.3$  years; stature:  $1.74 \pm 0.06$  m; body mass:  $64.9 \pm 9.1$  kg) were monitored during an IT consisting of  $5 \times 1000$  m with 5 min rest between bouts. Run speed was fixed at 95% of velocity associated with  $\text{VO}_{2\text{peak}}$  ( $v\text{VO}_{2\text{peak}}$ ). Edwards' summated heart rate zone method was used as a reference measure and the session RPE rating was obtained using the CR10 Borg's scale. The individual Session RPE was computed by RPE-based method proposed by Foster et al. (1996) by multiplying the duration of the training session by RPE obtained after 30 min (Rest Session-RPE). Moreover the session-RPE was also computed excluding rest periods (No-Rest session-RPE). Results The relationships between the training load assessment methods were estimated using Pearson product-moment correlation as well as the coefficient of determination ( $r$ =correlation coefficient  $R^2$ =coefficient of determination). Higher correlation ( $r$ : 0.86;  $R^2$ : 0.74) was observed between Edwards' HR and the No-Rest session-RPE compared to Rest session RPE ( $r$ : 0.82;  $R^2$ : 0.67). Discussion Despite the rest periods exclusion from the session RPE computation seem more appropriate, the statistical analysis indicates that there is no significant difference between the two correlation coefficients. These findings suggest that the session-RPE can be a useful tool to monitor internal training load during IT and that the inclusion/exclusion of rest period in its computation needs further investigation. ### ALLOMETRIC SCALING OF PEAK POWER OUTPUT ACCURATELY PREDICTS TIME TRIAL PERFORMANCE AND MAXIMAL OXYGEN CONSUMPTION IN TRAINED CYCLISTS

LAMBERTS, R.P., LAMBERT, M.I., SWART, J., NOAKES, T.D.

*UCT/MRC RESEARCH UNIT FOR EXERCISE SCIENCE AND SPORTS MEDICINE, DEPARTMENT OF HUMAN BIOLOGY, FACULTY OF HEALTH SCIENCES, UNIVERSITY OF CAPE TOWN, THE SPORT SCIENCE INSTITUTE OF SOUTH AFRICA, NEWLANDS*

Introduction Being able to predict several performances parameters from a single test is important for monitoring purposes in well trained and elite athletes. As performance tests, such as a peak power output test (PPO) and a 40km time trial test (40km TT), generally interfere with the normal training habits of athletes monitoring of a regular basis is difficult. As maximal oxygen consumption ( $\text{VO}_{2\text{max}}$ ) is related to exercise capacity (Arts and Kuipers, 1994),  $\text{VO}_{2\text{max}}$  has become a popular measurement to determine training status in athletes. However, this parameter loses its predictive accuracy in well-trained cyclists (Lamberts et al., 2009). In an attempt to overcome this limitation, Swain (1994) has suggested that body mass should be corrected to the power of 0.32 ( $\text{kg}^{0.32}$ ) when predicting flat time trail performance. Therefore the purpose of this study was to determine if peak power output adjusted for body mass $^{0.32}$  is able to accurately predict 40km TT performance and possibly maximal oxygen consumption. Methods Forty-five trained male cyclists completed a peak power output test, including respiratory gas analysis, and a 40km TT after being familiarized. Performance parameters such as peak power output (PPO), maximal oxygen consumption ( $\text{VO}_{2\text{max}}$ ) and 40km time trial time were measured. Peak power output was normalized for body mass to the exponent of 0.32 ( $\text{W} \cdot \text{kg}^{-0.32}$ ) after which the relationship with 40km TT performance and maximal oxygen consumption was determined. Results As expected, a strong relationship occurred between peak power output and  $\text{VO}_{2\text{max}}$  before adjustment for body mass ( $r = 0.96$  (95%CI:  $0.93 - 0.98$ );  $P < 0.0001$ ). After adjusting PPO for body mass $^{0.32}$  ( $\text{W} \cdot \text{kg}^{-0.32}$ ), there was a strong relationship with 40km TT time ( $r = -0.96$ : 95%CI:  $-0.93 - -0.98$ ;  $P < 0.0001$ ), with a standard error of estimate of 52 s. Although significant relationships were also found between absolute (W) and relative PPO ( $\text{W} \cdot \text{kg}^{-1}$ ) and 40km TT performance, slope analyses showed that the relationships with 40km TT performance were significantly weaker than adjusted PPO ( $\text{W} \cdot \text{kg}^{-0.32}$ ) (both  $p < 0.0001$ ). Discussion This study shows PPO adjusted for body mass $^{0.32}$  ( $\text{W} \cdot \text{kg}^{-0.32}$ ) is able to accurately 40km TT performance in trained cyclists. In addition,  $\text{VO}_{2\text{max}}$  could also be accurately predicted from PPO measured within the same test. The practical relevance of this study is that  $\text{VO}_{2\text{max}}$  and 40km TT performance can be predicted with a reasonable amount of accuracy from just one PPO test. As this possibly can reduce the amount of performance tests throughout the year in well-trained and elite cyclists, this method might possibly allow more regular testing for monitoring purposes. ### THE RELATIONSHIP BETWEEN THROWING ABILITY ON- WATER AND ON DRY LAND IN ELITE JAPANESE WATER POLO PLAYERS

KOMORI, Y., KOBAYASHI, D., MURASE, Y., TAKAGI, H., KONO, I.

*DOSHISHA UNIVERSITY*

Introduction Throwing ability is one of the most important skills in water polo. Further, throwing movement on- water differs from that on dry land, because no ground support is available on- water. Throwing movements in water require the use of highly-complicated under-water techniques, such as sculling (hand movements) and eggbeater kicking (lower leg movements), which are very important. Clarifying the relationship between throwing ability on- water and on dry land makes it easier to estimate water polo players' ability. An understanding of this relationship can be applied to performance tests and identification of talent. Therefore, this study aims to examine the relationship between throwing ability on- water and on dry land, and the relationship between throwing ability and age or having a competitive career. Methods A total of 199 male water polo players participated in this study. The subjects included 55 elementary school water polo players (E-group,  $10.7 \pm 1.1$  years), 53 junior high school players (J-group,  $13.3 \pm 1.0$  years), 49 high school players (H-group,  $16.3 \pm 1.0$  years), 21 college players (Co-group,  $20.0 \pm 1.5$  years), and 21 club players (Cl-group,  $27.1 \pm 4.1$  years). Players from all the groups had participated in Japanese National Championships, and were ranked between the 1st and 4th positions. Furthermore, the group of club players included members of the Japanese national team. The following indicators of throwing ability were used: (1) throwing distance on- water and (2) throwing distance on dry land. Results There was a significant correlation between throwing distance on- water and on dry land ( $r = 0.91$ ,  $p < 0.01$ ). Further, both throwing distance on- water and on dry land were significantly different across all the groups. Throwing distance showed a significant increase with advancing age and having a competitive career. While, a significant decrease was observed in the difference between throwing distance on- water and on dry land with advancing age and having a competitive career. Discussion The correlation between throwing distance on- water and on dry land, revealed that throwing distance on dry land is effective as a test of performance and for dry land training. The comparison of throwing distance between on- water and on dry land indicates that creating specific techniques for throwing movements on- water will help improve throwing ability. In conclusion, the results of this study suggest that the measurement of throwing distance on- water and on dry land is an effective method for evaluating water polo player's throwing ability.

## INDICATORS OF SUCCESS BY U 18 ICE HOCKEY PLAYERS

GÁBOR, G.

SEMMELEWEIS UNIVERSITY

**INDICATORS OF SUCCESS BY U 18 ICE HOCKEY PLAYERS** Géczi G., Bognár J., Révész L., Benczenleithner O. Semmelweis University, Faculty of Physical Education and Sport Sciences (TF) Introduction Ice hockey is one of the fastest and multifactorial team sport on the world requires players to possess a number of different attributes (Vescovi et al, 2006). The success mainly depends on not only the player efficacy, but more on team efficacy, understanding, communication, cooperation, and team performance and humble (Feltz & Lirgg, 1998). The purpose of our investigation was to analyze and determine motor and psychometric factors which are the most deciding factors to the successful selection of the U 18 National team and to direct the coaches in the practice, that they should force the adequate skills improvement during the youth development program. Methods All players that attended this try out were preselected and sent by club coaches to participate in the study, so altogether 40 U18 players did all the on-ice and off-ice motor tests and filled out all psychometric measures. From the players that participated in this particular study, 20 were U18 National team Selected members (Mage=16,45, SD=,512) and another 20 Non-selected players (Mage=16,62, SD=,50). 19 on ice and off-ice motor tests were processed. Also, Athletic Coping Skills Inventory (ACSI-28), Perceived Motivational Climate in Sport Questionnaire-2 (PMCSQ-2), Sport Motivation Scale (SMS), State-Trait Personality Inventory (STPI-Y). Descriptive data for all variables are described by mean (M) and standard deviation (SD). Data of Selected and Non-selected ice hockey players were statistically compared and Independent T-test was conducted. Also, Stepwise discriminant analysis was used for differentiating motor and psychometric differences between Selected and Non-selected U18 players. Results According to T-test, there were significant differences between Selected and Non-selected U18 players in the following tests: Crossover test with puck, Passing skill drill (sec), 1500 m track, Freedom from worry and Unequal recognition. Discriminant analysis showed that the discriminating factors were in the sample: Unequal recognition, Concentration, Peaking under pressure, BMI, 36 m backward skating, Freedom from worry, Trait depression and Intra-team member rivalry ( $p < .05$ ). Discussion The main findings of the study were to determine the deciding factors to be successfully selected to the U18 National team (Géczi et al, 2008) and also we confirmed the major deciding factors in the youth development programs. ## A DEMOGRAPHIC PROFILE OF COMPETITORS IN THE COLORLINE SETESDAL TOUR 210KM CYCLE COMPETITION IN NORWAY

HØIGAARD, R.1, HAUGEN, T.1, TORSTVEIT, M.K.1, ØVERBY, N.C.1, FJELD, J.B.1, GRAMVIK, P.1, PETERS, D.M.1,2

1: UIA (KRISTIANSAND, NORWAY), 2: UIW (WORCESTER, UK)

**Introduction** Cycling is one of the fastest growing exercise sports in Norway with growing numbers of participants, races and recently extreme cycle events (Wiik, 2010). Whilst reasons why people compete in extreme sports events have been proposed, e.g. health motives, career promotion, self-realization and as a way of men handling midlife crisis, most are anecdotal at best. The aim of this study was to develop a demographic profile of competitors in one of the most popular cycling competitions in Norway, the Colorline Setesdal Tour (CST), and to explore reasons for participation. **Methods** An online questionnaire was sent via email to the 1370 competitors prior to the 210km CST event during which competitors have to climb 980 altitude meters, 600 meters of which are after 150 km. 433 questionnaires were completed representing a 32% participation rate; 92% were male reflecting the gender representation in the event and mean age was 43.6±8.6yrs. Results 60% of the participants were qualified to a higher education level (University); median income was 68400 per annum (Q1, Q3: 55485, 90324); 84% were married / living with their partner, and 80% had two or more children. On average they trained 4 times per week with a mean session time of 2 hours. The median cost for their cycle and cycle equipments was 3225 and they spent around 1100 per year on maintenance of their equipment and membership fees to gyms etc. 80% considered themselves as 'exercisers', not as competitive athletes, yet 76% had set themselves a time goal for the CST. Important motives for participation were the challenge or "just do it" (27%), positive personal and social motives (19%), and motivation for training and health (16%). Furthermore, 19% reported that participation in cycling competitions had positive work related effects, such as increased work performance (61%), increased mental toughness and concentration (24%), and lower sickness absence (21%). 70% reported that cycling affected their family relationships positively while 12% indicated that it had a negative effect. Discussion Participants had a fair income and were well educated. Even though self-described only as 'exercisers', participants invested a great deal of time, effort and money in cycling. They perceived many positive consequences for themselves and their relatives from cycling per se and as a result of training for and participation in this extreme event. From a public health perspective work to engage lower income, younger adults and females in cycling is required if the broader physical, psychological, social and environmental benefits of recreational and semi-competitive cycling are to be realised in Norway. #### MAINTENANCE OF PHYSICAL ACTIVITY AFTER INTERNET-BASED INTERVENTION IN ADOLESCENTS

OKAZAKI, K., OKANO, S., HAGA, S., SEKI, A., SUZUKI, H., TAKAHASHI, K.

WASEDA UNIVERSITY

**INTRODUCTION** We developed an Internet-based physical activity program (i-PAP), which has several interactive functions and e-mail tip sheets that promote physical activity. A four-month intervention showed that participants using the i-PAP increased energy expenditure significantly as compared to the control group (Okazaki et al., 2010). The purpose of this study was to evaluate whether the improvement in physical activity following the completion of the four-month intervention was maintained eight months later. **METHODS** A total of 77 Japanese college students (49 intervention: I-Group, 28 control: C-Group) who responded completely to our scheduled inquiries during the intervention and follow-up were studied. A total of 21 students from the I-Group and 17 from the C-Group were not engaged in regular college sports clubs. Students from the I-group were able to use the i-PAP continuously through the follow-up, whereas neither the e-mails nor the web-quiz was newly uploaded. All students answered the International Physical Activity Questionnaire and the Stages of

Change Scale for physical activity (SCSPA) at baseline, that is, 4 months and 12 months respectively. RESULTS The I-group exhibited significant improvement in the SCSPA ( $\chi^2(2) = 15.9$ ,  $p < 0.05$ ), whereas the C-group did not. Further, those groups that did not belong to regular college sports clubs were compared. Those in the I-Group exhibited a significant increase in energy expenditure ( $F(2, 72) = 3.5$ ,  $p < 0.05$ ) as compared to those in the C-Group. DISCUSSION Some reports show that an internet-based intervention for physical activity resulted in a successful increase in the participants' energy expenditure, whereas few controlled studies on the efficacy of follow-up coupled with such intervention are presently available (Marcus et al., 2009; Ciccolo et al., 2008; Vandelanotte et al., 2007; Norman et al., 2007). The i-PAP would promote physical activity through the follow-up. Particularly, the students who did not engage in regular college sports clubs promoted the physical activity. These results suggested that internet-based interactive intervention like the i-PAP had a long-term efficacy of promoting and maintaining the physical activity after the students completed the course. ## RELATIONSHIP BETWEEN TIME WATCHING TV, COMPUTER USING, ELECTRONIC GAMES, AND TIME PRACTICING PA OF CHILDREN

MARQUES, A., MARTINS, J., SARMENTO, H., MARTINS, M., COSTA, J., ONOFRE, M., CARREIRO DA COSTA, F.

TECHNICAL UNIVERSITY OF LISBON, FACULTY OF HUMAN KINETICS

Introduction: Due to rapid technological and societal changes, opportunities to undertake convenient and attractive sedentary behaviours as part of a contemporary lifestyle are likely to have increased. Objective: The purpose of this study was to examine the relationship between the time spent watching TV, the use of computer, electronic games, and time practicing physical activity (PA) on week days and weekends, according to gender. Methods: A total of 416 boys (age  $10.7 \pm 0.7$ ) and 386 girls ( $10.6 \pm 0.7$ ), age ranged between 10 and 12 years old, participated in the study. Data was collected using a questionnaire used on international research project on children's lifestyles. Pearson's correlations were applied to identify the relationships between the time spent in watching TV, computer usage, playing electronic games, and the time practicing PA on week days and weekends. Significance level was  $p < 0.05$ . Results: On week days, boys spent more hours than girls in PA ( $3.4 \pm 2.1$  vs  $2.8 \pm 1.9$ ), using computer ( $1.8 \pm 1.3$  vs  $1.6 \pm 1.2$ ) and playing electronic games ( $1.9 \pm 1.4$  vs  $1.3 \pm 0.9$ ), and less hours watching TV ( $2.0 \pm 1.4$  vs  $2.1 \pm 1.3$ ). On weekends, the tendency between genders remains whereas the time in PA decreases ( $1.9 \pm 1.4$  vs  $1.8 \pm 1.2$ ) and increases in using computer ( $2.6 \pm 1.7$  vs  $2.4 \pm 1.6$ ), playing electronic games ( $2.6 \pm 1.8$  vs  $1.6 \pm 1.1$ ), and watching TV ( $2.8 \pm 1.7$  vs  $2.9 \pm 1.7$ ). In both genders no significant correlations were established between PA and the others activities on week days. On weekends only a weak but significant negative correlation was found between PA and time spending watching TV for boys ( $r = -0.176$ ,  $p = 0.049$ ). Regarding the correlation between activities in front of a screen during the week days, positive significant correlations were observed between time spent watching TV and computer usage ( $r = 0.281$  boys, girls  $r = 0.370$ ) and playing electronic games ( $r = 0.416$  boys, girls  $r = 0.183$ ). On the weekends the correlation patterns remain, however with a slight increase. Correlation between watching TV and computer usage was  $r = 0.382$  and  $r = 0.433$ , and between watching TV and electronic games was  $r = 0.321$  and  $r = 0.285$  for boys and girls, respectively. Conclusion: Those who were only interested in computer games and TV-watching were the most inactive, although many computer game players were also physically active.

## INDIVIDUAL, FRIEND AND FAMILY-BASED SOCIAL PREDICTORS OF SCREEN VIEWING AMONG SPANISH SCHOOL CHILDREN

HOYOS CILLERO, I., JAGO, R., SEBIRE, S.J.

UNIVERSITY OF THE BASQUE COUNTRY

INDIVIDUAL, FRIEND AND FAMILY-BASED SOCIAL PREDICTORS OF SCREEN VIEWING AMONG SPANISH SCHOOL CHILDREN Hoyos Cillero, I. 1, Jago, R. 2, Sebire, S.J. 2 1: University of the Basque Country (Bilbao, Spain), 2: University of Bristol (Bristol, United Kingdom) Introduction In southern European countries many children exceed suggested screen-viewing guidelines and this is likely to be a risk factor for obesity. Understanding the predictors of screen-viewing may be the first step in designing interventions that target these behaviours, but there is lack of information on predictors of screen-viewing among Spanish children. Therefore, this study aimed to examine associations between individual, friend and family-based social variables and a wide range of screen-viewing behaviours, and how these associations differ by age and gender in a sample of Spanish children. Methods Participants were 247 primary school-aged and 256 secondary school-aged children and their parents from different socio-economic backgrounds. Children reported time spent in screen-viewing and information about individual (self-efficacy and behavioural capability) (Norman et al., 2004) and friend (sedentary group norms and social reasons for sedentary behaviour) (Jago et al., 2009) and family-based social variables (parent rules for screen-viewing). Body Mass Index was assessed and children were classified using International Obesity Task Force cut-off points (Cole et al., 2000). Parents reported sociodemographic characteristics and family co-viewing practices. Statistical analyses: t-test, chi-square and logistic regression models ( $>2$ h/day TV viewing,  $>2$ h/day console playing and  $>2$ h/day overall screen-viewing as outcomes; individual and social factors as exposure variables). Results Older children (TV  $p < 0.001$ ; console  $p < 0.01$ ; overall  $p < 0.001$ ) and males (TV  $p < 0.01$ ; console  $p < 0.001$ ; overall  $p < 0.01$ ) were likely to spend more time screen-viewing. Lower self-efficacy for reducing screen-viewing (console  $p < 0.05$ ; overall  $p < 0.01$ ), stronger sedentary group-norms (TV  $p < 0.001$ ; console  $p < 0.05$ ; overall  $p < 0.05$ ) and stronger social reasons (console  $p < 0.05$ ) were associated with higher screen-viewing in both age groups. For younger children, lower parental rules appeared to be significant predictors for exceeding screen-viewing guidelines while greater co-viewing time was a strong determinant for higher screen-viewing among older children. Discussion Individual and social factors influence children's screen-viewing and operate differently in children of different ages. Increasing self-efficacy may be important for screen-viewing based behaviour changes. Friends and parents play a central role, therefore understanding the dynamics of friends and targeting family influences may be critical to the success of interventions to reduce screen-viewing. ## PHYSIOLOGICAL RESPONSE TO WII SPORTS AND MODIFIED WII SPORTS IN YOUNG ADULTS

MONEDERO, J., MCDONNELL, A., KEOGH, M., O'GORMAN, D.J.

DUBLIN CITY UNIVERSITY

**Introduction** The increasing rates of obesity are partly due to decreased physical activity and increased sedentary behaviours (Kay and Fiatarone, 2006). Innovative approaches are required to reverse these behaviours and increase daily energy expenditure. Interactive video games have become popular in recent years but it is not clear if they provide a sufficient stimulus for health enhancing benefits. The purpose of this study was to determine if a modified interactive video game (modified Wii) would elicit a higher cardiovascular and metabolic response than a traditional stationary (Playstation "Burnout 3") or interactive game (Wii Sport: tennis and boxing). **Methods** A total of thirteen healthy subjects (eight women and five men) volunteered for this study. Maximal aerobic capacity (VO<sub>2</sub>max) was measured using an incremental treadmill test and subjects were familiarised with all games prior to testing. Subjects played each of the games at the same time of day, for 46-minutes, in random order, with at least 2-days between trials. The standard Wii Sport was modified by requiring participants to move across a 2.4m distance between tennis shots and 1.3m diagonally and back during the boxing. During the trials oxygen consumption was measured using a portable metabolic system (Cosmed Ltd, Rome, Italy) and heart rate (HR) was measured by radiotelemetry (Polar, Kempele, Finland). These measures were used to calculate relative oxygen consumption (%VO<sub>2</sub>max), heart rate reserve (HRR), metabolic equivalents (METs) and the rate of energy expenditure (REE). **Results** When playing a traditional sedentary game, the HRR ( $5.39 \pm 1.25\%$ ), %VO<sub>2</sub>max ( $8.6 \pm 0.67\%$ ), MET ( $1.43 \pm 0.05$ ) and REE ( $1.84 \pm 0.09$  kcal/min) were all significantly lower than those of the active games ( $p < 0.01$ ). The modified Wii resulted in a significantly greater oxygen consumption ( $41.2 \pm 2.69\%$  vs  $18.9 \pm 2.65\%$ ), HRR ( $46.63 \pm 3.76\%$  vs  $22.43 \pm 2.89\%$ ,  $p < 0.01$ ), METs ( $6.9 \pm 0.48$  vs  $3.28 \pm 0.28$   $p < 0.01$ ) and REE ( $8.40 \pm 0.83$  vs  $4.11 \pm 0.44$  kcal/min,  $p < 0.01$ ) than the standard Wii Sport game. **Discussion** The main finding of this study was that the modified Wii was the only game to meet the American College of Sports Medicine (ACSM) and American Heart Association (AHA) guidelines to promote and maintain health. While interactive video games can increase cardiovascular and metabolic responses, these games need to be carefully designed to provide a stimulus sufficient to meet the ACSM/AHA recommendations for daily physical activity for healthy adults. **References** Kay, S.J., and Fiatarone Singh, M.A. (2006). *Obes. ## THE NIE INT-HINT TEST – A LABORATORY-BASED PROTOCOL FOR THE ASSESSMENT OF FITNESS IN YOUTH ELITE SOCCER PLAYERS

MUKHERJEE, S., CHIA, Y.H.M.

NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY, SINGAPORE

**THE NIE INT-HINT TEST – A LABORATORY-BASED PROTOCOL FOR THE ASSESSMENT OF FITNESS IN YOUTH ELITE SOCCER PLAYERS** Mukherjee, S. & Chia, YHM National Institute of Education Nanyang Technological University Singapore **Introduction** The overall activity pattern of soccer is that of intermittent high-intensity (Int-HINT) type and higher-level players have a greater repeated high-intensity running capability. Therefore, the aim of this study was to develop a laboratory-based protocol on the motorized-treadmill to specifically assess the Int-HINT running capability in youth elite soccer players. **Methods** Twenty youth elite soccer players (mean  $\pm$  SD age,  $17.5 \pm 0.3$  yrs; stature,  $1.73 \pm 0.04$  m; body mass,  $67.2 \pm 7.5$  kg) performed on the laboratory-based test of Int-HINT running on motorized treadmill during the pre-season, early in-season and end mid-season phases of the soccer season. Briefly, the Int-HINT test has alternate periods of high-speed running starting from  $13 \text{ km} \cdot \text{h}^{-1}$  for 12 s and low-speed recovery periods at  $9 \text{ km} \cdot \text{h}^{-1}$  for 8 s. Running speed increased by  $1 \text{ km} \cdot \text{h}^{-1}$  after six alternate repetitions with the recovery run. Performance was measured as total distance covered on the treadmill. The participants also performed the YoYo Intermittent Recovery Test Level 2 and the match play work intensity was also determined using heart rate monitoring for two matches during each phase of the competition season. **Results** The reliability of the Int-HINT test was established during pilot studies ( $n=14$ ; ICC, 0.98; 95% CL, 0.93 – 0.99; CV, 2.1%; 95% CL, 1.4 – 4.4%; ratio limits of agreement (rLOA)  $0.99 \times / \div 1.03$ ). The players covered (Mean  $\pm$  SD)  $2799 \pm 585$ ,  $3084 \pm 636$  and  $3038 \pm 797$  m respectively on the Int-HINT test during the three phases of the season. A positive and significant correlation ( $p < 0.05$ ) was consistently found between the performance in the Int-HINT test and the YoYo IRT L2 performance ( $r = 0.74-0.81$ ) and also with the amount of high-intensity work (HR  $> 90\%$  of HR<sub>max</sub>) performed during soccer matches ( $r = 0.72-0.82$ ). **Discussion** This study supported the understanding that repeated high-intensity running capability in soccer players changes through the season and that the NIE Int-HINT test was sensitive to these changes. Furthermore, the consistently significant correlation of this test performance with the YoYo IRT L2 and the match play work intensity strongly supported the criterion validity of the Int-HINT test with respect to assessment of repeated high-intensity running capability and to evaluate match-related physical capacity in youth elite soccer players. Moreover, the Int-HINT test being a laboratory-based protocol provides the option of measuring the physiological responses to intermittent exercise that might not be feasible during the field-based assessments. More studies are needed to evaluate the applicability of this test in adult elite players and other soccer populations.

## EFFECTS OF ASTAXANTHIN SUPPLEMENTATION ON CHANGE IN ACNE CONDITION IN YOUNG ELITE SOCCER PLAYERS

RADIOJEVIC, N.1, DIKIC, N.1, BARALIC, I.2, DJORDJEVIC, B.2, ANDJELKOVIC, M.1, VUJIC, S.1

1:SPORTS MEDICINE ASSOCIATION OF SERBIA-OUTPATIENT CLINIC VITA MAXIMA (BELGRADE, SERBIA), 2:INSTITUTE FOR BROMATOLOGY, FACULTY OF PHARMACY, UNIVERSITY OF BELGRADE (BELGRADE, SERBIA)

**Introduction** The skin is the organ that is most exposed to the effects of environmental factors and parameters of oxidative stress. Physical activity and specificity of soccer make effects on the skin much more pronounced. Astaxanthin (Asx), a red carotenoid pigment, is a biological antioxidant that occurs naturally in a wide variety of living organisms. The aim of this study was to determine the effects of Asx supplementation on young elite soccer players skin. **Methods** Sixty healthy young soccer players have participated in double blind placebo controlled study during three months that monitored effects of Asx supplementation on sports performance. Of that number, 17 athletes (age  $17.5 \pm 0.5$ ) have had skin problems (8 Asx group, 9 P group). The intervention group received 4 mg Asx capsules daily. We monitored skin changes of 17 athletes using Grading Scale for Comedones, Papules and Macules (GS-CPM) and Grading Scale for Overall Severity (GS-OS). Before starting the dietary supplementation, baseline of skin changes for each of the subjects were obtained. Changes in acne condition were graded after 45 and 90 days of supplementation. All athletes were photographed in accordance to recommended standards (Cook et al, 1979). **Results** Any significant changes in acne condition between groups were not observed among the grade values after 45 and 90 days of administration period. In Asx group, there was significant improvement ( $p < 0.05$ ) in GS-OS after 90 days of supplementation (mean stage value  $1.7/1.2$ ). Also, there was significant improvement ( $p < 0.05$ ) in GS-CPM after 45 days of supplementation (mean stage value  $2.1/1.5$ ) and after 90 days of supplementation ( $2.1/1.4$ ). There were no significant changes in

P group. Discussion The present study suggests that Astaxanthin may have beneficial effect on acne condition in young athletes. Limitation of this research was a small number of participants with skin disorders. Larger studies are necessary in order to evaluate a mechanism of Astaxanthin improvement on skin condition. References Cook C., et al. (1979). Arch Dermatol-Vol. 115.

### PHYSICAL ACTIVITY AND PSYCHOSOCIAL ASPECTS AT WORK IN FLEMISH SECONDARY SCHOOL TEACHERS

BOGAERT, I., ZINZEN, E., DE MARTELAER, K., DEFORCHE, B., CLARYS, P.

*VRUE UNIVERSITEIT BRUSSEL*

Physical activity and psychosocial aspects at work in Flemish secondary school teachers Bogaert, I.I, Zinzen, E.I, De Martelaer, K.I, Deforche, B.2, Clarys, P.2 1 VUB, Movement and Sportstraining, Brussels, Belgium 2 VUB, Human Biometry and Biomechanics, Brussels, Belgium Introduction: Current research indicates an increased rate of absenteeism amongst teachers due to psychological problems. Regular physical activity (PA) is believed to improve physical and mental health. The purpose of this study is to examine PA levels of Flemish secondary school teachers and possibly related psychosocial aspects at work (PAW): job satisfaction(JS), social support(SS) and mental stress(MS). Methods: Moderate-to-vigorous PA (MVPA) measured by the International Physical Activity Questionnaire (IPAQ), PAW and demographics were collected by means of an online survey in a representative sample of teachers (n=413, age 39.6±9.7 years, 69% female). Independent samples t-tests and correlation analyses were performed. Results: Over 60% of the teachers met the current PA guidelines. Male teachers (72.7±61.0 min/dayMVPA) were more active than their female colleagues (57.4±51.3 min/dayMVPA; p<.05), especially during leisure time. The amount of MVPA was not related to age or absenteeism at work, nor to PAW scores. Teachers showed high PAW scores (JS=79.3±16.5; SS=81.7±14.7; MS=81.5±12.3) on a 0-100 scale. Teachers on sick leave for more than 7 days/year had a significantly lower JS (74.3±7.1; p<.05) and show tendency towards higher MS (84.5±13.5; p=0.056) compared to the lower absence group (JS=80.4±15.4; MS=81.0±12). Female teachers were more satisfied (80.4±16.3) and had a more positive perception of SS (83.8±14) at work than the male teachers (JS=76.7±17; SS=77.1±15.5; p<.05). Females' MS was higher (82.7±12.2) than males' (79.0±12.5; p<.05). Discussion: The majority of teachers had a physically active lifestyle (PALS) and high psychosocial scores. Gender-related differences occurred for both MVPA and PAW scores. However, a more PALS was not related to better psychosocial aspects at work.

### SEDENTARY BEHAVIOR IN PORTUGUESE YOUTH: THE SEASONALITY EFFECT.

SILVA, P., SANTOS, R., VALE, S., MARTINS, C., AIRES, L., MOTA, J.

*FACULTY OF SPORT - UNIVERSITY OF PORTO*

Introduction Sedentary behavior (SB) is directly associated with a greater risk of death from cardiovascular problems, cancer and all causes. Moreover, SB is directly associated with obesity in children. This study examined whether there was a significant seasonal variation in objectively measured SB in Portuguese youth across five months of data collection. Methods A total of 344 participants (aged 14.7 ± 2.04), 196 girls and 148 boys, were assessed in five months. SB was assessed with the Actigraph GT1M accelerometer for 7 consecutive days (15 seconds epochs). Gender patterns of SB were assessed for 5 distinct month periods: February; March; April; May; June. The difference in the amount of SB was assessed with a gender-by-month comparison using a ANOVA. Results Participation in SB varied by gender and month of assessment. The ANOVA for SB revealed significant main effects for Gender (F= 22.62 p<.001), Month (F= 7.34 p<.001), and Gender\*Month (F= 2.51 p<.042). Girls were significantly more sedentary (minutes) than boys in these months: 3) 689.49 vs 651.37 (p<.006); 4) 670.86 vs 625.55 (p<.019); 6) 656.89 vs 564.76 (p<.001). In both genders SB decreased from winter to spring, but more marked in boys. Discussion The weather or sunlight exposure cannot be changed, but knowledge of how weather conditions affect youth SB can help to adapt recommendations to diminish its effects. The seasonal patterns suggest that interventions must be modified during different seasons of the year, to specifically decrease SB in winter months.

### PEDOMETER DETERMINED PHYSICAL ACTIVITY, BMI, AND TV-WATCHING BEHAVIOR IN PRESCHOOLERS

KAMBAS, A., MICHALOPOULOU, M., GIANNAKIDOU, D., AVLONITI, A., HABERER, E., AGGELOUSSIS, N., VENETSANO, F., FATOUROS, I., ZIMMER, R.

*DEMOCRITOS UNIVERSITY OF THRACE, UNIVERSITY OF OSNABRUECK*

Introduction Nowadays, there is a widespread belief that preschool children are not active enough (Kelly et. al. 2005) and that the amount of physical activity has been decreasing as the opportunities for pleasurable sedentary activities have increased. High levels of physical activity for preschool children can delay the assault of a critical period of adiposity rebound, after the age of six (Moore et al., 2003). The purpose of the current study was to examine the association between pedometer determined PA, BMI, and TV-watching in preschool children. Methods The sample consisted of 1560 preschoolers (783 boys and 777 girls), aged 48 to 79 months (Mean=60.63, SD=7.03 months). PA was assessed for 7 consecutive days using an OMRON HJ-720IT-E2 pedometer, while hours of TV-watching were recorded using a parental questionnaire-diary. Results One-way ANOVA was utilized to detect group differences. When BMI was used as an independent factor, statistical analysis revealed significant effect in steps×week-1 (p<.05) and in km×week-1 (p<.005) but not in hours of TV-watching×week-1. Bonferroni post-hoc analysis showed that "normal" children differed from the "overweight-obese" children in nr. steps×week-1 (p<.05) and in km×week-1 (p<.005). The results of the ANOVA using TV-watching as independent factor revealed statistically significant effect in steps×week-1 (F=5.23, p<.05) and in km×week-1 (F=5.42, p<.05). Children "watching" TV less than 4 hours×week-1 had significantly more steps×week-1 (p<.05) and km×week-1 (p<.05) compared with children watching more than eight hours×week-1. Discussion In contrast with other study (Janz et. Al., 2002), BMI was found to have a significant effect on PA of preschoolers. Additionally, TV-watching appeared to be contributing to low levels of pedometer determined PA. Present findings showed that TV watching was associated with low activity levels but not with BMI. ## PHYSICAL ACTIVITY BENEFITS, HARM OF SEDENTARY BEHAVIOUR AND ACTIVITY GUIDELINES FOR TODDLERS – WHAT DO MOTHERS KNOW?

COSTA, S., CLEMES, S., BARBER, S., AKHTAR, S., VARELA-SILVA, M.I., GRIFFITHS, P., CAMERON, N.

LOUGHBOROUGH UNIVERSITY

PHYSICAL ACTIVITY BENEFITS, HARM OF SEDENTARY BEHAVIOUR AND ACTIVITY GUIDELINES FOR TODDLERS – WHAT DO MOTHERS KNOW? Costa S.1, Clemes S.1, Barber S.2, Akhtar S.2, Varela-Silva M.I.1, Griffiths P.1, Cameron N.1 1: Loughborough University (UK), 2: Born in Bradford Cohort Study (UK) Introduction Childhood obesity is a worldwide public health problem. Regular physical activity (PA) is protective against various chronic diseases, while time spent in sedentary behaviour (SB) is considered an independent risk factor for many illnesses. UK South Asians (SA) are at higher risk for several chronic diseases (Forouhi & Sattar, 2006). However, SA are reported to lead a sedentary lifestyle (Forouhi & Sattar, 2006), and SA women have reported lack of knowledge about the health benefits of PA, and the appropriate type or level of PA needed (Srisantharajah & Kai, 2007). The preschool age is considered a key period of life for the establishment of lifestyle behaviours such as PA and SB, for which parents are regarded as the most important influence (Oliver et al, 2009). Guidelines for PA and TV viewing time have been published, but parents' knowledge on this has not yet been assessed. The aim of this research was to assess mothers' knowledge about the health benefits and harms of PA and excessive SB, and the guidelines for PA and TV viewing for toddlers, in an ongoing study of a bi-ethnic population from Bradford. Methods Five focus groups (N= 3 to 6 per group) were conducted to date with White and Pakistani mothers of 2-3 year olds, at Children's Centres. The focus groups were conducted in English or Urdu. Audio recordings were transcribed verbatim and analysed following a Thematic Analysis approach. Results All mothers recognized PA as important to keep healthy. White mothers cited specific health benefits, such as good circulation, or keeps weight low, while Pakistani mothers cited the general concept of its importance for a healthy body. Furthermore, doing too much was recognized as detrimental for health. Feeling lazy and obesity were commonly identified harms of SB. However, half of the mothers also recognized sitting for long periods of time as beneficial, to have a rest. No mothers had knowledge about existing recommendations for PA and TV viewing time. Discussion Although all mothers recognized PA as an important healthy habit, Pakistanis in this sample did not express knowledge of specific health benefits of regular PA. Half of the mothers associated excessive SB with obesity. However, guidelines about PA and TV viewing for toddlers need to be disseminated more effectively to enable mothers to regulate these behaviours and actively have the information to intervene to form healthy activity habits and reduce the risk of their child becoming obese. ## PHYSICAL ACTIVITY DURING SCHOOL RECESS

ESCALANTE, Y.1, BACKX, K.2, SAAVEDRA, J.M.1, GARCIA-HERMOSO, A.1, DOMINGUEZ, A.M.1

UNIVERSIDAD DE EXTREMADURA

Escalante, Y.1, Backx, K.2, Saavedra, J.M.1, Garcia-Hermoso, A.1, Dominguez, A.M.1 1: Facultad de Ciencias del Deporte. AFIDES Research Group, Universidad de Extremadura (Caceres, Spain), 2: Cardiff School of Sport. University of Wales Institute (Cardiff, United Kingdom) Introduction One appropriate and convenient setting for the promotion of PA is the school environment because the children spend a large portion of their day in school (Van Sluijs et al., 2007) Physical education and recess provides the two main opportunities for school-based PA (Naylor et al., 2009). Therefore, the aim of this study was to describe the sex specific daily and school recess physical activity of primary school children aged 6 to 11. Methods 783 children (379 boys and 359 girls; age=8.5±1.7 years) participated in the study. Daily PA of each child was measured using a validated questionnaire (Cale, 1994) that was completed by the parents of each child, whilst playground recess PA was measured using uni-axial accelerometer. Results Boys reported higher daily PA levels than girls across all age groups ( $p < 0.001$ ). Measured recess PA was higher for boys compared to girls from the ages of 9 to 11 years. Across age group, higher level of daily PA level were reported by children aged ten compared to those aged six and eight. In contrast the PA measured during recess revealed a higher level count in eight-year olds compared to eleven-year olds. Boys were more active than girls on both measures of PsA (METs  $48.4 \pm 8.0$  versus  $43.8 \pm 7.1$ ,  $p < .001$ ; Counts  $28.0 \pm 11.6$  versus  $23.7 \pm 10.4$ ,  $p < .001$  respectively). Discussion The results showed that boys were more active than girls overall, as well as within each age group (Kimm et al., 2000). The major difference in age was observed at 8 years, where boys reported participating in 16% more daily PA than girls, these results are similar other study. No differences were found in reported PA or measured recess PA across age groups in boys. This finding is in contrast to studies that indicate that after age 9 to 10 a reduction in PA takes place in boys (Troiano et al., 2008). These data provide greater understanding of sex- and age-specific PA patterns and the relative contribution of daily and recess PA in primary school children References Cale L. (1994). *Health Educ J*, 53, 439-453. Kimm SY, Glynn NW, Kriska AM, et al (2000). *Med Sci Sports Exerc*, 32, 1445-1454. Naylor PJ, McKay HA (2009). *Br J Sports Med*, 43, 10-13. ## EFFECT OF PULSED ELECTROMAGNETIC FIELD EXPOSURE PROCEDURES ON MORPHOLOGICAL, BIOCHEMICAL AND IMMUNOLOGICAL INDICES OF ATHLETES' BLOOD

MILASIUS, K., DADELIENE, R., RASLANAS, A., TUBELIS, L.

VILNIUS PEDAGOGICAL UNIVERSITY

Introduction In high performance athletes training, procedures of pulsed EM fields have been started to apply quite recently. It was found that pulsed EM field stimulates aerobic metabolism, enhances the recovery processes after high volume physical loads (Nieman et al., 2000; Kafka, Spodaryk, 2003; Lewis, 2003; Maffiuletti, 2006; Gazurek, Spodaryk, 2008). However, there is a shortage of studies on the efficacy of the application of define intensity pulsed EM in the dynamics of blood morphological, biochemical and immunological indices. Aim of the study was to research the effect of the 14-days-long application of procedures using pulsed electromagnetic field emitting

apparatus BEMER-3000 on the dynamics of some morphological, biochemical and cellular immunological indices of blood in physically active young men's aged 20-21 years. Methods The experimental (E) and control (C) groups comprised 14 healthy, physically active men aged 20-21 years (PE students). Testees from group E for 14 days were exposed to dosed electromagnetic fields emitted by BEMER-3000. Members of the C group were lying on a turned-off mat for the same time. Before, after the 14 days application of the BEMER-3000 and in after the next 2 weeks we have taken venous blood sample and conducted measurements to establish morphological and biochemical composition of the blood, indices of immune state of the blood. Results Positive changes were noticed in leukocyte formula. While leukocyte count decreased, percentage of monocytes increased statistically reliably, and increase of lymphocytes count was not reliable statistically. Increase of granulocytes count also was not statistically reliable. Under the effect of pulsed EM field, cholesterol concentration decreased in blood of testees. After the pulsed EM field procedures of 14 days duration, count of lymphocyte subtypes characteristic for immune response, especially CD3+ (T lymphocytes) and CD19+ (B lymphocytes) had tendency to increase. Due to BEMER-3000 therapy, response of lymphocytes increase when stimulating with mitogene phytolac (PWM), that was statistically reliable and may be considered as quite active. Changes in organism, occurring due to the application of pulsed electromagnetic waves, almost completely disappear in following two weeks. References Gazurek D, Spodaryk K. ## MODULATION OF NON-RECIPROCAL INHIBITION AT VOLUNTARY MUSCLE CONTRACTION IN TEENAGERS AND YOUTHS

CHELNOKOV, A.

*VELIKIYE LUKI STATE ACADEMY OF PHYSICAL EDUCATION AND SPORTS*

The purpose of our research was to study non-reciprocal inhibition (NI) of spinal  $\alpha$ -motoneurons in regulation of a voluntary muscle contraction in teenagers and youths. Methods 14-15 (n=10) and 17-18 year-old teenagers (n=10) took part in the research. NI spinal  $\alpha$ -motoneurons was evaluated according to the degree suppression of a testing m. soleus H-reflex amplitude in conditioning stimulation of afferents m. gastrocnemius med. (Pierrot-Deseilligny, 1979) in rest, during and after static effort. The lower the m. soleus H-reflex suppression is, the stronger is the NI. The interval between the conditioning and testing stimuli in 14-15 year-old teenagers was 1 ms, and in 17-18 year-old teenagers it was 6 ms. The subjects performed a isometric muscle contraction (plantar flexion) with a 5% and 25% of maximal voluntary contraction (IVN) effort within 2 minutes in a sitting position in the dynamographic system Biodex (Biodex Medical System, USA). Results In the relative muscular rest condition NI is more intense in 14-15 year-old teenagers (64%), than in 17-18 year-old teenagers (83,50%). During a static 5% of MVC effort NI was practically identical in 17-18 year-old teenagers (74,92%) and in 14-15 year-old teenagers (75,11%). At 25 % of MVC in 14-15 year-old teenagers NI was 63,62%, and in 17-18 year-old teenagers it made 125,09 %, i.e. it was non-reciprocal excitation. After the static 5% and 25% of MVC effort NI is more intense in 14-15 year-old teenagers, (57,29% and 21,45%, correspondingly), than in 17-18 year-old teenagers (70,17% and 74,31%, correspondingly). Discussion The presented changes of NI of  $\alpha$ -motoneurons at the spinal level specify structural change of neuromuscular systems functional condition in a critical ontogenesis period of the human. The teen age is characterized by intensifying of NI in rest, during and after a voluntary muscle contraction, and the youth age characteristics is weakening of NI in the same conditions. According to Stephens, Yang (1996) the decrease of NI can be caused by of m. triceps surae activation, that also took place at plantar flexion performance in our research. According to Pierrot-Deseilligny et al. (1982) and Gossard et al. (1994), a presynaptic component seems to influence reduction of NI during strong voluntary muscle contractions as the current data about of presynaptic inhibition afferents Ib (Lafleur et al., 1992). In our opinion, the difference of the NI intensity in teenagers and youth can be connected with morfofunctional spinal and supraspinal interneural pathways maturation, heterochronism interior cortex structures development and the endocrine system central section activities. ## FURTHER STUDY OF THE RELATION BETWEEN MUSCLE HARDNESS AND MECHANOMYOGRAM FINDINGS DURING VOLUNTARY ISOMETRIC CONTRACTIONS

MURAYAMA, M.1, HONDA, N.2, UCHIYAMA, T.2, YONEDA, T.3

*1:KEIO UNIVERSITY, 2:KEIO UNIVERSITY, 3: JUNTENDO UNIVERSITY*

Introduction: Recently, we have developed a contact-type muscle hardness meter by using an ultra-slim pressure sensor that is capable of continuously assessing changes in muscle hardness (Murayama et al.; 2009, 2010). Muscle hardness is a valuable index of muscle conditioning. In our previous study, the muscle hardness determined using our contact-type device was linearly related to the isometric force level. Additionally, mechanomyogram (MMG), which reflects the intrinsic mechanical activity of the contracting muscle, is also a non-invasive tool used to investigate muscle activity. In the present study, we further examined the relation between muscle hardness and MMG at various muscle contraction levels to understand the utility of muscle hardness as a parameter of muscle mechanics. Methods: The contact-type muscle hardness meter and an accelerometer were placed 2 cm apart on the rectus femoris muscle. The hardness meter was wound to the muscle belly using an adhesive non-elastic surgical tape. The accelerometer was attached to the skin using a double-side adhesive tape. The subjects performed ramp and stepwise isometric knee extensions from 20% to 90% maximal voluntary contraction (MVC). The recording of MMG was rectified and integrated during the contraction period (hereafter, integrated MMG (IMMG)). The mean power frequency (MPF) of MMG was calculated using the fast-Fourier transform method. Results: Muscle hardness increased up to 90% MVC in both ramp and stepwise conditions. However, in the ramp condition, the slope of the regression equation between muscle hardness and %MVC was gentler than that in the stepwise condition. IMMG increased up to 60% MVC and decreased thereafter. MPF of MMG increased up to 90% MVC. Discussion: IMMG increased with an increase in motor unit recruitment but decreased at high contraction levels of isometric force because of the fusion-like mechanical activity of the motor units. The increase in the MPF of MMG can be attributed to an increase in the firing rate of motor units. Ebersole et al. (1999) suggested that a decrease in MMG above 80% MVC could be associated with changes in the intramuscular pressure and muscle stiffness, i.e. the number of attached cross-bridges. The increase in muscle hardness might also be associated with these changes. Therefore, high levels of muscle hardness may lead to a decrease in the MMG amplitude by restricting muscle fibre oscillation. References Ebersole KT et al. ## FLUTTER KICK SWIMMING VELOCITY IS RELATED TO ISOKINETIC KNEE MUSCLE STRENGTH BUT NOT TO ISOKINETIC TRUNK MUSCLE STRENGTH IN ELITE MALE UNDERWATER HOCKEY PLAYERS

OZGIDER, C., KORKUSUZ, F., OZDEMIR, R.A., SALCI, Y., CUG, M., ARTUT, V.

CANAKKALE ONSEKIZ MART UNIVERSITY, MIDDLE EAST TECHNICAL UNIVERSITY

**Introduction** Underwater hockey is a developing team sport that is played in more than 20 countries on six continents. It has improved and became a very fast-paced dynamic game with strict rules and regulations (Collopy, 1998). Strength for the underwater swimming is generally produced by the lower extremities and swimming fins supply speed and efficiency (Neuhaus et al., 2004). In order to cope with the resistance of the fin, the diver should have adequate leg strength and power (Pendergast et al., 2003). Thus, the purpose of this study was to examine whether swimming performance of participants were differ based on their isokinetic strength scores. **Methods** Twelve elite male underwater hockey players participated in this study. Their isokinetic leg and trunk muscle strength were measured by the Biodex System 3 Pro Isokinetic Dynamometer (Biodex Medical Inc, Shirley, NY) at three different angular speeds for knee (60°/s, 180°/s and 360°/s) and at two angular speeds for trunk (60°/s and 120°/s). Moreover, participants' underwater swimming velocity was measured in a pool. Participants were encouraged to swim 25 m in underwater three times by holding their breath with flutter kicking style at their maximal velocity. Data was collected by three electronic stopwatches. **Results** Findings of this study stated that 360deg/s measurements revealed significant differences. Participants who have higher peak torque/body weight scores (high group) on dominant knee extension, dominant knee flexion and non-dominant knee extension, are significantly faster swimming performance than those who have lower scores on isokinetic knee strength at 360deg/s. **Discussion** The present findings have some implications for further investigations. Firstly, the results seem to suggest that isokinetic knee strength is more critical than isokinetic trunk strength for underwater swimming performance. Secondly, the results also indicated that rather than maximal isokinetic knee strength, explosive isokinetic knee strength is more important for underwater swimming performance. The latter conclusion was based on the present findings that although swimming performance did not change significantly according to participants' maximal strength values measured at 60deg/s (Carus et al. 2009), participants who have higher explosive knee strength measured at 360deg/s (Dvir, 2004) have significantly faster swimming performance than those who have lower explosive knee power. **References** Davis, F., Graves, M., Guy, J., Prisk, K., Tanner, T., (1987). ## EFFECTS OF HANDGRIP FORCE GENERATION ON THE MAXIMUM ISOMETRIC KNEE EXTENSION

YAMAUCHI, J.1,2, KAWADA, S.2,3

1: TOKYO METROPOLITAN UNIVERSITY, 2: FUTURE INSTITUTE FOR SPORT SCIENCES, 3: THE UNIVERSITY OF TOKYO

**[Introduction]** Many activities are performed using both hands and legs in multi-dimensional movements. The integration of muscle activities in the extremities with those in trunk muscles is often required for activities of everyday life and better performance in sports. This believes to be an effective way to stabilize body trunk and to generate larger force in the movements by transferring energy through each joint of extremities. However, despite requiring the integrity of extremities in daily activity, there are only few researches on the study of the integration of extremities on the muscle force generating capacity. The present study investigated the effects of handgrip force generation on the maximum isometric knee extension. **[Methods]** Thirty-eight healthy young individuals (mean $\pm$ S.D.; age, 20.6 $\pm$ 0.8 yr; height, 162.4 $\pm$ 7.8 cm; weight, 55.8 $\pm$ 9.3 kg) participated in this study. In experiment I, maximum isometric knee extension force of the right leg was measured at six different knee angles (90, 110, 130, 150, 170°) with the knee extension dynamometer. During the measurements, subjects placed their arms in front of their chest. Separately, maximum isometric handgrip force of the right and left hand together was measured with a handgrip dynamometer. In experiment II, based on the knee joint angle-force relation in the knee extension movement determined in experiment I, the knee joint angle at optimum force was applied to obtain the maximum isometric knee extension force with the maximum handgrip force. For MVC measurement, subjects exerted maximum force for ~3 seconds. Measurements were repeated three times with at least one-minute rest period between bouts, and the mean value among the measurements was calculated for MVC. Data are presented as mean $\pm$ SD. **[Results]** In experiment I, the knee joint angle-force relation in the knee extension movement was determined. The isometric force exhibited a peak when the knee joint was flexed at 110 degree on average. Based on this result, the joint angle at 110 degree was set for the measurement in experiment II. In experiment II, the maximum isometric knee extension force with the maximum handgrip significantly increased when compared with the maximum isometric knee extension force alone, and these represent 172.47 $\pm$ 57.47 Nm and 151.23 $\pm$ 52.68 Nm ( $p$ <0.001), respectively; however, the maximum handgrip force did not significantly different between the maximum handgrip force together with the maximum isometric knee extension and the maximum handgrip force alone, and these represent 56.82 $\pm$ 19.47 kg and 60.45 $\pm$ 17.74 kg ( $p$ >0.05), respectively. **[Discussion]** The results indicate that the leg muscle force generation integrated with hand force generation is effective to elevate the leg muscle force generation. The mechanism underlying this new phenomenon is not fully understood, but this can be speculated with the stabilizing the trunk through force generation of upper limbs and hands.

## RESPIRATORY KINETICS FOLLOWING CONCENTRIC-ECCENTRIC ISOKINETIC ARM AND LEG EXERCISE

MOOKERJEE, S.1, DRESCHER, U.2, STEEGMANN, A.2, KNICKER, A.2, HOFFMANN, U.2

1 BLOOMSBURG UNIVERSITY OF PENNSYLVANIA, USA, 2 GERMAN SPORT UNIVERSITY, COLOGNE, GERMANY

**Introduction** Assessments of dynamic changes in recovery respiratory kinetics following resistance exercise can provide information on the control and regulation of O<sub>2</sub> transport and utilization. The purpose of this study was to evaluate the effects of intensity and muscle mass on changes in respiratory and metabolic variables during recovery following concentric-eccentric, isokinetic exercise. **Methods** Fourteen healthy male subjects aged 26.9 $\pm$ 3.1 years, performed a 20-repetition isokinetic (combined, concentric and eccentric) arm or leg exercise protocol at 60 °sec<sup>-1</sup>, 150 °sec<sup>-1</sup>, and 240 °sec<sup>-1</sup>, in randomized order. Recovery (150 seconds) breath-by-breath gas exchange data were recorded to determine post-exercise half- time (t<sub>1/2</sub>) for V'O<sub>2</sub>, V'CO<sub>2</sub>, and V'E denoted as the time taken to reach 50% from maximum to resting. Three-way repeated measures ANOVA was used to determine the effect of parameter, exercise intensity and muscle mass, as well as Pearson's r, in combination with a t-test. **Results** The time course of V'O<sub>2</sub>, V'CO<sub>2</sub> and V'E showed a steep increase within the first 10 seconds of recovery. The V'O<sub>2</sub> at 150 °sec<sup>-1</sup> and 240 °sec<sup>-1</sup> velocities following leg exercise, exhibited a second wave with a peak around 20 seconds. V'E declined steeply followed by a slower phase to recovery. Both parameter and exercise intensity

significantly impacted the  $\dot{V}O_2$ . Integrated recovery  $\dot{V}O_2$  was significantly correlated with work intensity (arm:  $r=0.42$ ,  $p<0.05$ ; leg:  $r=0.62$ ,  $p<0.05$ ). Discussion These results indicate that  $\dot{V}E$  is decoupled from  $\dot{V}O_2$  after the initial first 10 seconds of recovery. Even the typical ranking of kinetics with  $\dot{V}O_2$  exhibiting the fastest change and  $\dot{V}E$  as the slowest parameter, cannot be supported in general here. The second increase or stagnation of  $\dot{V}O_2$  indicates the delayed arrival of venous blood from the exercising muscles. This phenomenon can also explain the trend toward a higher  $\dot{V}O_2$  for leg exercise, even though this finding was not statistically significant.

### THE EFFECTS OF WEARING AN UPPER BODY COMPRESSION GARMENT ON MAXIMAL UPPER BODY PERFORMANCE

MILLER, S.C., BARKER, N., TURNER, A.N.

MIDDLESEX UNIVERSITY

**Introduction** Improved performances in lower body activities, whilst wearing compression garments (CG), have been noted in high force/power actions such as jumping (Doan et al., 2003) and sprinting (Higgins et al., 2009). Duffield and Portus (2007) assessed upper body performance whilst wearing full body CG on a cricket ball throw, however no difference was found. Due to the mass of the cricket ball, the performance assessed was at the high velocity end of the force-velocity relationship. Therefore, the aim of this study was to assess whether wearing an upper body compression garment improves a high force action of the upper body. **Methods** Ten male participants (age  $24.2 \pm 6.2$  years, mass =  $77.8 \pm 12.9$  kg, height =  $176.7 \pm 8.8$  cm;  $\mu \pm SD$ ) performed a one-repetition maximum (1RM; Beachle and Earle, 2008) protocol on two separate days (counter-balanced), with and without wearing a commercially available upper body CG. Participants were experienced in weight training and had a minimum of three months experience with the bench press exercise; all participants could bench press their own body mass. **Results** There was a significant increase of  $1.79 \pm 1.75\%$  ( $\mu \pm SD$ ; effect size =  $1.04 \pm 0.93$ ;  $\mu \pm 95\%$  confidence interval) on the participants' 1RM bench press when performed wearing a compression garment (control,  $95.75 \pm 14.24$  kg; compression,  $97.5 \pm 14.94$  kg;  $p < 0.05$ ). Importantly, no participants scored lower whilst wearing the compression garment. **Discussion** Through wearing a commercially available upper body CG, we have shown a small increase in the 1RM bench press. Increased joint stiffness (Doan et al., 2003; Brughelli and Cronin, 2008) and muscle temperature (Duffield and Portus 2007; Racinais and Oksa, 2010) are potential explanations for the increased performance. Further testing is required which looks more at the underlying mechanisms that could cause the increase in high force and power actions. **References** Doan BK, Kwon YH, Newton RU, Shim J, Popper EM, Rogers RA, Bolt LR, Robertson M, Kraemer WJ. ### THE EFFECT OF THE BENCH PRESS GRIP ON THE UPPER BODY MUSCLE ACTIVITY IN THE BENCH PRESS

LEE, H.J.1, PARK, H.H.2, PARK, K.S.1, JEON, C.B.1, KWAK, H.M.1, JEON, I.S.1, KIM, J.H.1

1: UNIVERSITY OF ULSAN, KOREA, 2: YONSEI UNIVERSITY, KOREA

The purpose of this study was to investigate the effect of varying bench press grip on the ECG activity of the upper body muscle during bench press exercise. Twelve male students ( $22.5 \pm 2.7$  yrs) were participated. To assess the electromyography of selected muscles, surface electrodes were attached to pectoralis majors, trapezius, front deltoid and triceps brachii. IEMG (Integral EMG) and NEMG (Normalization EMG) were measured for each muscles. For each variable, one-way repeated ANOVA was used to determine whether these were significant difference among three grips bench press. From the above experiment, this study analyzed muscle activity and participations in wide grip (WD), normal grip (NM), narrow grip (NR) during bench press. When a significant difference was found in three grip bench press, post hoc analysis was performed using Turkey procedure. Significant level was .05. IEMG of triceps brachii muscle was significantly affected depending on the change of bench press grip (WD  $35.42 \pm 9.25\%$  vs NM  $52.68 \pm 11.02\%$ ,  $p < .05$ ). NEMG of pectoralis major was significantly different between WD and NM & NR ( $30.91 \pm 6.93\%$  vs  $17.61 \pm 3.75\%$  &  $15.56 \pm 5.53\%$ ,  $p < .05$ ). NEMG of trapezius was significantly different between WD and NM ( $3.63 \pm 1.21\%$  vs  $10.86 \pm 2.23\%$ ,  $p < .05$ ). NEMG of triceps brachii was significantly different between WD and NM ( $28.17 \pm 4.36\%$  vs  $40.97 \pm 7.53\%$ ,  $p < .05$ ). Conclusively, pectoralis major muscle activity reduced as a grip narrow. And muscle activity of trapezius and tricep brachii increased as a grip narrow.

### NEUROMUSCULAR ADJUSTMENTS TO REPEATED CYCLING SPRINTS

BISHOP, D., GIRARD, O., RACINAIS, S.

VICTORIA UNIVERSITY

**Introduction** It has been proposed that a number of adaptations in both the muscular and the nervous systems may compromise fatigue resistance during repeated-sprint exercise (RSE) [1]. To date however, there is conflicting evidence regarding the contribution of central fatigue during RSE [2-4]. The aim of the present study was to investigate the precise locus of impairment in neural drive, if any, after repeated cycling sprints by using trans-cranial magnetic stimulation (TMS), in addition to conventional motor nerve (MN) stimulation. **Methods** Ten active males performed 10, 6-s "all-out" sprints on a cycle ergometer, interspersed with 30 s of recovery, followed, after 6 min of passive recovery, by five 6-s sprints, again interspersed with 30 s of recovery. Neuromuscular tests included motor nerve (MN) and trans-cranial magnetic (TMS) stimulation during brief (5-s) isometric contractions of the knee extensors performed before and after exercise. Root mean square (RMS) was utilized to quantify EMG activity from the vastus lateralis (VL) muscle of the right leg during both the all-out sprints and the warm up (sub-maximal sprints at 70, 80 and 90% of the perceived maximum). The EMG during the warm-up sprints was used to establish the power-EMG relationship and to determine whether the decrease in EMG previously observed during RSE was consistent with the decrease in power output. **Results** The RSE resulted in a decrease in peak power output (-12%), and a decrease in maximal strength (-12%) and the rate of force development (-20%) during briefs isometric contractions ( $P < 0.05$ ). Resting twitch amplitude declined by 42% and 40% (MN and TMS, respectively). Following the RSE there were no significant changes in voluntary activation estimated from either MN (80%) or TMS (90%). Interestingly, there was only a 5.5% decrease in EMG, which was significantly less than that estimated from the power-EMG relationship established during the warm up (-23%). **Discussion** An original finding of the present study is that the decrease in EMG was much less than that which would be predicted from the decrease in power output. This was accompanied by substantial reductions in muscle contractility following the repetition of cycle sprints. These changes, along with the lack of change in muscle activation, suggest that peripheral mechanisms were the predominant cause of fatigue during our repeated-sprint task. **References** 1. ### EFFECT OF ACUTE RUGBY SPECIFIC FATIGUE ON WHOLE MUSCLE CONTRACTILE PROPERTIES.

HASLAM, S.J., ANESTIK, M., BELL, K., BAXTER, T., HUNTER, A.M.

UNIVERSITY OF STIRLING

EFFECT OF ACUTE RUGBY SPECIFIC FATIGUE ON WHOLE MUSCLE CONTRACTILE PROPERTIES. Haslam, S.J.<sup>1,2</sup>, Anestik, M.<sup>2</sup>, Bell, K.<sup>1</sup>, Baxter, T.<sup>1</sup>, Hunter, A.M.<sup>1</sup> <sup>1</sup>University of Stirling, Scotland, <sup>2</sup>SportScotland Institute of Sport Stirling, Scotland Introduction Muscle function of rugby players is currently assessed by tests such as 1 RM (Bevan et al, 2010), isokinetic (Edouard et al, 2009), maximal voluntary contractions and countermovement jumps (Pournot et al, 2010). The disadvantages to such tests are the requirements for: firstly, 100% motivation from the players (Tod et al, 2009) and; secondly, often heavy immobile equipment. We propose an alternative assessment tool tensiomyography (TMG) which is both a passive measure and uses portable equipment. TMG is a measured mechanical response to stimulation of skeletal radial muscle belly (Dm). The aim of this study was to determine the effectiveness of TMG in tracking the fatigue induced following two rugby specific fatigue interventions. Methods 9 university rugby players had Dm recorded for Biceps Femoris (BF) and Rectus Femoris (RF) before and after 2 separate rugby specific fatigue interventions. The first, a sprint intervention (SPR), consisting of 6x6 maximal sprints over 30m (10 sec recovery between reps and 3 min recovery between sets). The second, a contact intervention (CON), consisting of 6x6 maximal tackle bag hits, sprinting from a supine position 5m away (3min recovery between sets). Performance times for each repetition were recorded via light gates. Counter-movement jump (CMJ) and rate-of-perceived-exertion (RPE) were recorded after every set. Results Sprint repetition times significantly ( $p<0.01$ ) declined within and across the sets for both interventions. CON showed a significantly ( $p<0.01$ ) greater rate of fatigue over the sets than SPR (15.8% vs. 7.6%). RPE and CMJ significantly ( $p<0.01$ ) increased and decreased respectively for both interventions ( $p<0.01$ ) across the sets. CMJ declined significantly ( $p<0.01$ ) more and at a greater rate than SPR. There was a significant ( $p<0.01$ ) decline in RF Dm following the sprint sets after CON ( $P=0.041$ ) but a tendency for SPR ( $P=0.058$ ). There was a tendency for BF Dm to decline for CON ( $P=0.073$ ) but not for SPR ( $P=0.13$ ). Discussion It is clear that CON significantly fatigued the participants more than SPR, which was effectively tracked by TMG RF Dm. There was a tendency for decline in RF Dm post SPR, however, it is clear that the extent of fatigue was much less within this protocol than CON. BF Dm remained the same following both interventions indicating that RF contributed to the fatigue shown whereas BF did not. #### HAMSTRING QUADRICEPS RATIOS: THEIR RELATIONSHIP TO HIGH SPEED MOTOR CAPABILITIES AND DIFFERENT FOOTBALL POSITIONS

FLETCHER, I.

UNIVERSITY OF BEDFORDSHIRE

HAMSTRING QUADRICEPS RATIOS: THEIR RELATIONSHIP TO HIGH SPEED MOTOR CAPABILITIES AND DIFFERENT FOOTBALL POSITIONS Fletcher, I.1, Mills, D.1 1: UoB (Bedford, UK) Introduction Football has a number of essential motor capabilities, including turning, sprinting, jumping and changing pace (Cometti et al., 2001), with the ability to perform these actions seeming to differ between outfield positions (Hoff & Helgerud, 2004). The aim of this study was to explore if these physiological differences were apparent and whether Hamstring:Quadricep (HQ) ratio varied between positions. Methods 30 male collegiate footballers (age  $22.4 \pm 2.5$ yr., height  $129 \pm 4.9$ cm, mass  $78 \pm 7.8$ kg) were split into equal groupings of defenders, midfielders and attackers before performing a maximum voluntary contractions at angular velocities of  $60^\circ/\text{s}$  and  $180^\circ/\text{s}$  on a Kincom Isokinetic Dynamometer (Chattanooga 125E). HQ ratios were measured by dividing maximal eccentric knee flexion force by maximum concentric knee extension force (Aagaard et al., 1998). On a separate day participants were tested for counter movement jump, flying 30m and Illinois agility test performance. Tests were repeated 3 times with the peak score being used for analysis. Results HQ ratios for defenders, midfielders and attackers were calculated as 0.93, 0.82 and 0.90 at  $60^\circ/\text{s}$  and 1.13, 0.99 and 1.06 at a  $180^\circ/\text{s}$  velocity. No significant difference ( $P>0.05$ ) were found between positions at either velocity. There was no significant differences ( $P>0.05$ ) between the three positions in any of the physical capacity tests used. HQ ratios had no significant relationship with performance tasks accept jump height and  $180^\circ/\text{s}$  ratios ( $P<0.05$ ). Discussion The findings of this study are contrary to a number of other studies. No difference in capacities was observed between positions, possibly due to participants not playing at a high enough level to do enough training specific to their chosen position; players trained or played at least three times a week, but would not have trained at the same volume as elite footballers. Interestingly the functional HQ ratios found in this study were all in the healthy range, above 0.6 (Svensson and Drust, 2005), despite a number of studies finding large muscle imbalances in football populations. It may be that by using a functional measure, where the hamstrings eccentric capacity is compared to the quadriceps concentric force, higher ratios can be achieved. HQ ratios did not seem to be linked to other performance tests at a slow velocity, but the higher ratios achieved at the faster velocity were linked to the simple task of jumping, but not to more complex motor skills. ## EFFECTS OF DYNAMIC STRETCHING ON THE HAMSTRINGS-TO-QUADRICEPS FUNCTIONAL RATIO IN RECREATIONALLY ACTIVE FEMALES.

AYALA, F., DE STE CROIX, M., SAINZ DE BARANDA, P.

CATHOLIC UNIVERSITY OF SAN ANTONIO

**EFFECTS OF DYNAMIC STRETCHING ON THE HAMSTRINGS-TO-QUADRICEPS FUNCTIONAL RATIO IN RECREATIONALLY ACTIVE FEMALES.** Ayala, F.I., De Ste Croix, M.2 and Sainz de Baranda, P.3 1:Catholic University of San Antonio (Spain), 2:University of Gloucestershire (UK), 3:University of Castilla La Mancha (Spain). **Introduction** Low hamstring-to-quadriceps isokinetic peak torque ratios have been associated with an increased risk of injury. Since stretching may decrease isokinetic peak torque, it is possible that pre-stretching may adversely affect the hamstrings-to-quadriceps functional ratio. The purpose of this study was to examine the acute effects of a short lower limb dynamic stretching program on knee extension (KE) and flexion (KF) peak torque (PT) and the hamstring-to-quadriceps functional ratio (H/QFUNC) in recreationally active female young adults. **Methods** Twenty-five recreationally active female young adults provided written informed consent to participate in this study. All participants visited the lab three times, one for familiarization and two for testing (stretching and control conditions completed in a random order) with 3-days between sessions. The dynamic stretching program consisted of a 5 different unassisted stretching exercises. Each exercise was designed to stretch one of the major lower limb muscles and was performed twice, bobbing in 1:2-second cycles for 30s with 30s rest between repetition and exercise. In the control condition no stretching was performed. Immediately after the stretching or control condition participants performed 2 maximal efforts on an isokinetic dynamometer to determine maximal PT during CON/CON and ECC/ECC cycles at 60 and 240°/s-1. Participants were placed in a prone position with the hip flexed at 10° and active range of motion was from 0 to 90°. **Results** There were no stretching-related changes in PT during both KE and KF maximal CON and ECC muscle actions at 60 and 240°/s-1 ( $p < 0.05$ ). In addition, no significant changes were found in H/QFUNC between sessions (control and stretching) in both velocities (0.64 v 0.69 and 1.0 v 0.98). **Discussion** Short and contextualized dynamic stretching has no effect on maximal CON and ECC peak torque as well as on H/QFUNC. In addition, it is well known that dynamic stretching routines are effective in improving joint range of motion. Therefore, we suggest that a dynamic stretching routine should be performed as a fundamental part of a typical warm-up because it does not seem to cause stretch induced deficits in strength performance and subsequent dynamic knee stability, as well as its effectiveness for improving range of motion of the muscle stretched. **References** Aagaard P, Simonsen EB, Magnusson P, Larsson B, Dyhre-Poulsen P. ## EFFECTS OF STATIC STRETCHING ON THE HAMSTRINGS-TO-QUADRICEPS FUNCTIONAL RATIO IN RECREATIONALLY ACTIVE ADULT MALES

AYALA, F., DE STE CROIX, M., SAINZ DE BARANDA, P.

CATHOLIC UNIVERSITY OF SAN ANTONIO

**EFFECTS OF STATIC STRETCHING ON THE HAMSTRINGS-TO-QUADRICEPS FUNCTIONAL RATIO IN RECREATIONALLY ACTIVE ADULT MALES.** Ayala, F.I., De Ste Croix, M.2 and Sainz de Baranda, P.3 1:Catholic University of San Antonio (Spain), 2:University of Gloucestershire (UK), 3:University of Castilla La Mancha (Spain). **Introduction** Low hamstring-to-quadriceps isokinetic peak torque ratios have been associated with an increased risk of injury. Since stretching may decrease isokinetic peak torque, it is possible that pre-stretching may adversely affect the hamstrings-to-quadriceps functional ratio. The purpose of this study was to examine the acute effects of a short lower limb static stretching program on knee extension (KE) and flexion (KF) peak torque (PT) and the hamstring-to-quadriceps functional ratio (H/QFUNC) in recreationally active male young adults. **Methods** Twenty-five recreationally active male young adults provided written informed consent to participate in this study. All participants visited the lab three times, one for familiarization and two for testing (stretching and control conditions completed in a random order) with 3-days between sessions. The static stretching program consisted of a 5 different unassisted stretching exercises. Each exercise was designed to stretch one of the major lower limb muscle and was performed twice, holding the position for 30s with 30s rest between repetition and exercise. In the control condition no stretching was performed. Immediately after the stretching or control condition participants performed 2 maximal efforts on an isokinetic dynamometer to determine maximal PT during CON/CON and ECC/ECC cycles at 60 and 240°/s-1. Participants were placed in a prone position with the hip flexed at 10° and active range of motion was from 0 to 90°. **Results** There were no stretching-related changes in PT during both KE and KF maximal CON and ECC muscle actions at 60 and 240°/s-1 ( $p < 0.05$ ). In addition, no significant changes were found in H/QFUNC between sessions (control and stretching) in both velocities (0.75 v 0.71 and 0.84 v 0.91). **Discussion** Short and contextualized static stretchings have no effect on maximal CON and ECC peak torque as well as on H/QFUNC. In addition, it is well known that short static stretching routines (60s per muscle group) are as effective as longer routines for improving joint range of motion. Therefore, we suggest that a short static stretching routine should be performed as a fundamental part of a typical warm-up because it does not seem to cause stretch induced deficits in strength performance and subsequent dynamic knee stability, as well as its effectiveness for improving range of motion of the muscle stretched. **References** Aagaard P, Simonsen EB, Magnusson P, Larsson B, Dyhre-Poulsen P. ## THE RELATIONSHIP BETWEEN THE BALL VELOCITY AND ANAEROBIC POWER, STRENGTH, ANTHROPOMETRIC CHARACTERISTICS AND REACTION TIME IN TEAM HANDBALL AND SOCCER

AKAN, I.I, SIRMEN, B.I, RAMAZANOGLU, N.I, UZUN, S.I, BOZDOGAN, Z.I

UNIVERSITY OF MARMARA SCHOOL OF PHYSICAL EDUCATION AND SPORTS

**Introduction:** The aim of this study was to analyse "How is the relation with ball velocity between anaerobic power, specific anthropometric characteristics, motor abilities and reaction time?" **Methods:** Anaerobic power was calculated by Lewis Formula (Fox, 1984). Ball velocity was measured by Sports Radar Gun. Vertical jump and Reaction time were measured by MPS-5001F Kompe System. Correlations were evaluated Pearson Correlation Sig(2 tailed) test. **Results:** Ball velocity of male and female handball players (standing throw after 3 steps) is 72.64±5.32kmh, 72.16±6.92kmh. At the side-foot and close up of foot kicking, the ball velocity of male soccer players is related with foot length ( $p=.028$ ), ( $p=.004$ ). At the close up of foot kicking, the ball velocity of male soccer players is related with arm relaxed girth measurement ( $p=.019$ ), arm flexed girth measurement ( $p=.004$ ), waist ( $p=.042$ ), chest ( $p=.014$ ). Ball velocity of female handball players (standing throw after 3 steps) is related with anaerobic power ( $p=.004$ ), thigh circumferences ( $p=.011$ ), arm span ( $p=.050$ ), vertical jump ( $p=.003$ ). At the same throwing, ball velocity of male handball players is related with hand grip ( $p=.006$ ). Ball velocity of female handball players (vertical

jump throw after 3 step) is related with anaerobic power( $p=.002$ ), leg strength( $p=.003$ ), arm span( $p=.005$ ), vertical jump( $p=.002$ ) and height( $p=.027$ ). Discussion: The present study was the ball velocity of female and male player in handball standing throw after 3 step is  $72.16 \pm 6.92$  km/h and  $72.64 \pm 5.32$  km/h. Ball velocity of female handball player At the same throw, was stated 85 km/h (Joris et al., 1985), and international male handball player was stated 94.08 km/h (Jensen et al., 1999). The present study was the relation with ball velocity (that both standing throw after 3 step and vertical jump throw after 3 step) between arm span and height. Handball players who throw the ball at a higher velocity seem to have a wider arm span related to their body height (Skoufas et al., 2003). Another relation with ball velocity (standing throw after 3 step) of male handball players between hand grip strength. Grip force that is important in handball, from the moment pass is received till the throw is affected from the arm segment isometric muscle force. ### PEAK POWER AND ANAEROBIC CAPACITY OF THE UPPER BODY IN ELITE IRANIAN MALE CANOE POLO PLAYERS

KHALILI, E.1, AGHA-ALINEJAD, H.2,3, BAYATI, M.2, SHEIKHLOUVAND, M.3, ISANEJAD, A.2, FARZAD, B.4

1: ISLAMIC AZAD UNIVERSITY, KARAJ BRANCH (KARAJ, IRAN), 2: NATIONAL CANOEING, ROWING & SAILING ACADEMY (TEHRAN, IRAN), 3: ISLAMIC AZAD UNIVERSITY, CENTRAL TEHRAN BRANCH, 4: TARBAT MODARES UNIVERSITY

This study is supported by National Canoeing, Rowing & Sailing Academy (Tehran, Iran) Introduction Canoe Polo is a strength-power type of sport and competition performance depends on factors such as strength and anaerobic power, physical power, canoe polo technique and tactics. An anaerobic activity is defined as energy expenditure that uses anaerobic metabolism (without the use of oxygen) that lasts less than 90 seconds, utilizing an exhaustive effort (Zupan et al., 2009). This study examines the aspect of upper-body peak power and anaerobic capacity using the 30-second exhaustive Wingate Anaerobic Test (WAnT). Methods The subjects were fifteen elite male canoe polo players from the Iranian National team (Mean  $\pm$  SD: age  $24.6 \pm 3.1$  years, height  $179.4 \pm 5.1$  cm, body mass  $82.9 \pm 7.6$  kg) who competed at the 2011 Asian canoe polo championships in Tehran, Iran. The Wingate Anaerobic Test (WAnT): Peak power output (PPO) and mean power output (MPO) or anaerobic capacity were assessed Wingate test on a mechanically braked cycle ergometer (model 891E, Monark, Sweden). Participants performed a Wingate test against a resistance equivalent to 0.040 kg/kg body mass. Participants were instructed to begin pedaling as fast as possible against the ergometer's inertial resistance, and then the appropriate load was manually applied. Participants were verbally encouraged to continue pedaling as fast as possible throughout the 30-s test. PPO was defined as the highest work output in a 5-second period, and MPO as the average work output for the 30-second test period (Nottle and Nosaka., 2007). Previously determined intraclass correlation coefficient (ICC) for Wingate variables was 0.94 (Bar-Or., 1987). Results Peak power and anaerobic capacity in absolute (W) and relative to body weight (W/kg-1) were determined for the WAnT. Peak power output (Mean  $\pm$  SD: absolute  $413.1 \pm 75.3$  watts (w), relative to body weight  $5.2 \pm 0.9$  watts per kilogram body weight (W/kg-1), and mean power output (Mean  $\pm$  SD: absolute  $281.9 \pm 32.5$  watts (w), relative to body weight  $3.44 \pm 0.3$  watts per kilogram body weight (W/kg-1). Discussion This is the first study to present a detailed analysis of the anaerobic profiles elite Iranian male canoe polo players. Success in many sports requires high upper power and anaerobic capacities. Some sports require absolute power, or the highest power output possible, independent of body size, such as canoe polo linemen, power lifters, or hammer throwers. If 2 players' skill level or techniques are equal, then the more powerful athlete will usually outperform the less powerful opponent. Where the athlete must move his or her body across a field or ice rink with a quick burst of energy, require a high relative peak power and anaerobic capacity. References Bar-Or O. (1987). ### INFLUENCE OF THE POWER-BALANCE HOLOGRAM ON BALANCE, STRENGTH, FLEXIBILITY AND ENDURANCE

PISCH, M.

RUHR UNIVERSITY, BOCHUM

INFLUENCE OF THE POWER-BALANCE HOLOGRAM ON BALANCE, STRENGTH, FLEXIBILITY AND ENDURANCE Maren Pisch, Stefanie Cappell, Maik Drzensla, Julia Hämel, Holger Neumann, Alexander Ferrauti, Petra Platen Ruhr-University Bochum, Faculty of Sports Sciences (Bochum, Germany) Introduction More and more athletes use the so called "Power-Balance technology" to seemingly improve their sports specific performance. According to Consumer News and Business Channel (CNBC) it was the "Sports Product of 2010" and it was a best-seller on "Amazon.com". In contrast to its widely spread usage in sports there are no scientific studies about the real efficacy of this technology, yet. Therefore, the aim of this study was to examine the influence of the Power-Balance hologram on different skills like balance, strength, flexibility and endurance. Methods 19 (5 female and 14 male) healthy physical education students (age:  $22.5 \pm 1.9$  years; height:  $181 \pm 13$  cm; weight:  $76.2 \pm 15.7$  kg) participated in the study. On three experimental days at least one week apart, subjects took part in a partially blinded cross-over designed study under three conditions: B(-) (placebo, blind without hologram), B(+) (blind with hologram), and NB(+) (not blind with hologram). Parameters were flexibility (stand-and-reach/finger-ground distance (cm)), maximum thorax rotation (degree), strength (dominant hand-grip strength (kg)), balance (regulatory distance on a Posturomed (mm)), and endurance (20 m shuttle-run test (VO2max)). Results No significant differences were found for any parameter between the three testing conditions: stand-and-reach (cm): NB(+):  $3.3 \pm 11.6$  cm, B(+):  $3.0 \pm 10.9$  cm, B(-):  $2.7 \pm 10.8$  cm ( $p=0.50$ ); thorax rotation: NB(+):  $153 \pm 17^\circ$ , B(+):  $154 \pm 21^\circ$ , B(-):  $154 \pm 17^\circ$  ( $p=0.84$ ); grip strength (kg): NB(+):  $43.5 \pm 11.6$ , B(+):  $44.8 \pm 13.9$ , B(-):  $44.1 \pm 13.2$  ( $p=0.58$ ); balance (mm): NB(+):  $0.05 \pm 0.02$ , B(+):  $0.05 \pm 0.03$ , B(-):  $0.06 \pm 0.04$  ( $p=0.34$ ); VO2max (ml/min\*kg): NB(+):  $47.2 \pm 9.9$ , B(+):  $47.3 \pm 9.8$ , B(-):  $47.3 \pm 9.4$  ( $p=1.00$ ). Conclusion Our study clearly demonstrated no influence of the Power-Balance technology on any motor skill like balance, strength, flexibility and endurance. We, therefore, conclude that any individual impression of a positive influence of the hologram on any performance parameter is based on a placebo effect.

## ENHANCEMENT OF POWER IN CONCENTRIC PHASE OF CHEST PRESSES AT DIFFERENT WEIGHTS LIFTED ON STABLE AND UNSTABLE SURFACE

ZEMKOVA, E., HAMAR, D.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY

**Introduction** It has been shown that activation of stretch-shortening cycle (SSC) during countermovement (CM) weight exercise enhances power production in concentric phase compared to lift from the rest. However, it is unknown how this potentiation of power is influenced by stability of support surface. Therefore, the study compares the differences in mean power in concentric phase of chest presses with and without CM at different weights lifted with back supported by stable bench and unstable Swiss ball. **Methods** A group of 16 PE students (age  $23.4 \pm 1.9$  y, height  $181.5 \pm 6.1$  cm, weight  $75.1 \pm 6.1$  kg) performed randomly in different days 8 reps of barbell chest presses without and with CM on the bench and Swiss ball, respectively. Initial weight of 20 kg was increased by 10 kg or 5 kg (at higher loads) until 85% of previously established 1RM. A PC based system FITRO Dyne Premium was used to monitor power in concentric phase of lifting. **Results** As expected, there were higher power outputs during CM than concentric-only chest presses on both stable and unstable surface. This potentiating effect under stable conditions was rather modest at lower weights ( $34.1 \pm 6.2$  W at 20 kg) and become more pronounced with increasing weights reaching a maximum of  $114.8 \pm 16.8$  W at 57.1% 1RM. From this point the power gradually decreased to  $62.2 \pm 10.1$  W at 90 kg. However, during chest presses on Swiss ball the differences between power produced with and without CM were greater at lower weights ( $51.3 \pm 8.3$  W at 20 kg) with maximum of  $104.3 \pm 12.1$  W achieved at 47.6% 1RM. Towards heavier weights this potentiating effect substantially diminished to  $24.9 \pm 6.0$  W at 90 kg. **Discussion** Maximal enhancement of power in concentric phase of lifting due to CM occurred at lower % of 1RM under unstable than stable conditions. Higher weights compromised such potentiation of power more profoundly during chest presses on Swiss ball than on the bench. The mechanism underlying this enhancing effect is usually ascribed to utilization of elastic energy stored in elastic components in combination with reflexively induced neural input. However, during chest presses on Swiss ball, presumably lower amount of energy is accumulated in elastic tissues of muscles and tendons involved and consequently can be utilized for subsequent concentric contraction. This is mainly due to delayed and prolonged amortization phase of SSC. Around the turning point, where the eccentric phase changes into the concentric one, maximal force is produced. At the same time subject must stabilize the torso on unstable surface in order to provide firm support for contracting muscles. This additional task may compromise the contraction of muscles acting on the barbell. Their less intensive contraction not only prolongs the change of movement direction, but because of lower peak force, negatively impairs accumulation of elastic energy. Consequence is lower power in concentric phase of lifting on unstable than stable surface.

## VELOCITY- AND POWER-LOAD RELATIONSHIPS FOR THE BENCH PRESS VS. BENCH PULL EXERCISE

SÁNCHEZ-MEDINA, L., PÉREZ, C.E., GARCÍA-PALLARÉS, J.

PABLO DE OLAVIDE UNIVERSITY, SEVILLE

**VELOCITY- AND POWER-LOAD RELATIONSHIPS FOR THE BENCH PRESS vs. BENCH PULL EXERCISE** Sánchez-Medina, L.1, Pérez CE.2, García-Pallarés J.2 1: UPO (Seville, Spain), 2: UMU (Murcia, Spain) **Introduction** Although less popular than the bench press (BP), the prone bench pull (PBP) is a resistance training exercise commonly used in sport disciplines which require upper-body pulling such as canoeing, rowing, judo or wrestling. However, the PBP has received little research attention and only one study (Pearson et al., 2009) has examined its kinematics and kinetics. This study aimed to analyze the opposing upper-body actions of pushing (BP) and pulling (PBP). **Methods** Seventy strength-trained males [mean(SD): age  $23(5)$  yr, height  $177(7)$  cm, body weight  $76(9)$  kg, body fat  $12(4)\%$ ] performed an increasing loading test up to the 1RM in the concentric BP and PBP. Exercises were performed in random order, separated by 48 h. A linear velocity transducer sampling at 1,000 Hz (T-Force, Ergotech, Spain) was attached to a Smith machine. The load (%RM) that maximized power output (Pmax) was compared using three different variables: mean power (MP), mean propulsive power (MPP) and peak power (PP). Mean propulsive velocity (MPV) attained with each %RM (30-95% RM, 5% increments) and with the 1RM load (V1RM) were also compared. One-way ANOVA was used to detect differences between exercises and power at different loads. **Results** The following variables were significantly different ( $p < 0.001$ ) between exercises: 1RM,  $90.2(16.7)$  kg for BP and  $80.0(12.1)$  kg for PBP; V1RM,  $0.16(0.05)$  m/s for BP and  $0.52(0.05)$  m/s for PBP. MPV attained with each %RM was significantly higher for PBP than BP. Pmax was found to be dependent on the variable used: 56% (BP) vs. 70%RM (PBP) using MP, 38% (BP) vs. 46%RM (PBP) using MPP, and 37% (BP) vs. 41%RM (PBP) using PP. No significant differences were found for loads between 40-70% (BP) or 50-90% (PBP) using MP; 25-60% (BP) or 20-70% (PBP) using MPP; 20-65 (BP) or 20-75% (PBP) using PP. Prediction equations to estimate load from MPV were:  $\%RM = 11.01 \text{ MPV}^2 - 77.66 \text{ MPV} + 113$ ,  $R^2=0.97$ ,  $SEE=4.44\%RM$  for BP; and  $\%RM = 13.89 \text{ MPV}^2 - 94.99 \text{ MPV} + 144.7$ ,  $R^2=0.94$ ,  $SEE=5.98\%RM$  for PBP. **Discussion** Velocity and power were considerably higher for PBP than BP throughout the entire load range. These differences increased as load approach the 1RM, with V1RM for the two exercises being remarkably different. Our findings regarding the power-load relationship support and extend those of Pearson et al. (2009); however, velocities obtained in this study are much higher than those reported by the aforementioned authors which may be due to the counter-weight Smith machine they used. Differences in the Pmax are reduced when choosing MPP or PP over MP (Sánchez-Medina et al., 2010). Differences in velocity and power between BP and PBP are attributable to the differing muscle architecture. **References** Pearson SN, Cronin JB, Hume PA, Slyfield D (2009). ## LIFTING WEIGHTS CLOSE TO MAXIMAL POWER DIFFERS UNDER STABLE AND UNSTABLE CONDITIONS

ZEMKOVA, E., HAMAR, D.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY

**Introduction** It has been documented (Bosco, 1992) that repetitions performed above 90% of maximal power with particular weight lifted are the most efficient for improvement of maximal strength and explosive power. Decrease of power production throughout repetitions has usually been attributed to fatigue and/or lack of voluntary effort. Provided that the exercise is performed with maximum effort, muscular performance will depend on fatigue. However, its level may differ under stable and unstable conditions due to different demand on neuromuscular system. The study compares the rate of power reduction below the above-mentioned critical level during chest presses and squats on stable and unstable surface. **Methods** A group of 12 PE students (age  $21.7 \pm 2.4$  y, height  $186.4 \pm 9.2$  cm, weight  $82.1 \pm 8.7$  kg) performed randomly in different days a set of a) barbell chest presses on either bench or Swiss ball, and b) barbell squats on either stable support or Bosu ball (all of them with 70% 1RM). A PC based system FITRO Dyne Premium was used to monitor power in concentric phase of lifting. **Results** Power in concentric phase of chest presses on the bench decreased below 90% of the maximum within four reps

(from  $774.9 \pm 14.7$  to  $695.4 \pm 12.4$  W). However, when the same exercise was performed on Swiss ball the power fell below this level within two reps (from  $705.2 \pm 13.5$  to  $633.7 \pm 11.2$  W). Similarly, reduction of power was faster during squats on Bosu ball than on stable surface (from  $789.7 \pm 18.1$  to  $708.3 \pm 15.7$  W within four reps and from  $921.8 \pm 17.9$  to  $824.4 \pm 16.8$  W within seven reps, respectively). Discussion Faster decrease of power below the critical level is most likely due to more pronounced and/or earlier fatigue of neuromuscular system. On unstable surface, subject must stabilize torso in order to provide firm support for contracting muscles. This is an additional task requiring greater co-contractile activity of trunk-stabilizing muscles. This may be corroborated by significantly higher EMG activity of deltoid and abdominal muscles during chest presses (Marshall, Murphy, 2006) and abdominal stabilizers, upper lumbar erector spinae and lumbo-sacral erector spinae muscles during squats (Anderson, Behm, 2005) on unstable than stable surface. Increased EMG activity in the soleus indicates also higher demand on postural muscles. It may be assumed that faster drop of power below the critical level under unstable conditions is a consequence of these challenges in neuromuscular system. This fact has to be taken into account in assessment of individuals, in which the ability to tolerate the fatigue and work close to the maximal power may differ significantly. Hence, information obtained from monitoring of power under stable conditions cannot be simply applied to the exercise on unstable surface. References Anderson K, Behm D (2005). ## ACCELERATION, MAXIMUM SPEED AND AGILITY IN RELATION TO STRENGTH PARAMETERS IN SWISS ELITE WOMEN SOCCER PLAYERS

SONDEREGGER, K., HUEBNER, K., LUETHY, F., TSCHOPP, M.

SWISS FEDERAL INSTITUTE OF SPORTS (MAGGLINGEN)

Introduction In team sports like soccer, sprinting becomes more and more important. To improve sprint performance, it is crucial to understand its limiting factors. However, little evidence exists about these determinants, especially for elite women soccer players. The aim of this study was to analyze the interdependence of speed abilities assessed in field tests and strength parameters in elite women soccer players. Methods Thirty-eight Swiss national women soccer players ( $19.8 \pm 2.8$  y,  $165.8 \pm 6.2$  cm,  $60.4 \pm 5.5$  kg) completed a 40m all-out sprint. Times were measured for acceleration (t10) and maximum speed (t30-40). A stop-and-go test to assess agility (5m-10m-5m with two 180 degree turns (SGT)) was made. Bilateral (bCMJ) and unilateral (uCMJ) countermovement jumps, squat jumps (SJ) and drop jumps from heights of 20cm, 40cm and 60cm (DJ20, DJ40, DJ60) were performed on a force plate. The bCMJ, uCMJ and SJ were measured at peak power and DJs as "jump height/contact time". Vertical and leg stiffness during the sprint were calculated based on the method used by Morin (2005). Leg tapping was measured on a contact mat. Results The t10 correlated (Pearson) significantly with bCMJ ( $r = -.62^{**}$ ), SJ ( $r = -.52^{**}$ ), uCMJ ( $r = -.40^{*}$ ), tapping ( $r = -.33^{*}$ ), DJ40 ( $r = -.33^{*}$ ) and vertical stiffness ( $r = -.32^{*}$ ). There was no correlation between t10 and leg stiffness. The t30-40 correlated with vertical stiffness ( $r = -.60^{**}$ ), bCMJ ( $r = -.60^{**}$ ), uCMJ ( $r = -.55^{**}$ ), SJ ( $r = -.49^{**}$ ) and tapping ( $r = -.39^{*}$ ). Only DJ20 correlated with t30-40 ( $r = -.37^{*}$ ), DJ40 and DJ60 did not. Contrary to t10, t30-40 correlated significantly with leg stiffness ( $r = -.35^{*}$ ). SGT correlated with bCMJ ( $r = -.45^{**}$ ), uCMJ ( $r = -.43^{**}$ ) and SJ ( $r = -.34^{*}$ ), as well as with DJ20 ( $r = -.43^{**}$ ), DJ40 ( $r = -.48^{**}$ ) and DJ60 ( $r = -.40^{*}$ ). Vertical and leg stiffness did not correlate with SGT. Although the correlation between t10 and t30-40 was high ( $r = .72^{**}$ ), SGT correlated only moderately with t10 ( $r = .45^{**}$ ) and t30-40 ( $r = .46^{**}$ ). Discussion For good acceleration by women soccer players, it seems crucial to have high explosive strength qualities and, for maximum speed, stretch-shortening qualities become more important. For SGT, both explosive and reactive strength are important while stiffness is negligible. A high tapping frequency is only important in linear sprints and not in SGT. Thus, differences do exist in the relationship between strength parameters and the following three speed abilities acceleration, maximum speed and agility. These findings suggest that it is essential to consider different strength parameters when testing and training to improve women soccer players' speed. References Morin, J. B. et al. (2005). ## COMPARISON OF THREE DIFFERENT METHODS TO EVALUATE MUSCULAR POWER DURING VERTICAL JUMP

COMTOIS, A.S.1, DESJARDINS, P.2, TREMBLAY, M.2, FORTIN, A.M.2, PARENT, G.2, BUI, H.T.2, LEONE, M.2

1UNIVERSITÉ DU QUÉBEC À MONTRÉAL, 2UNIVERSITÉ DU QUÉBEC À CHICOUTIMI

Introduction Traditionally, muscular power is assessed using the Sargent jump (SJ). This method has the advantage of being simple and costless. However, many technical factors associated to this test indicate a possible lack of precision. Another option is to use a Bosco mat (BM). Its principle of operation is to measure the time of flight which can be used to calculate the height of a vertical jump. A timer is activated when the pressure on the mat is zero and is stopped when the feet hit the mat. Although the precision is better when compared to the SJ, the BM is expensive and is prone to mechanical wear and tear because of the repeated feet impacts. Our group has recently developed a new concept based on laser light (LL) which is a low-cost alternative to the BM. The physics equations involved in its operation are similar to that of the BM and the LL yields results that are as accurate. However, in addition to costing less, the proposed system does not deteriorate with repeated use. Thus, the purpose of this study is to compare the three methods to determine the validity and the level of precision of each of them. Methods A total of 41 kinesiology students (18 women, 23 men, mean age  $23.2 \pm 4.5$  years old) have participated in this study. The physical layout was made so that the three systems (BM, LL and SJ) could simultaneously measure the height of each jump. All participants were asked to jump vertically as high as possible using the SJ procedure. The data (height in cm) of the three systems were recorded for each jump. Results No significant differences have been observed between the BM ( $35.9 \pm 8.5$  cm) and the LL ( $35.6 \pm 8.1$  cm). However, significant differences have been noted between both BM and LL versus SJ ( $40.3 \pm 11.1$  cm;  $p \leq 0.000$ ). The correlation coefficient was excellent between the BM and LL ( $r = 0.97$ ). However, correlations were lower for BM and SJ ( $r = 0.90$ ) and for LL and SJ ( $r = 0.87$ ). When gender is taken into account, the correlations between BM-LL and SJ were respectively 0.78 and 0.75 for men 0.80 and 0.69 for women. Discussion The BM and LL present the same precision when assessing jump height. However, SJ overestimates the height by more than 5cm. The difference becomes even larger when the jump is higher. For example, the difference was 2cm (6.4%) for jumps lower than 36cm but was 7cm (14.3%) for jumps over 36cm. The regression equation with the BM as the dependent variable and LL as the independent variable determined that the standard error of estimate is 2.0cm which represents an error of  $\pm 5.6\%$ . Conclusion LL is an excellent alternative to evaluate vertical muscular power. The traditional SJ overestimates the real value for the vertical jump. The accuracy of the SJ is particularly affected for higher jumps.

## THE ROLE OF GRIP STRENGTH AND ISOMETRIC BENCH PRESS STRENGTH ON POWER LIFTING PERFORMANCE

PLATZER, H.P., PATTERSON, C., RASCHNER, C., NACHBAUER, W.  
UNIVERSITY OF INNSBRUCK

**Introduction** Grip strength and isometric bench press tests are frequently used to assess the athlete's strength abilities. These tests are easy to perform and show a high correlation to upper body strength and to specific sport performance (Milliken et al., 2008; Platzer et al., 2009). Scientific literature about performance diagnostics in power lifting is scarce. The aim of the study was to find out if these tests are important in power lifting performance and should be part of a test battery. **Methods** 10 elite male power lifters (age 30 +/- 7 years) took part in this study. Tests for grip strength (TKK 5401, Takei, Tokyo, Japan), isometric bench press (Platzer et al., 2009) and 1 RM for squat, bench press and dead lift (raw and equipped) were administered. The subjects mean performances for raw squat, bench press and dead lift were 218 +/- 56 kg, 180 +/- 42 kg and 261 +/- 51 kg respectively. The subjects mean performances for equipped squat, bench press and dead lift were 289 +/- 60 kg, 223 +/- 40 kg and 276 +/- 54 kg respectively. Depending on the discipline, equipment included wrist and knee wraps, bench press shirts, squat or dead lift suits. Pearson's correlation coefficient was used to analyse relationships. **Results** Grip strength showed a significant correlation only to the raw/equipped ratio for 1RM bench press ( $r=0.763$ ,  $p=0.028$ ) but to none of the other variables. Isometric bench press strength elicited no significant correlation to 1 RM bench press or any other variable ( $p > 0.6$ ). **Discussion** Power lifters use wrist wraps because of their performance enhancing and protective abilities. In bench press they support wrist stability and in dead lift they ought to tighten the bar grip (Coutinho, 2007). According to the results grip strength might increase raw performance in bench press but the overall importance in power lifting seems to be minor. It appears that a wrist wrap supports the athlete to achieve the necessary amount of grip strength. For weaker athletes it acts performance enhancing and for stronger power lifters it may be more a psychological and protective aid. The missing correlation between isometric and 1RM bench press implies that the Hill curve does not apply in this power lifting discipline. Isometric bench press can not be used to predict bench press performance in power lifting. **In conclusion** we suggest that grip strength and isometric bench press should not be part of a testing battery in power lifting. Furthermore it is not necessary to focus on grip strength in the training prescription. **References** Coutinho M (2007). ### PP-PM62 Physiology: Exercise Training 2

## THE EFFECTS OF A 6-MONTH INTERVENTION WITH INTRADIALYTIC EXERCISE TRAINING AND DOPAMINE AGONISTS IN HEMODIALYSIS PATIENTS WITH RESTLESS LEGS SYNDROME

GIANNAKI, C.D, SAKKAS, G.K., KARATZAFERI, C., HADJIGEORGIOU, G.M., LAVDAS, E., KOUTEDAKIS, Y., STEFANIDIS, I.  
SCHOOL OF HEALTH SCIENCES, UNIVERSITY OF THESSALY

**Introduction:** Restless Legs Syndrome (RLS) is a common neurological disorder in hemodialysis (HD) patients. Briefly, RLS is characterized by an urgent need to move the limbs, usually accompanied by unpleasant sensations. The symptoms begin or worsen during inactivity periods while a temporary relief occurs by movement. So far there are no comparative studies available comparing a non-pharmacological treatment to a classical treatment over their effectiveness on syndromes' severity and quality of life (QoL) in HD patients with RLS. **Methods:** In this six-month randomized, partially double-blind, placebo-controlled comparative study, thirty two HD patients with RLS were randomly assigned into three groups: 1) the exercise training group (N= 16, 56.4±12.5 years), 2) the dopamine agonists group (Ropinirole 0.25mg/d) (N= 8, 55.7±10.4 years) and 3) the placebo group (N= 8, 56.8±16.5 years). RLS severity was assessed using the International RLS severity scale, physical performance by a battery of tests, muscle size and composition by computed tomography, body composition by DEXA, while depression score, sleep quality, daily sleepiness and QoL were assessed through validated questionnaires. **Results:** Exercise training and dopamine agonists were effective in reducing the RLS symptoms by 46% and 54% respectively with no significant adverse effects. Both approaches significantly improved QoL, however, only the dopamine agonists significantly improved sleep quality. On the other hand, only the exercise training increased lean body mass, reduced fat infiltration in muscles and improved physical performance. **In contrast** in the placebo group the depression symptoms score became significantly worse after the 6 month intervention. **Discussion:** A 6-month exercise training intervention was as effective as a 6-month low dosage dopamine agonist treatment in reducing RLS symptoms and improving several aspects related to the health related QoL, in HD patients with RLS. However, only exercise training was effective in improving parameters related to patients survival, such as physical performance, muscle and body composition.

## EFFECTS OF ONE WEEK OF SWIM TRAINING ON RESTING HEART RATE VARIABILITY IN YOUNG SWIMMERS

MORGADO, J., ALVES, F., MONTEIRO, C.P., REIS, J., LAIRES, M.J.  
FACULTY HUMAN KINETICS, TECHNICAL UNIVERSITY OF LISBON, PORTUGAL

**Introduction** Researches about training effects on cardiac autonomic control activity, inferred by measurement of Heart Rate Variability (HRV), have been insufficient to generate a sustained relationship between HRV parameters fluctuations and the training process in any sport or physical exercise. The purpose of this study was to investigate the effect of the antepenultimate microcycle of the training season on young swimmers resting HRV parameters. **Methods** 12 swimmers (7 female, 13±0.3 yrs and 5 male, 14±0.6 yrs) undertook HRV recordings and maximal tests at the first (M1) and last (M3) days of 1-wk of swim training and at the 3rd day (M2) for HRV also. Subjects swam an incremental maximal step test (2x200 m front crawl) and blood lactate was monitored. HRV indexes were assessed after awakening in supine position under controlled breathing from 5-min R-R interval (RR) data using the Polar RS800™. Time and frequency domain analyses with HRV Analysis software gave: mean RR interval (RR), standard deviation of normal RR intervals (SDRR), square root of the mean of the sum of the squares of differences between adjacent NN interval (RMSSD), number of interval differences of successive NN intervals greater than 50 ms (NN50) and percent of difference between adjacent NN intervals greater than 50 ms (pNN50). Power spectrum was calculated using a Fast-Fourier Transform determining: very low (VLF; 0.003-0.04 Hz), low (LF; 0.04-0.15 Hz), and high (HF; 0.15-0.4 Hz) frequency bands, which were analyzed in absolute (ms<sup>2</sup>), percentage (%) and normalized units (n.u.) power. The LF/HF ratio was calculated. Parametric T test and non-parametric Friedman and Wilcoxon tests were used ( $p<0.05$ ). **Results** SDRR augmented from M1 to

M3 in both genders and from M2 to M3 in males. RMSSD rise from M1 and M2 to M3 in both genders and from M1 to M2 in males. pNN50 ascended from M1 and M2 to M3 in females and from M1 to M2 in males. In female swimmers RR and HF% augmented from M2 to M3 and HF n.u. from M1 and M2 to M3. On the contrary, LF% declined from M1 to M3 and LF/HF ratio from M1 and M2 to M3. Swimming speed on the 2nd 200 m repetition at M3 was higher than at M1 in females. Discussion Training seems to be the main determinant of the increases on SDRR, RMSSD and pNN50. The variations in HRV frequency domain indexes, suggesting an increased parasympathetic and suppressed sympathetic modulations, occurred only in females. This predominance of vagal influence could be associated with the elevated performance observed following 1-wk of swim training, but both could reflect the cumulative effects of training. Yet, further studies are needed to determine whether these measures can represent fatigue condition during a swimming season and their gender dependency.

### **CARDIOVASCULAR EFFECTS AND QUALITY OF LIFE OF SUPERVISED TRAINING PLUS METFORMIN THERAPY VERSUS METFORMIN THERAPY ALONE IN AN INSULIN RESISTANCE POPULATION**

CUGUSI, L.I., NOCCO, S.I., CADEDDU, C.I., CADEDDU, F.I., BINA, A.I., DEMURU, P.I., ORRÙ, F.I., BANDINO, S.I., COSSU, E.I., BARONI, M.I., MERCURO, G.I.

UNIVERSITY OF CAGLIARI

Introduction: Insulin resistance (IR) seems to play a major role both in the evolution towards diabetes and in affecting cardiac performance and endothelial function (An and Rodrigues, 2006; Witteles, 2008). It was showed that metformin therapy (MET) can produce benefit to glucidic profile (Anderson, 2005), but can reduce maxVO<sub>2</sub> consumption in healthy population (Johnson et al., 2008). Combining MET with exercise could optimize the treatment efficacy and compliance. Therefore, we evaluated cardiopulmonary performance, endothelial function and health-related quality of life in IR population, after 12-weeks of MET and after 12-weeks of supervised aerobic exercise program plus MET. Methods: 27 patients (18W, 9M age 45±15) with IR (HOMA-IR=4.92±2.8), were randomly assigned to 12-weeks of supervised training plus MET (MEg=13), versus 12-weeks of MET alone (Mg=14). Cardiopulmonary exercise test (CPET), peripheral arterial tonometry to measure the endothelial flow reserve (EFR) and SF-36 to evaluate physical (PSC) and mental (MSC) summary component, were assessed before and after 12-weeks. Results: At enrollment, all patients showed a decreased average peakVO<sub>2</sub> (67%) in comparison with the theoretical values of healthy population. BMI was significantly reduced both in MEg (31.5±3.9 vs 29.5±3.9 p<0.05) and in Mg (30.1±5.1 vs 28.2±5.1 p<0.05), also the increase of EFR was significant in both groups (Mg:1.93±0.5 vs 2.1±0.4 p<0.05; MEg:2.0±0.8 vs 2.2±0.6 p<0.05). The CPET showed a significant reduction of peakVO<sub>2</sub> (1.67±0.39 l/min vs 1.55±0.36 l/min p<0.05) in Mg with a non significant Work reduction (113.5±35.3 vs 109.7±31.4 p=ns), in contrast, a significant increase in MEg (1.46±0.48 l/min vs 1.62±0.43 l/min p<0.05) with a significant Work increase (101.8±32.8 vs 118.6±35.3 p<0.05) at 12-weeks. SF-36 highlighted a significant increase of PSC (56.66±19.09 vs 75.77±14.91 p<0.001) and MSC (58.77±19.11 vs 73.22±17.63 p<0.01) in MEg only. Discussion: These data emphasize that supervised training in combination with MET, is decisive to optimize the IR population treatment. Additional benefits of increasing oxygen consumption and improving HRQoL identify supervised training as a feasible and effective component in the management program for IR population. ### **CORRELATIONS BETWEEN STRENGTH AND HEART RATE VARIABILITY AFTER 16 WEEKS OF CONCURRENT TRAINING IN POSTMENOPAUSAL WOMEN**

FERRARI, S., GASPARI, A., BONGANHA, V., ANTUNES, M., CONCEIÇÃO, M., CHACON-MIKAHIL, M.P.T., MADRUGA, V.A.

STATE UNIVERSITY OF CAMPINAS - BRAZIL

Introduction Heart rate variability (HRV) is an important marker of cardiac autonomic nervous system control and has been used as a risk marker for cardiovascular disease (Heffernan et al., 2007). High fitness level can minimize physiological changes in vagal modulation related to aging process, regardless of gender (De Meersman, Stein 2007). Furthermore, changes pronounced during the aging process of women are decrease in strength (Douchi et al., 2002) and aerobic fitness that is connected to central and peripheral adaptations (Hawkins, Wiswell, 2003). Concurrent training (CT) has shown the same benefits as isolated training, although to a lesser magnitude (Leveritt et al., 1999). This research has the goal of verifying the effects of CT on correlations between strength and HRV. Methods Nine healthy and non-physically active women were analyzed (52 ± 6.14 years old). The CT proposed consists of 16-training weeks (3 d.wk-1), 3 sets of 8-10 maximal repetitions (RM) with 60-90s of rest between sets, 6 exercises, followed by 30 min jogging at 55-85% VO<sub>2</sub>peak. Maximal upper-body (UBS) and lower-body strengths (LBS) were measured by 1-RM test involving two exercises that were part of the training routine (bench press and leg press). The RR intervals were recorded for 20 min at rest in supine position using the Polar® S810, the data was analyzed using FFT algorithm by Polar Precision Performance and the variables of time and frequency domain were calculated. Results Maximal UBS (38.44±5.59 to 46.66±6.20 kg; p=0.008) and LBS (140.11±36.70 to 173.00±36.45 kg; p=0.011) improved after the training program. There were no changes at the HRV markers analyzed. The significant correlation coefficients between UBS, LBS and HRV are: r=0.67 (p=0.04) UBS vs. pNN50 (time domain) before training and r= 0.72 (p=0.02) LBS vs. HF (high frequency domain) after training. Discussion Before, the training correlations were found between UBS and pNN50 suggesting a preserved parasympathetic heart rate autonomic control in this population. After 16wk of CT strength levels it increased without any modification in the autonomic markers. Moreover, the correlation after training between LBS and HF reinforces that the increase in strength did not affect negatively the autonomic control. Perhaps some peripheral changes could have improved some central control that is reflected in the heart. References DE MEERSMAN, RE; STEIN, PK. (2007) Biol Psyc, 74,165-173. DOUCHI, T. et al. ### **EVALUATION OF RISK FACTORS RELATED TO HEALTH IN UNDERWEIGHT AND OBESITY**

ODABAS, I., BULGAN, C., GULER, L., MEHMET, T., AYDIN, S., AGOPYAN, A.

HALIC UNIVERSITY, SCHOOL OF PHYSICAL EDUCATION AND SPORT

Introduction Both fatness and thinness, two extreme points of body structure, are a risky structural condition. Therefore, the aim of this study was to evaluate the risk factors related to health of those whose body mass index levels are too low, those who are underweight and who are in a high level obesity condition. Method The study was carried out on the people who have attended to a sport-health

group for 5 years and they were in various age groups. Bone lengths, skinfold thickness and circumferences of the participants were measured and anthropometric standardization manual was used as the reference. Yuhazs formula was used for the body composition. They were asked Par- Q test and the questionnaire of the family history and sport habits of the participants. All data was evaluated by SPSS programme. Results There were total 227 participants in the study group and it was formed into two groups. First group was underweight group (N=105 mean age  $26,55 \pm 6,68$ , BMI:  $17,84 \pm 6,3$ ). Second group was obesity group (N= 112, mean age  $29, 41 \pm 9, 12$ ,  $33,37 \pm 2,8$ ), 34.3 % of the underweight group and 25.9 % of the obesity group had never been involved in sport activity. 5.7% of the underweight group had coronary heart disease, 14.3 % of the same group's mothers and 2.9 % of the group's fathers had the same disease while 9 % of the obesity group had this disease and 17.9 % of this group's fathers and 8% of this group's mothers had coronary heart disease. According to the Par Q test results, 14.3% of the underweight group and 12.5% of the obesity group had some chest pain because of the exercise. 3.8% of the underweight group and 4.5% of the obesity group had disorderly heart rate rhythms. The ratio of early heart attack risk in the family was 21.9 % for the underweight group while it was 25.9 % for the obesity group. Discussion The underweight group had done the exercises more than the obesity group and also they smoked and used alcohol more than the obesity group. Obesity group had more vascular heart problems, diabetes and respiratory problems than the other group. Metabolic disease ratio for both groups was similar. According to the Par Q test results, both groups had cardio vascular problems. Joint problems were intensive in the obesity group. Excessive thinness has risk factors like obesity but the risks for fatness more than the risks for thinness. References 1. Ha do T, Feskens EJ, Deurenberg P, Mai le B, Khan NC, Kok FJ. ### EFFECT OF PHYSICAL TRAINING ON BLOOD PRESSURE OF UNMEDICATED HYPERTENSIVE WORKERS

MELLO, A., SIMÃO, R., ALBUQUERQUE, M., SERRA, R.

UF RJ & PETROBRAS CPS/RBG

**Introduction** The employees' health is the concern of large corporations. The Brazilian company Petrobras / RBG, at its CENPES unit, has been promoting a fitness program for six years oriented by the School of Physical Education at Universidade Federal do Rio de Janeiro, Brazil. As part of the risk factors control for non-transmissible chronic diseases, physical exercises are recommended for the prevention, treatment and control of blood pressure (BP). The aim of this study was to investigate the BP behavior after four months of training in unmedicated hypertensive subjects. **Methods** Fifty-seven sedentary subjects participated in the program (time  $\geq 1$  year), divided into a training group (TG) and a control group (CG). All were physically assessed and the TG had three sessions per week, totaling 48 sessions, each lasting 60 minutes. They performed a 25-minute aerobic training between 50 to 70% of heart rate reserve, a strength training in two series ranging from 8 to 12 repetitions, and a flexibility training applying the static stretching method. BP was measured by auscultation at pre- and post training and data were processed by two-way ANOVA using the Scheffé post hoc when needed ( $p < 0.05$ ) for intragroup and intergroup comparison. **Results** The intragroup outcome for the TG showed an 11.4% reduction in systolic BP (SBP) ( $P < 0.05$ ) and 5.3% in diastolic BP (DBP) ( $P > 0.05$ ). The CG showed no changes in BP ( $P > 0.05$ ). Comparing CG and GT, there was a significant difference in SBP in post-training situation, but this did not occur in other measurements. **Discussion** Studies confirm the hypotensive effect after aerobic work (Pescatello et al., 2004), but few have investigated the post-exercise strength hypotension. Martins et al. (2004) followed medicated hypertensives subjected to strength, aerobic and flexibility sessions and after eight weeks they found no significant differences regarding the resting values in both groups; however the BP in the TG showed a tendency to reduction. Despite the methodological differences between our experiment and Martins and co-workers', we found higher reductions in BP, probably because our sample was not medicated and training lasted 16 weeks. With measurements taken 48 hours after the last session aiming to decrease the acute hypotensive effect immediately after exertion, we found a clinically significant reduction in BP at rest. **References** Pescatello LS, Franklin BA, Fagar R, Farquhar WB, Kelley GA, Ray CA. ### TRAINING, DETRAINING AND NON-ALCOHOLIC FATTY LIVER DISEASE IN RATS FED A HIGH FAT DIET

MOURA, L.P.1, SILVA, A.C.1, ARAÚJO, M.B.1, DALIA, R.A.1, JUNIOR, M.C.1, RIBEIRO, C.1, VOLTARELLI, F.A.1, MELLO, M.A.R.1

SÃO PAULO STATE UNIVERSITY

**TRAINING, DETRAINING AND NON-ALCOHOLIC FATTY LIVER DISEASE IN RATS FED A HIGH FAT DIET** Moura, LP.1, Silva, AC.1, Araújo, MB.1, Dalia, RA.1, Junior, MC.1, Ribeiro, C.1, Voltarelli, FA.1, Mello, MAR.1. 1: UNESP (Rio Claro-Brazil) **INTRODUCTION** In face to the nutritional transition, fat intake increased significantly in developing countries and this has been associated to fatty liver disease (NAFLD). Regular physical activity is recommended as a nonpharmacological treatment of NAFLD, but little is known on the effects of physical detraining. **OBJECTIVE** The aim of this study was to analyze the effect of exercise training, of detraining and of the administration of a high fat diet (HFD) on body weight (BW), insulin sensitivity (insulin tolerance test-ITT), serum Free Fat Acids (FFA) and triglyceride concentrations in the liver (LTG). **METHODS** Forty weanling rats (28 days) were fed up to 90 days of age with a commercial rat chow. From there, they were divided into four groups: control (C), sedentary rats fed AIN-93M diet (Reeves et al., 1996) from 90 to 160 days of age; High-Fat Diet (HFD) sedentary rats fed a diet containing 35% fat from 90 to 160 days of age; Trained High-Fat Diet (THFD) rats exercised from 28 to 160 days of age, fed a diet containing 35% fat from 90 to 160 days; Detrained High -fat Diet (DHFD) rats exercised from 28 to 90 days, whose exercise training was suspended, fed a diet containing 35% fat from 90 to 160 days. The exercised groups swam at 80% of anaerobic threshold, determined by the lactate minimum test performed every 25 days (Mello et al., 2010). **RESULTS** It was evident that the detraining accelerated BW gain (g) and physical training counteracted this (C:  $429.06 \pm 66.23$ ; HFD:  $461.73 \pm 63.51$ ; THFD:  $394.31 \pm 64.15$ ; DHFD:  $486.57 \pm 60.28$ ). The HFD group showed reduced insulin sensitivity, as estimated by the KITT (%/min) compared to the other groups and this situation is reversed by exercise training (C:  $3.67 \pm 0.61$ ; HFD:  $2.91 \pm 1.24$ ; THFD:  $8.42 \pm 2.72$ ; DHFD:  $3.24 \pm 1.78$ ). HFD rats had higher serum FFA concentrations ( $\mu\text{Eq/L}$ ) compared to the others groups (C:  $554.76 \pm 191.85$ ; HFD:  $747.74 \pm 176.61$ ; THFD:  $564.02 \pm 273.83$ ; DHFD:  $575.74 \pm 230.75$ ). The accumulation of LTG (mg/g) was higher in the groups receiving HFD and detraining worsened the condition (C:  $14.93 \pm 3.62$ ; HFD:  $17.56 \pm 4.44$ ; THFD:  $18.77 \pm 3.35$ ; DHFD:  $20.35 \pm 2.51$ ). **CONCLUSION** The high fat intake induced obesity and led to insulin resistance, increasing circulating FFA and accelerating liver fat accumulation. Detraining aggravates this scenario, contributing to the installation of NAFLD. **REFERENCES** 1. REEVES et al. aerobic threshold in weanling rats by lactate minimum test. Book of Abstracts 15th Annual Congress of the European College of Sport Science, 2010.15:171-172.

### **ASSOCIATIONS BETWEEN FREE LIVING ACTIVITY INTENSITY, ADIPOSITY, AND RISK MARKERS FOR CARDIOVASCULAR AND METABOLIC DISEASE**

KHALID S. ALJALOUD, ADRIENNE R. HUGHES, STUART D.R. GALLOWAY

*KING SAUD UNIVERSITY*

Associations between free living activity intensity, adiposity, and risk markers for cardiovascular and metabolic disease. Khalid S. Aljaloud, Adrienne R. Hughes, Stuart D.R. Galloway. Health and Exercise Science Research Group, University of Stirling, SCOTLAND, U.K. Introduction: Vigorous physical activity has been linked to greater longevity, greater loss of body fat mass, and improved insulin sensitivity. Current exercise guidelines now include recommendations for vigorous activity in recognition of these findings. The present study aimed to describe the free living physical activity intensity profile of lean (L) and overweight / obese (O/O) Scottish adults, and to investigate associations between activity intensity, adiposity, and risk markers of disease. Methods: 55 adults (n=33 L and n=22 O/O) attended the laboratory on 2 occasions. On the first session body mass, height, BMI, body fat and resting blood pressure and heart rate (HR) were recorded. Participants were then instructed to wear an ActiGraph accelerometer and HR monitor for two periods of 6 consecutive days to monitor free living activity intensity. Participants then attended the laboratory in the morning after an overnight fast (>10 hrs) to obtain a resting venous blood sample for analysis of cardiovascular and metabolic disease risk markers. Results: There was no significant difference between L and O/O groups in the percentage of registered time spent in sedentary behaviours or active behaviours (L 54.5±1.2%, O/O 54.9±2.1%, for sedentary behaviour). O/O and L adults completed 54.9±3.6 and 47.7±6.5 mins of moderate to vigorous physical activity (MVPA) per day, respectively. No differences were noted for percentage of active time in light or moderate intensity between groups. However, a significant difference (p<0.05) between groups was observed for percentage of active time spent in vigorous and very vigorous activity (L 2.7±0.5%, 65.3±12.3 mins/wk, O/O 1.4±0.4%, 33.4±11.0 mins/wk). O/O adults had higher total cholesterol (p<0.05), higher triglycerides, LDL and VLDL (all p<0.01), and lower HDL (p<0.01) than L. O/O also had higher leptin, insulin, HOMA-IR and hsCRP than L (all p<0.01). BMI and body fat (%) were most strongly correlated with many of these risk markers (r>0.45, p<0.01) but vigorous and very vigorous activity was correlated with HDL (r=0.30, p<0.05), LDL (r=-0.26, p=0.05) and ARA/EPA ratio (r=-0.30, p<0.05). Conclusion: The O/O adults had elevated cardiovascular and metabolic disease risk markers but L adults did not. Both groups achieved 30 min of MVPA per day, but the L group also met current guidelines for vigorous physical activity. Adiposity was strongly associated with disease risk markers, but vigorous activity was also associated with some risk markers. These data suggest that more work is needed to explore the beneficial effects of vigorous intensity exercise on adiposity and cardiovascular and metabolic risk markers.

### **THE EFFECTS OF A 12 WEEK WALKING PROGRAMME ON PHYSIOLOGICAL AND PSYCHOLOGICAL HEALTH.**

HOLLOWAY, K., WAKEFIELD, C., WATT, S.

*LIVERPOOL HOPE UNIVERSITY*

The Effects of a 12 Week Walking Programme on Physiological and Psychological Health. K. Holloway, C. Wakefield and S. Watt Faculty of Science and Social Sciences, Liverpool Hope University Background- The World Health Organisation (WHO) recommends that people should aim to walk 10,000 steps per day to improve their health and wellbeing. Many physiological (Bassuk & Manson, 2005) and psychological (Asci, 2003) benefits can be gained through increased physical activity levels. However, few studies have utilised both physiological and psychological measures to gain a holistic view of the benefits of exercise. Therefore, the aim of our study was to determine whether a 12 week walking programme could enhance both physiological and psychological health. Methods- Sixteen health-screened sedentary women (age 46±5years, body mass 72±11kg, BMI 27±4) completed the walking programme after giving their informed consent to the ethically approved procedures. The pedometer based walking programme consisted of each participant completing 10,000 steps per day for 12 weeks. Before, and at the end of the 12 weeks, percentage body fat was measured using bioelectric impedance, blood pressure using manual oscillation, and hip:waist ratio using standard procedures. Maximum oxygen consumption was also measured using the Rockport Fitness Test. Participants also completed the BREQ-2 (Markland & Tobin, 2004), EMI-2 (Markland & Ingledew, 1997), SPAS (Martin et al., 1997), PANAS (Watson et al., 1988) and SMBI (Stunkard et al., 1983). Results- Maximal oxygen consumption increased significantly (P<0.05) by 14% over the 12 week programme. A significant increase (P<0.05) was also found in hip:waist ratio due to a significant (P<0.05) decrease in hip circumference, but no change in waist circumference (P=0.243). Additionally, no significant alterations were found in blood pressure or percentage body fat. Positive affect decreased (P<0.05) and difference in weight showed a significant negative correlation (r=-.585, P<0.05) to current silhouette rating. Conclusion- This 12 week walking programme showed improvements in physical fitness but no indication of chronic disease risk reduction or a decline in body fat. The relationship between weight and current perception of body image indicates that focussing on a programme of this kind can raise awareness of current weight status. We conclude that walking 10,000 steps a day at a relatively low intensity can improve fitness, but contrary to WHO recommendations, is not sufficient to achieve improvements in health and psychological well being. #### **CALF AND FOREARM VENOUS COMPLIANCE IN ENDURANCE- AND RESISTANCE-TRAINED MEN**

KAWANO, H., MINETA, M., GANDO, Y., ASAKA, M., HIGUCHI, M.

*WASEDA UNIVERSITY*

Venous compliance of the extremities is a major determinant of the amount of blood that may be translocated to the central region, because small changes in peripheral blood volume can greatly impact cardiac filling pressure and subsequently cardiac output. Aerobic exercise as well as resistance exercise has become a popular modality of exercise performed by most populations, and has become an

integral component of exercise recommendations endorsed by a number of national health organizations. The purpose of the present study was to determine the calf and forearm venous compliance in daily endurance- and resistance-trained, age-matched sedentary control men. Fifteen endurance-trained (ET; age,  $21.0 \pm 0.4$  yrs; height,  $173.9 \pm 1.1$  cm; body weight,  $61.0 \pm 1.3$  kg), 12 resistance-trained (RT; age,  $20.8 \pm 0.6$  yrs; height,  $170.1 \pm 2.0$  cm; body weight,  $80.2 \pm 4.0$  kg), and 11 age-matched sedentary control men (SC; age,  $22.1 \pm 0.3$  yrs; height,  $172.5 \pm 2.1$  cm; body weight,  $66.0 \pm 2.4$  kg) were studied. Changes in calf and forearm volume were measured noninvasively using strain-gauge plethysmography at the maximal forearm circumference. Calf and forearm venous compliance were measured in supine subjects by inflating a venous collecting cuff, placed around the thigh and upper arm, respectively. After keeping cuff pressure 60 mmHg for 8 min, the cuff pressure was decreased at 1 mmHg/s to 0 mmHg. Venous compliance was determined using the first derivative of the pressure-volume relation during cuff pressure reduction (compliance =  $\beta_1 + 2 \cdot \beta_2 \cdot \text{cuff pressure}$ ). Maximal oxygen consumption was higher in ET ( $60.8 \pm 1.7$  ml/kg/min) compared with RT ( $37.1 \pm 1.7$  ml/kg/min) and SC groups ( $42.7 \pm 1.5$  ml/kg/min; both  $p < 0.05$ ). Calf and forearm muscular cross-sectional area measured by magnetic resonance imaging, was greater in RT ( $81.2 \pm 3.1$  cm<sup>2</sup> and  $47.2 \pm 1.1$  cm<sup>2</sup>) compared with ET ( $72.0 \pm 2.0$  cm<sup>2</sup> and  $32.2 \pm 1.3$  cm<sup>2</sup>) and SC ( $74.3 \pm 1.7$  cm<sup>2</sup> and  $36.1 \pm 1.0$  cm<sup>2</sup>; both  $p < 0.05$ ) groups. Calf venous compliance at 20 mmHg cuff pressure was 91% and 41% greater in ET ( $0.129 \pm 0.009$  ml/dl/mmHg) compared with RT ( $0.067 \pm 0.007$  ml/dl/mmHg) and SC groups ( $0.091 \pm 0.010$  ml/dl/mmHg; both  $p < 0.05$ ), respectively. Forearm venous compliance was not different between 3 groups. We concluded that venous compliance of the lower extremities were increased by habitual endurance training and decreased by resistance training, but unchanged upper extremities by these training in young men.

## EFFECTS OF AN INVERTED BODY POSITION ON MUSCLE FORCE AND CARDIOVASCULAR PARAMETERS

NEARY, J.P., SALMON, D.M., PRITCHETT, E., BEHM, D.G.

UNIVERSITY OF REGINA, REGINA SK; MEMORIAL UNIVERSITY, ST. JOHN'S NFLD, CANADA

**Introduction** Previous research has shown that significantly higher force production can be generated during a maximal voluntary contraction (MVC) in an upright vs. inverted postural position. It is suggested that this difference could be related to alterations in sympathetic nerve stimulation, which could alter cardiovascular (CV) responses (Paddock & Behm 2009). Our purpose was to determine the effects of postural changes on CV responses during MVC. We hypothesized that inversion would elicit a significantly different effect on selected CV parameters. **Methods** Twelve male subjects (age =  $22.5 \pm 1.6$  yr; mass =  $82.1 \pm 17.1$  kg; BMI =  $22.3 \pm 3.5$ ) completed three postural trials in random order on separate days: upright seated (U), supine seated (S), and inverted seated (I) position in a specially designed inversion chair. At baseline, a five-second MVC was performed using the dominant thigh (rectus femoris muscle) positioned at 90 degrees. The subject was then positioned for 150 sec in each posture, followed by a 30sec MVC (MVC30). During each trial, stroke volume (SV), cardiac output (CO), heart rate (HR) and mean arterial blood pressure (MAP) measurements were recorded using continuous monitoring finger plethysmography (Finometer). MVC force (N) was averaged over the 30sec. Results ANOVA showed no statistical differences in MVC force ( $U = 288.1 \pm 66.9$  N;  $S = 316.3 \pm 84.7$  N;  $I = 277.0 \pm 61.9$  N) but approached significance ( $p = 0.10$ ). Statistical differences were found for CV variables (SV, MAP, HR) from baseline to MVC30. While HR showed significant increase from baseline to MVC30 for each postural position ( $U = 33\%$ ;  $S = 34\%$ ;  $I = 25\%$ ), SV showed a corresponding significant decrease ( $U = 30\%$ ;  $S = 36\%$ ;  $I = 33\%$ ), resulting in no statistical changes in CO. Only HR showed differences between postural conditions post-MVC30, i.e., U ( $110 \pm 9.8$  bpm) and S ( $109.8 \pm 13.6$  bpm) vs. I ( $92.6 \pm 14.8$  bpm; 17%, 16% respectively). However, decreases in MAP (11%,  $p = 0.08$ ) and CO (18%,  $p = 0.08$ ) approached statistical significance from U vs. I. **Discussion** There are a number of scenarios where individuals may have to perform muscle contractions under inverted conditions (e.g., overturned submerged helicopter or motor vehicle, military operations). Research has shown that MVC force is impaired in a seated inverted position (Paddock & Behm 2009) ( $p = 0.10$  in our study), and this impairment was related to neuromuscular activation. Collectively, the CV results presented here suggest that the reduction in HR (17%,  $p = 0.003$ ), MAP (11%,  $p = 0.08$ ) and CO (18%,  $p = 0.08$ ) may be related to an inversion-induced inhibition of sympathetic stimulation (Bosone et al. 2004; Hearn et al., 2009). Further research is warranted to investigate whether prolonged inversion has an effect on neuromuscular and cardiovascular parameters. Paddock N, Behm D. Appl Physiol Nutr Metab, 34:673-680, 2009 Bosone et al. Funct Neurol, 19: 31-35, 2004 Hearn et al. Eur J Appl Physiol, 106:139-147, 2009 Support: NSERC Canada (JPN, DGB)

## CUTANEOUS MICROVASCULAR FUNCTION FOLLOWING ECCENTRIC EXERCISE IN HUMANS

MCNULTY, C., SMITH, C.A.J., PATEL, K.H., STREATER, R.L., VAN ZANTEN, J.J., WAGENMAKERS, A.L.M., FISHER, J.P.

UNIVERSITY OF BIRMINGHAM

Muscle damage induced by eccentric exercise (i.e. the lengthening of a muscle under tension) can induce inflammation and oxidative stress. Inflammation and oxidative stress are associated with vascular dysfunction. The purpose of the present study was to test the hypothesis that eccentric exercise induced muscle damage would cause short term (24-48 hr) microvascular dysfunction. Ten healthy, non-weight trained males (mean age  $19 \pm 0.2$  yr) performed eccentric exercise (50 repetitions at 110% concentric 1 repetition max) with the knee extensors of the non-dominant leg. Cutaneous microvascular responses to iontophoresis of acetylcholine (1%, endothelial-dependent vasodilatation) and sodium nitroprusside (1%, endothelial-independent vasodilatation) were assessed with laser Doppler flowmetry. Heart rate, blood pressure, whole limb blood flow (venous occlusion plethysmography) and leg muscle pain were also assessed. All measurements were made pre-exercise (baseline), 24 and 48 hr post exercise. Rating of leg muscle pain was increased 24 and 48 hr post exercise ( $P < 0.05$ ). Endothelial-dependent cutaneous vasodilatation tended to increase at 24 hr ( $P = 0.16$  vs. baseline), but was unchanged at 48 hr ( $P > 0.05$  vs. baseline). Heart rate, arm blood flow and leg blood flow remained unchanged 24 and 48 hr post eccentric exercise. Blood pressure was reduced at 48 hr ( $< 5$  mmHg,  $P < 0.05$  vs. baseline). Our preliminary data suggest that muscle damage following single-legged knee extensor eccentric exercise does not induce cutaneous microvascular dysfunction in humans.

## INDUCED PERIPHERAL AUTONOMIC SURFACE POTENTIALS OF ELITE ATHLETES

SUKHOV, S., IVANOV, A.

NATIONAL RESEARCH AND PRACTICAL CENTRE OF PHYSICAL CULTURE

**Introduction** Induced peripheral autonomic surface potentials (PASP) are the change of electrodermal activity in response to a stimulus. Analysis of PASP allows getting the information on the status of vegetative nervous system (VNS). Goal of the study was to investigate PASP in elite athletes and young male non-athletes. **Methods** PASP were studied with use of a hard- and software complex VNS-Spectrum. There were taken measures of the PASP: latent period (s) - LP PASP; A1 (mV) - first phase amplitude, S1 (s) - duration of the first phase, A2 (mV) - second phase amplitude, S2a (s) - duration of the ascending portion of the second phase, S2b (s) - duration of de-

scending portion of the second phase. Twenty-five judoists (experimental group) and fifteen healthy male non-athletes (control group) have been examined. Results At electric stimulation, the LP was similar in both groups (experimental group –  $1.40 \pm 0.05$ s, control group –  $1.39 \pm 0.12$ s). Amplitude of the first phase (A1 –  $0.83 \pm 0.15$ mV) and second phase (A2 –  $3.01 \pm 0.36$ mV) in the experimental group was significantly higher than in the control group (A1 –  $0.39 \pm 0.10$ mV, A2 –  $1.16 \pm 0.31$ mV, respectively) ( $p < 0.05$ ). Durations of S1 and S2a were the same in both groups (S1 –  $0.82 \pm 0.10$ s in the experimental group and  $0.81 \pm 0.09$ s in the control group; S2a –  $1.22 \pm 0.15$ s and  $1.24 \pm 0.16$ s, respectively). S2b in the experimental group at electric stimulation was somewhat higher as compared with the control group (S2b –  $2.65 \pm 0.23$ s and  $1.96 \pm 0.25$ s, respectively), while at spatial stimulation (electric + acoustic stimulation), these indicators were equal (S2b –  $2.79 \pm 0.17$ s and  $2.63 \pm 0.19$ s, respectively). At spatial stimulation the A1 and A2 were somewhat higher in both groups as compared with electric stimulation (A1 – experimental group –  $1.12 \pm 0.12$ mV, control group –  $0.65 \pm 0.14$ mV, A2 – experimental group –  $0.65 \pm 0.14$  mV, control group –  $2.64 \pm 0.27$ mV), and the athletes also had a significantly higher figures. A1 increases at parasympathotonia and decreases at sympathicotonia. A2 reflects activity of the above-the-segment (primarily hypothalamic) ergotropic centers. Based on the above date, one can suggest a well balance of parasympathetic and sympathetic parts of VNS in athletes. Conclusion Amplitudes of the first and second phase of PASP in athletes are higher as compared with young male non-athletes but such increase is synchronous and evidences to a higher level of VNS function at maintaining the balance between its parasympathetic and sympathetic parts.

## REGIONAL DIFFERENCES IN BLOOD FLOW, GLUCOSE UPTAKE, AND FATTY-ACID UPTAKE WITHIN QUADRICEPS FEMORIS MUSCLE GROUP DURING DYNAMIC KNEE-EXTENSION EXERCISE

LAAKSONEN, M.S., KEMPPAINEN, J., KNUUTI, J., NUUTILA, P., KALLIOKOSKI, K.K.

MID SWEDEN UNIVERSITY

Regional differences in blood flow, glucose uptake, and fatty-acid uptake within quadriceps femoris muscle group during dynamic knee-extension exercise Laaksonen, M.S. 1, Kemppainen, J. 2, Knuuti, J. 2, Nuutila, P. 2, Kalliokoski, K.K. 2 1: Swedish Winter Sports Research Centre, Mid Sweden University, Sweden, 2: Turku PET Centre, University of Turku, Finland Introduction During exercise the deeper muscle parts (vastus intermedius; VI and vastus medialis; VM) of quadriceps femoris (QF) seem to have higher blood flow (BF) compared to the more superficial parts (vastus lateralis; VL and rectus femoris; RF) (1, 3). In the present study we tested the hypothesis that glucose (GU) and free fatty acid uptake (FFAU) are similarly dispersed between QF muscle parts as blood flow during dynamic knee-extension exercise. Methods Totally 17 healthy male subjects were studied during 70 min low-intensity dynamic knee-extension exercise at 5 W. BF, GU and FFAU were measured in the four parts of the QF muscle group using positron emission tomography, and [ $^{15}\text{O}$ ]H $_2$ O, [ $^{18}\text{F}$ ]FDG and [ $^{18}\text{F}$ ]FTHA tracers. Results Muscle BF was higher ( $p < 0.05$ ) in VI ( $46 \pm 17$  mL 100g $^{-1}$  min $^{-1}$ ) than in VL ( $30 \pm 13$  mL 100g $^{-1}$  min $^{-1}$ ), but not significantly different compared to the other two parts (RF  $35 \pm 16$  and VM  $37 \pm 15$  mL 100g $^{-1}$  min $^{-1}$ ). In contrast, GU was highest in RF ( $40 \pm 31$  mikromol 100g $^{-1}$  min $^{-1}$ ) and significantly higher than in VL ( $15 \pm 6$  mikromol 100g $^{-1}$  min $^{-1}$ ) and VM ( $18 \pm 10$  mikromol 100g $^{-1}$  min $^{-1}$ ), both  $p < 0.01$ , but not significantly in comparison to VI ( $25 \pm 14$  mikromol 100g $^{-1}$  min $^{-1}$ ). FFAU was similar in all muscle areas (VL  $1.8 \pm 0.8$ , RF  $1.8 \pm 0.9$ , VI  $2.4 \pm 0.9$ , VM  $2.1 \pm 0.8$  mikromol 100g $^{-1}$  min $^{-1}$ ; ns). Calculated extraction of glucose was significantly higher in RF than in all other areas, but FFA extraction was not different between the QF parts. Discussion According to the present results there are regional differences in muscle BF and metabolism within the working muscle during exercise. Interestingly, BF seems to be highest in VI, while GU was highest in RF. This resulted in significantly higher glucose extraction in RF than in VI and other two muscles. The reason for this is unknown, but we can speculate that it might be due to i) different fiber type distribution between the studied muscles leading to different fuel selection (5), ii) differences in sarcolemmal glucose transport (2) or iii) different muscle activation and its relation to BF between these muscles (4). An important methodological point from these results is that one sample of an individual part of QF does not represent the response in the entire QF muscle group, since the dispersion between parts may vary according to measured parameters. ## COMPARISON OF VARIATIONS OF SYSTOLIC AND DIASTOLIC TIMES ON INCREASING HEART RATE DURING ERGOMETRY TESTS ON HEALTHY ATHLETES VS. SEDENTARY SUBJECTS HAVING STRESS-INDUCED ISCHEMIA.

GALINDO, M., CUPEIRO, R., CALDERÓN, F.J., TOLEDO, G.

PHYSICAL ACTIVITY AND SPORT SCIENCES COLLEGE. UNIVERSIDAD PLITÉCNICA MADRID.

The purpose of this study is to compare the variations in systole duration and diastole duration during increasing intensity exercise in two different populations: sedentary subjects having stress-induced ischemia vs. healthy athletes. Methods: the population of our study is formed by two different groups. The first one consists of 23 healthy asymptomatic male athletes. The second group is formed by 24 sedentary subjects who had a stress induced ischemia when undergoing the stress test. The individuals of the first group were screened obtaining a 12 lead electrocardiography (ECG), as well as an incremental ergoespirometry on cycle-ergometer. The second group underwent an incremental ergometry on treadmill with Bruce protocol. During stress tests, we continuously monitored the heart with a 12-lead ECG as well as blood pressure. All the subjects of the second group had stress-induced electrocardiographic signs of ischemia, so, to avoid false positive cases, a nuclear imaging procedure was carried out, confirming the ischemia. All the subjects of this group had positive results in both tests. Results: in both groups diastole time experienced a much larger decrease from resting heart rate to maximal heart rate than systole. It becomes especially remarkable from resting heart rate to approximately 50% of the maximal theoretical heart rate. Thereafter diastole time becomes slightly shorter than systole time until heart rate begins to slow down on recovery phase. This trend is very similar in some other studies. Even though, interaction between health status group and stress-induced ischemia group was found ( $p < 0.001$ ), since healthy subjects were found to have higher systole and diastole durations at rest, but lower durations at maximal effort. Rest and maximal-effort differences parameters were higher for healthy subjects ( $p < 0.001$ ). Conclusions: the duration of the cardiac cycle reduces at the expense of a bigger decrease in diastole time than systole time in both groups. Still, there are significant differences between systole and diastole duration in the two groups, which might be useful to help predict or diagnose ischemia after further research. **ORTHOSTATIC EFFECTS ON ECHOCARDIOGRAPHIC MEASURES OF VENTRICULAR FUNCTION**

UNNITHAN, V.1, ROWLAND, T.2, BARKER, P.3, GUERRA, M.4, LINDLEY, M.5, ROCHE, D.6

1: STAFFORDSHIRE UNIVERSITY 2: BAYSTATE MEDICAL CENTER, SPRINGFIELD, MA, USA, 3: DUKE UNIVERSITY, NC, USA, 4: UNIVERSITAT RAMON LLULL, BARCELONA, 5: LOUGHBOROUGH UNIVERSITY 6: LIVERPOOL HOPE UNIV.

Introduction Orthostatic-induced alterations in Doppler echocardiographic measures of ventricular function have not been well-defined. Identifying such changes may provide useful insights regarding the responses of these measures to variations in ventricular loading conditions. Methods Standard assessment of mitral inflow velocity and tissue Doppler imaging of left ventricular longitudinal myocardial velocities was performed on 14 young males (mean age  $17.9 \pm 0.7$  years) in the supine position and then five minutes after assuming a sitting position with legs dependent. Results Upon sitting, average values of stroke volume and cardiac output fell by 28 percent and 18 percent, respectively, while heart rate increased from  $64 \pm 10$  bpm to  $73 \pm 12$  bpm (+14 percent) and calculated systemic vascular resistance rose from  $12.9 \pm 2.2$  to  $16.4 \pm 3.1$  units (+27 percent). Mitral E peak velocity declined from  $87 \pm 16$  cm/s to  $64 \pm 16$  cm/s, and average TDI-E' and TDI-S both decreased (by -44% and -20 percent, respectively). The magnitude of these declines were similar when values were adjusted for left ventricular size. Discussion These findings suggest that a) decreases in TDI measures when assuming the upright position reflect responses to increases in systemic vascular resistance (afterload) rather than changes in ventricular filling (preload), and b) values of E/E' do not reflect alterations in ventricular preload which occur during an orthostatic challenge.

**EFFECT OF BLOOD FLOW RESTRICTION ON ECCENTRIC CONTRACTION INDUCED-MUSCLE FIBER DAMAGE AND HYPERTROPHY SIGNALING PATHWAY IN RAT MODEL**

SUDO, M., KANO, Y.

PHYSICAL ACTIVITY

Mizuki Sudo 1 and Yutaka Kano 2 1. Institute for Physical Activity, Fukuoka Univ., Fukuoka, Japan. 2. Department of Engineering Science, Bioscience and Technology Program, Univ. of Electro-communications, Chofu, Tokyo, Japan. Introduction Resistance exercise containing eccentric contraction (ECC) is an effective training method that can improve muscle mass compared with isometric / concentric contraction exercise. Also it is well known that ECC training occurs higher muscle fiber damage. Recently, low-intensity muscle contraction with blood flow restriction (BFR) has been shown to stimulate muscle hypertrophy signaling and muscle protein synthesis (Fry et al., 2010). However, the effect of BFR on ECC induced-muscle fiber damage and hypertrophy signaling pathway is unclear. Thus, we hypothesized that ECC with BFR activates hypertrophy-signaling pathway despite suppressed muscle damage due to low-intensity muscle tension. The purpose of present study was to investigate 1) the effects of ECC with BFR on degree of skeletal muscle fiber damage, 2) the activation level of muscle hypertrophy-signaling pathway in rat model. Methods In anesthetized rats (Wistar, male, 12 weeks old), the right tibialis anterior muscles were subjected to 40 times-repeated ECC with/without occlusion pressure (BFR: 120, 140, 160, 200 mmHg, by the cuff for occlusion). ECC was evoked by surface electric stimulation (100 Hz, ~ 10 V) while the muscle was being stretched by an electromotor. Three days after BFR+ECC, the muscle damage was evaluated from hematoxylin-eosin stained cross-sections as relative number of damaged fibers in relation to intact fibers. Protein phosphorylation of hypertrophy factor (S6K-Thr 389) was measured by Western blot. Results and Discussion The muscle fiber damage occurred in ECC with 120 mmHg BFR ( $26.1 \pm 1.4\%$ ,  $n=4$ ) and ECC ( $28.6 \pm 1.2\%$ ). However, the collapsed/obstructed muscle fibers were not observed in the 140 ( $2.6 \pm 0.7\%$ ,  $n=4$ ), 160 ( $2.7 \pm 1.2\%$ ,  $n=4$ ), 200 ( $3.1 \pm 0.3\%$ ,  $n=6$ ) BFR+ECC. These results reveal that muscle damage is inhibited depending on BFR level. This inhibition may be related with a reduction of muscle force level during 40 times-repeated ECC. In fact, the average tension was significantly reduced in BFR conditioning (ECC:  $7.47 \pm 0.75$  mNm, 200 ECC+BFR:  $4.56 \pm 0.53$  mNm). Interestingly, we also found that phosphorylation of p70S6K at Thr 389 significantly increased both BFR+ECC (290%) and ECC (279%) groups compared with non-exercise muscle. These results imply that activation of muscle growth factor signal independent of muscle damage. Conclusions We conclude that 1) ECC-induced skeletal muscle damage was suppressed by combination of BFR, 2) BFR+ECC activated the muscle hypertrophy-signaling at the same level as ECC without BFR. ECC in combination with BFR is a novel and effective approach for muscle mass developing. Reference Fry CS, Glynn EL, Drummond MJ, Timmerman KL, Fujita S, Abe T, Dhanani S, Volpi E, Rasmussen BB. **THE RELATIONSHIP BETWEEN SKIN-GAS NITRIC OXIDE AND SERUM NITRITE CONTENTS AFTER MUSCLE-DAMAGING EXERCISE**

ITO, H., OHKUWA, T., YAMAZAKI, Y., TSUDA, T., YAMANE, M.

NAGOYA INSTITUTE OF TECHNOLOGY

Introduction Muscle damage-induced reduction in force generation is accompanied by increased nitric oxide (NO) content in human skeletal muscle (Radák et al. 1999). Previously, we (Ohkuwa et al. 2006) have been detected NO emanating from human skin (skin-gas), however, no one has confirmed the relationship between skin-gas NO concentrations and serum nitrite concentrations after muscle damage-induced exercise. Therefore, we examined whether skin-gas NO concentrations on the surface of damaged muscle would relate in serum nitrite concentrations or not in human after muscle-damaging exercise. Methods Seven healthy male students volunteered as the subjects. None of them had performed muscle-damaging exercise at least six months prior to the experiment. The subjects performed 8 sets of 15 repetition-maximum (RM) knee flexion-extension exercise (left leg only) consisting of predominantly isokinetic eccentric contractions. The skin-gas samples were obtained from the surface of the belly muscle of the rectus femoris before exercise and 1, 2, 3, 7 days after exercise. The skin-gas NO concentration was measured by a chemiluminescence analyzer (Pico-Device Co., Ltd., Nagoya, Japan). Knee extension muscle strength (1RM), circumference of the thigh, muscle soreness (visual analog scale; VAS) of exercised left leg, and serum nitrites were also measured. Results Both the skin-gas NO concentration and the serum nitrite concentration significantly increased 2 days after the exercise compared to pre-exercise values ( $p < 0.01$ ). Thus, there was a significant relationship between the skin-gas NO concentration and the serum nitrite concentration ( $p < 0.05$ ). Muscle strength significantly ( $p < 0.05$ ) decreased, and VAS significantly ( $p < 0.05$ ) increased compared to the pre-exercise values 1-3 days after exercise, although no significant difference was found in the circumference of the exercised thigh during experimental period. Discussion In this study, the exercise induced mechanical muscle damages and pathological changes such as fiber necrosis and inflammatory cell infiltration that become apparent a few days later (Maruhashi et al. 2007). Moreover, delayed reactive oxygen species (ROS) production to inflammatory reactions induced in damaged muscle (Close et al. 2004). Therefore, increased skin-gas NO concentrations in this study may due to activation of induced NO synthase in the damaged muscle cells or in activated macrophages, and increased serum nitrite concentrations. Conclusions Skin-gas NO concentrations on the surface of damaged muscle increased and closely related to increasing serum nitrite concentrations after

muscle-damaging exercise. References Close, G. I. et al. (2004) *Eur J Appl Physiol* 91, 615-621. Maruhashi, Y. et al. (2007) *J Physiol Sci.* 57, 211-216. Ohkuwa, T. et al. (2006) *Int J Biomed Sci.* 2, 100-104. Radák, Z. et al. (1999) *Free Radic Biol Med.* 26, 1059-1063.

### THE EFFECT OF MUSCLE METABOREFLEX ON THE SUPERFICIAL VENOUS VASCULAR RESPONSE OF THE INACTIVE LIMB

OOUE, A., NAOI, N., SATO, K., HIRASAWA, A., SADAMOTO, T.

JAPAN WOMEN'S COLLEGE OF PHYSICAL EDUCATION

**Introduction** Blood vessels of the superficial vein in the inactive limb constrict sympathetically during exercise (Lorentsen 1975). However, this mechanism is unclear. One of the mechanisms which cause the increase in sympathetic nerve activity during exercise is thought that accumulation of metabolites within the muscle triggers chemosensitive afferents (metaboreflex). In addition, it is reported that this reflex causes the decrease in venous blood volume of the inactive limb (Duprez et al. 1992). Thus, the purpose of this study was to test our hypothesis that superficial venous vessel constriction in the inactive limb may be modulated by the sympathetic excitation via muscle metaboreflex. **Methods** Twelve young subjects performed 1.5-min static handgrip exercise at 45% of maximal voluntary contraction (MVC), and then had 2-min recovery period, which their exercising upper arm was occluded over 220 mmHg to activate metaboreceptors (OCCL) and was not occluded as control condition (CONT). Measurements were heart rate (HR), mean arterial pressure (MAP) and cross sectional area (CSA) in the basilic vein of the inactive upper arm. Venous CSA measurement, using B-mode ultrasound technique, was made under a congestive pressure of 50 mmHg by inflating a cuff placed on the inactive upper portion. **Results** During handgrip exercise, HR and MAP increased and venous CSA decreased from baseline level at both CONT and OCCL. During recovery period, HR returned baseline level at both conditions. However, the increase in MAP and the decrease in venous CSA were maintained during recovery period at OCCL, although MAP and venous CSA returned baseline level during recovery period at CONT. **Discussion** In this study, during recovery period at OCCL, the increase in MAP was maintained, suggesting that muscle metaboreceptors were stimulated by metabolites. In this time, the decrease in venous CSA was kept at OCCL, although venous CSA returned baseline level at CONT. During recovery period, central command and mechanoreflex, which is thought to cause the increase in sympathetic nerve activity during exercise, do not act. Thus, our result suggests that superficial venous vascular response might be modulated by the sympathetic nerve system via muscle metaboreflex. **References** Duprez DA, De Buyzere M, De Sutter JM, Deman SA, De Pue NY, Clement DL. ### PASSIVE EXERCISE WITH BLOOD FLOW RESTRICTION INCREASES CROSS-SECTIONAL AREA AND STRENGTH IN THIGH MUSCLES

KUBOTA, A.1, SAKURABA, K.1,2, KATO, H.2, OGURA, Y.3, KOH, S.4

1: SPORTOLOGY CENTER, JUNTENDO UNIVERSITY, JAPAN, 2: SCHOOL OF HEALTH AND SPORTS SCIENCE, JUNTENDO UNIVERSITY, JAPAN, 3: ST. MARIANNA UNIVERSITY SCHOOL OF MEDICINE, JAPAN AND 4: KOH ORTHOPAEDIC CLINIC

**Introduction** The high-intensity exercise must be done to increase muscle volume and strength generally, however, it cannot be applied for person who is impossible to perform any active exercises. Therefore, we aimed in this study to clarify the effects of passive exercise with blood flow restriction on cross-sectional area (CSA) and strength of thigh muscles. **Methods** Seven male college swimmers (Age: 19.1 ± 1.1 yr, Height: 176.1 ± 5.9 cm, Weight: 70.9 ± 5.4 kg) volunteered for this study. The right leg of all subjects was assigned to a control condition (CON) and the left leg of them was assigned to a passive exercise with blood flow restriction condition (PEB). In the PEB legs, the passive exercise was performed 3 days per week for 8wk. The passive exercise consisted of 3 or 4 sets of repeated (150 times) passive knee extension and flexion using a Biodex unit, separated by 3 min interval. Before and after the experimental period, knee extensor-flexor muscle strengths were evaluated in following settings: concentric contraction at angular speeds of 60, 180 and 300 deg/s (CC60, 180 and 300), eccentric contraction at angular speeds of 60 and 180 deg/s (EC60 and 180), and isometric contraction. In addition, both knee extensor and flexor muscle CSA were analyzed with MRI before and after the experimental period. All the subjects had participated in usual training programs of their swimming team throughout current experimental period. **Results** In knee extensor torque, the extent of increase in strength at CC60 was significantly higher ( $p < 0.05$ ) in the PEB legs ( $16.1 \pm 11.5\%$ ) than in the CON legs ( $4.6 \pm 4.8\%$ ). Although CSAs in knee extensor and flexor muscles were significantly increased after the experimental period in the both legs ( $p < 0.01$  respectively), the percent changes in the CSA of knee extensor muscles were significantly ( $p < 0.05$ ) higher in the PEB legs ( $5.2 \pm 2.5\%$ ) than in the CON legs ( $2.5 \pm 1.5\%$ ). **Conclusion** A passive exercise with blood flow restriction is an effective intervention to increase both the muscle volume and strength. **References** Takarada Y, Takazawa H, Ishii N. ### AEROBIC EXERCISE-INDUCED CHANGES OF ANKLE BRACHIAL PRESSURE INDEX AND MENSTRUAL CYCLE-DEPENDENT INFLAMMATION

HAYASHIDA, H., SHIMURA, M., SUZUKI, K.

WASEDA UNIVERSITY

**Introduction** Nitric oxide (NO) is the most important mediator, and its intrinsic vasodilator function is commonly used as an index of endothelial function. Shear stress on endothelial cells is a stimulus for endothelial nitric oxide synthase (eNOS) during acute exercise (Boo YC & Jo H, 2003). NO has vasodilatory effects and increases blood flow, which facilitates the delivery of glucose to the capillary of skeletal muscle. Meanwhile, inducible nitric oxide synthase (iNOS) is mainly expressed in leukocytes (Niess et al., 2000), which express high-levels of sustained NO synthase when cells are activated. However, the role of iNOS in exercise depending on the menstrual cycle is still not clear. The aim of this study was to examine the hypothesis that exercise-induced vascular reactivity decreases through NO which is increased by leukocyte activation. We investigated exercise-induced changes in variables of the ankle brachial pressure index (ABPI), NO production and leukocyte activation during the normal menstrual cycle. **Methods** Ten healthy sedentary females (aged 20.5±0.7 years, mean ± SD) performed 60 min of cycling at 75% of their individual anaerobic threshold (AT) at three phases of the menstrual cycle (menstrual, follicular and luteal phases). ABPI was evaluated before and after exercise. ABPI is a measure of the blood pressure in the arteries supplying legs relative to central, aortic pressure (approximated by measuring the blood pressure in the arm). Capillary blood samples were collected at three time points: before, immediately after and 30 min after exercise. We measured the concentrations of plasma nitrotyrosine as a marker of NO production, interleukin (IL)-6 and calprotectin as markers of inflammation and leukocyte activation. **Results** ABPI decreased after exercise in the menstrual phase ( $p < 0.01$ ), whereas no changes were observed in follicular and luteal phases. IL-6 increased following exercise in all phases and calprotectin increased immediately after exercise in the menstrual phase ( $p < 0.05$ ). A

positive correlation was observed between exercise-induced changes in nitrotyrosine and calprotectin in the menstrual phase only ( $r=0.49$ ,  $P<0.01$ ). Conclusion This study shows the possibility that aerobic exercise induces leukocyte activation, and NO which is produced by leukocyte activation might affect vascular reactivity after exercise, especially in the menstrual phase. #### EFFECT OF DIFFERENCE OF WATER TEMPERATURE ON ARTERIAL STIFFNESS DURING SUPINE POSITION IN WATER

SAITO, T.1, TAKAHARA, T.1, MATSUMOTO, N.2, TAKAGI, Y.1, NOSE, Y.1, ARAKANE, K.1, KURATO, R.1, OIKAWA, K.1, HARA, S.1, YOSHIOKA, A.3, ONODERA, S.4

1: GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE, 2: SHUJITSU JUNIOR UNIVERSITY, 3: KAGAWA UNIVERSITY, 4: KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: It is known that heart rate, oxygen uptake and body temperature are affected by the physical characterization of water (water temperature, buoyancy, viscosity, etc). Previous studies demonstrated that increase of venous return by physical characteristics of water caused decrease of heart rate, cardiac vagal activity was enhanced and sympathetic nervous activity was suppressed during supine floating set to a water temperature of 30 degrees Celsius. Core body temperature was changed by water temperature. Therefore, we hypothesized that cardiac autonomic nervous activity, heart rate and blood pressure could change. The purpose of this study was to make clarified the effect of difference of water temperature on arterial stiffness during supine position in water. METHODS: Healthy young Japanese males ( $n=6$ ) volunteered to participate in this study. We had informed consent prior to participation in this study. The age, body weight and body height of subjects were 21 (SD: 0.75) years old, 69.3 (SD: 14.3) kg and 171.8 (SD: 6.8) cm, respectively. This study was consisted in two water temperatures. One was 30 degrees Celsius, the other was 36 degrees Celsius. Subjects were measured baPWV (brachial-ankle pulse wave velocity), heart rate and blood pressure after supine position in water for 5 minutes. RESULTS: The baPWV at 30 degrees Celsius was significantly higher than at 36 degrees Celsius (30 degrees Celsius  $1187\pm 75$  cm/s, 36 degrees Celsius  $1071\pm 68$  cm/s;  $P<0.05$ ). Heart rate and blood pressure were no difference between 30 degrees Celsius and 36 degrees Celsius. DISCUSSION: Heart rate and blood pressure are potentially influential factor of the baPWV. These results did not find a clarified relationship between heart rate and blood pressure. It is suggested that the baPWV was influenced by difference of water temperature during supine position in water. CONCLUSION: Arterial stiffness is influenced by difference of water temperature during supine position in water. ### PP-PM64 Physiology: Altitude and Hypoxia 1

#### HYPOXIA MEDIATED INCREASES IN BASAL MONOCYTE EXPRESSED HSP32.

TAYLOR, L., HILLMAN, A., MIDGLEY, A., CHRISMAS, B., PEART, D., MCNAUGHTON, L.

THE UNIVERSITY OF BEDFORDSHIRE

HYPOXIA MEDIATED INCREASES IN BASAL MONOCYTE EXPRESSED HSP32. Taylor, L.1,2, Hillman, A.2, Midgley, A.2, Christmas, B.2,1, Peart, D.2, McNaughton, L.3. 1: University of Bedfordshire (ISPAR) (UK) 2: University of Hull (UK) 3: Bond University (Australia) Introduction Inducible haem oxygenase-1 or heat shock protein 32 (HSP32) is known to be inducible under conditions of oxidative stress. Eccentrically exercised rat muscles (Essig et al., 1997), and human leukocytes post endurance exercise (Niess et al., 1999), have shown increases in HSP32 post exercise. However, the in vivo monocyte HSP32 (mHSP32) response to hypoxia (elevated altitudes) has not been investigated. Such hypoxia mediated changes in mHSP32 may be related to in vivo alterations in redox balance; therefore, changes in redox balance were assessed in tandem with measures of mHSP32. Methods Eight healthy recreationally active male subjects (mean  $\pm$  SD age  $20.8\pm 3.2$  years, height  $1.77\pm 15.7$  cm, body mass  $72.1\pm 11.0$  kg) consented to take part in the study. The hypoxic exposure (75 min, 2980 m) was administered once daily for five consecutive days at rest, commencing and ceasing at 0930 and 1045 respectively. Hypoxia was generated via a hypoxicator. Blood samples were obtained pre day one and post day five of the hypoxic period. mHSP32 was analysed via Flow Cytometry. Reduced (GSH), oxidised (GSSG) and total (TGSH) glutathione as well as TBARS were assessed using commercially available kits. Results In comparison to pre exposure values (pre hypoxia day one) there were significant increases in mHSP32 ( $p = 0.03$ ), GSSG ( $p < 0.001$ ) and TBARS ( $p = 0.001$ ), whereas no significant changes were observed for GSH ( $p = 0.22$ ) and TGSH ( $p = 0.25$ ) post hypoxic exposure period (post hypoxia day 5). Discussion To our knowledge this is the first study to show the in vivo effects of hypoxia (75 min, 2980 m) on mHSP32 expression. This increase in mHSP32, may, through further work, be attributed to the increase in markers associated with negative changes in redox balance (GSSG and TBARS). This increase in mHSP32 is in line with previous hypoxia mediated increases in inducible heat shock protein 72 (Taylor et al., 2010; Taylor et al., 2011). The increase in basal mHSP32 values may confer cellular protection to subsequent challenges to redox balance, in line with in vitro models of cellular preconditioning, postulations such as these require further investigation. #### ACUTE MOUNTAIN SICKNESS DURING A NATURAL ALTITUDE TRAINING CAMP IN ELITE SWIMMERS

CALDERÓN, C.1, RODRÍGUEZ, F.2, IGLESIAS, X.2, FERICHE, B.3, PÉREZ, I.2, TRUIJENS, M.4, VÁZQUEZ, J.2, ÁBALOS, X.2, RODRÍGUEZ, L.2, RODRÍGUEZ, C.2, BARRERO, A.2

1: CAR SIERRA NEVADA (GRANADA, SPAIN), 2: INEFC (UNIVERSITY OF BARCELONA, SPAIN), 3: FCAFD (UNIVERSITY OF GRANADA, SPAIN), 4: ROYAL DUTCH SWIMMING FEDERATION (NETHERLANDS).

Introduction Altitude training (AT) has great potential for improving athletic performance but it may also be associated to some potential health risks, as those related to acute mountain sickness (AMS). The aim of this study is to analyze the prevalence and features of AMS in

a group of elite athletes training at moderate natural-terrestrial altitude. Methods 29 elite swimmers of two national teams (14 women, 15 men), mean age 21.2 (SD 2.2), lived and trained during 3 weeks at 2320 m (Altitude Training Center of Sierra Nevada, Spain). Each day subjects filled in the AMS Lake Louise questionnaire (LL, 5 items, 0-3 score), and a modified, extended version (TSF10, 10 items, 1-7 score) of the Total Score of Fatigue questionnaire (Atlaoui 2004). In both cases mean and 50-percentile (P50) was calculated (LL-score and TSF10-score). Training load was quantified during each individual session by the Training Impulses method (Banister 1991) and estimated for total daily training (TRIMPS-d). Results All subjects experienced AMS symptoms, main of all fatigue, headache and sleep disturbances. In most cases AMS was mild, but 24% of the swimmers experienced some severe symptoms. Mean LL-score was 2.03 (SD 1.96), with no gender differences but with great individual variability (0 to 11 points). The highest LL-score value was observed the first day (mean=2.43, P50=3), while the lowest was at the end of the first week (day 7, mean=1.37, P50=1). A positive correlation was found between LL-score and TSF-score ( $r=0.60$ ,  $p<0.001$ ) but not between LL-score and TRIMPS-d. Discussion AT in competitive athletes is associated with a relatively high prevalence of AMS, generally of mild severity (Bartsch 2008), although some swimmers can experience severe symptoms. LL and TSF10 questionnaires may be helpful in detecting and quantifying clinical symptoms related to altitude exposure and training load, particularly during the early stage of the acclimatization period. Nevertheless AMS seems to be independent of training load estimated by the TRIMPS method. References Atlaoui D, Duclos M, Gouarne C, Lacoste L, Barale F, Chatard JC (2004). ## DOES SHORT DURATION INTERMITTENT HYPOXIC TRAINING IMPROVE REPEATED SPRINT CYCLING PERFORMANCE?

HURST, H.T., ATKINS, S.

UNIVERSITY OF CENTRAL LANCASHIRE

Introduction Altitude training has been used to aid performance for the past forty years. However, altitude training studies have traditionally used prolonged exposures of several hours per day over three to four weeks (Vallier et al., 1996; Levine and Stray-Gundersen, 1997). The focus of these studies has primarily been on haematological improvements and endurance based performance. Few studies have looked at shorter durations and high intensity intermittent exercise. It was therefore the purpose of this study to investigate the use of short duration hypoxic training (HT) on repeated sprint cycling performance. Methods Fourteen male participants (age 27.5  $\pm$  8.5 yrs; stature 179.4  $\pm$  4.49 cm; mass 72.9  $\pm$  8.55 kg) were randomly assigned to either a normoxic training group (NT) or a hypoxic training group (HT). All participants completed an intermittent performance test (IPT) on an SRM cycles ergometer. This consisted of 6 x 3 min efforts at 65% of each individual's maximal aerobic power, interspersed with 6 x 10 s maximal sprint efforts. Participants then cycled for 15 min on a Monark 834E cycle ergometer three times per week for three weeks. The NT group performed the sessions under normoxic conditions, whilst the HT group performed them at a simulated altitude of 3048 m using a hypoxic generator. Following the intervention participants repeated the IPT. Differences in mean power (Wmean) and peak power (Wpeak) averaged over all sprints were analysed using a 2 (HT, NT) by 2 (pre and post-intervention) repeated measures ANOVA. Where a significant interaction effect was found, post-hoc comparisons were performed. Significance was set at  $p \leq 0.05$ . Results No significant interaction effect was found for Wmean ( $p = .21$ ). However, the HT group showed a pre to post-intervention increase of 11.99% compared to 3.75% by the NT group. A similar trend was also reported for Wpeak ( $p = .17$ ), with the HT group increasing 11.82% pre to post-intervention compared to 3.45% by the NT group. Discussion Despite no significant differences in Wmean and Wpeak between groups, the HT group increase both more than the NT group. The non-significant nature of these results may in part, be due to the low number of participants. However, hypoxic training may have resulted in greater cardiorespiratory adaptations and thus enhanced recovery between sprints. References Levine, B.D. and Stray-Gundersen, J. ## THE EFFECT OF SIMULATED ALTITUDE EXPOSURE VIA REBREATHING ON INTERVAL PERFORMANCE

BALDWIN, C., WALSH, M., COX, R., MASSIE, B., HARPER, E.

MIAMI UNIVERSITY

THE EFFECT OF SIMULATED ALTITUDE EXPOSURE VIA REBREATHING ON INTERVAL PERFORMANCE Baldwin, C., Walsh, M., Cox, R., Massie, B., Harper, E. Miami University, Oxford, Ohio Introduction Altitude training became popular during the 1968 Olympic Games held in Mexico City. Since then, there has been extensive research conducted on the effects of altitude on cardiovascular endurance. The goal of this study is to examine the effects of simulated altitude via rebreather training on maximal interval performance. Methods Subjects had blood drawn at the Miami University Health Center for analysis of red blood cell (RBC), hemoglobin (HGB) and hematocrit (HCT) levels. For the duration of the study subjects were asked to maintain their current workout regime. Subjects performed pre exercise performance tests, which included a VO2max and a 90% repeated interval performance test. During the 90% repeated interval performance test subjects ran at the last stage of their VO2max for 3 minutes or until failure. At this time the subjects returned to a 0% grade at a speed of 1.56 m/s for 3 minutes. They repeated this for a total of 5 sets. Following the exercise performance tests, subjects used rebreathing apparatuses developed by Alto2 Lab for 15 minute sessions, five days a week for three weeks. The three weeks were divided into three O2 saturation levels, 90%, 87%, and 84%. Following this simulated exposure to altitude, subjects performed a post 90% repeated interval performance test and a post blood draw. A repeated measures ANOVA was conducted to analyze RBC, HGB, HCT, and total time to exhaustion. The experiment controlled for a treatment effect and exhaustion. Results A significant difference was found between the control and experimental groups in the total time run. The experimental group ran 642.67 seconds for the pretest compared to the 759.33 seconds for the posttest. The control group ran 780 seconds for the pretest compared to the 779.60 seconds for the posttest. However, no significant difference was found between the RBC, HGB, and HCT levels. Discussion At moderate altitudes physiological adaptations occur which may improve performance. Living at moderate altitude and training at low altitude elicit beneficial effects for aerobic performance (Levine and Stray-Gundersen, 1997). These beneficial effects may be transferred over into interval performance. The experimental group showed marked improvements in the total time run during the 90% interval treadmill test. On the other hand, the control group maintained their current performance level. The changes in RBC, HGB, and HCT levels were not found to be significant; however, that may be due to the low subject pool. With more subjects a significance of blood values may be found between the two groups. References Levine, B. D. & Stray-Gundersen, J. (1997). Living high-training low': Effect of moderate-altitude acclimatization with low-altitude training on performance. *Journal of Applied Physiology*, 83(1), 102.

**METABOLIC AND THERMAL RESPONSES TO COMBINED HYPOXIC AND THERMAL CHALLENGE**

WHITE, A., SARGEANT, A., PARRY, S., MORGAN, C., MOLPHY, J., LANGAN-EVANS, C., IMPEY, S., FLOWER, D., CRIGHTON, B., CABLE, N.T., HULTON, A.

LIVERPOOL JOHN MOORES UNIVERSITY

Metabolic and thermal responses to exercise in the heat are elevated compared to exercise in the cold (Hargreaves & Febbraio, 1998) and exercise in hypoxic conditions also causes an exaggerated cardiorespiratory response compared with sea level (Reeves et al. 1992). As athletes are often exposed to the combined challenge of exercise in hypoxic and hot conditions, this study investigated the combined effect of these challenges on the cardiorespiratory and thermal response to exercise. Nine healthy well trained males participated in this ethically approved study. Following assessment of VO<sub>2</sub> peak on a recumbent cycle ergometer, subjects attended the laboratory on 3 separate occasions, exercising for 15 min at 70% VO<sub>2</sub> peak in the following 3 climatic conditions; SL at 32°C, 2300m at 18°C and 2300m at 32°C. Rectal temperature (RT) was measured using a grant thermometer and skin temperature measured at 4 sites using squirrel thermistors and data logger. Blood lactate was measured using a Lactate Pro and glucose was measured and plasma volume changes were assessed. HR and SaO<sub>2</sub> were measured using Dynamap. Sweat production rate was measured by changes in nude body mass and urinary osmolality assessed by osmometry. Statistical differences assessed by two way ANOVA with repeated measures. There was no significant difference ( $p > 0.05$ ) in RT between the conditions, although there was a significant effect of time ( $p < 0.05$ ). There was no significant ( $p > 0.05$ ) effect of time of skin temperature, but there was a condition effect ( $p < 0.05$ ) and interaction ( $p < 0.05$ ). Mean ( $\pm$ SD) skin temperature values before exercise for SL at 32°C, 2300m at 18°C and 2300m at 32°C, were  $32.88 \pm 0.88$ ,  $32.87 \pm 0.70$  and  $30.06 \pm 1.26$  respectively alternating to levels of  $34.22 \pm 0.80$ ,  $33.91 \pm 0.98$  and  $28.04 \pm 1.31$  after the 15 minute exercise protocol. There was no significant difference in sweat production rate between the three conditions as ( $p > 0.05$ ). There was a significant difference in blood lactate concentrations over time ( $p < 0.05$ ), increasing from baseline with mean ( $\pm$  SD) values of  $1.27 \pm 0.56$  (SL at 32°C),  $1.4 \pm 0.57$  (2300m at 18°C) and  $1.51 \pm 0.70$  (2300m at 32°C) to peak levels of  $7.23 \pm 2.57$  (SL at 32°C),  $7.41 \pm 2.83$  (2300m at 18°C) and  $6.88 \pm 3.26$  (2300m at 32°C) respectively at termination of exercise. However, there was no difference between conditions. Blood glucose changed over time ( $p < 0.05$ ). This data suggests that the combined influence of exercise at altitude and in the heat causes no greater metabolic or thermal strain, compared with either heat or altitude alone. The absence of effect may relate to the relatively short exercise duration. Hargreaves, M. and Febbraio, M. (1998). Limits to exercise performance in the heat. *Int J Sport Med*. 19: S115 – S116. **EFFECT OF ACUTE HYPOXIA ON MUSCLE OXYGENATION AND NEUROMUSCULAR ACTIVITY DURING REPEATED SPRINT CYCLING**

KOBAYASHI, Y.1, NAKAGAKI, K.1, KON, M.1, NISHIYAMA, T.2, SUZUKI, Y.1

1: JAPAN INSTITUTE OF SPORTS SCIENCES (TOKYO, JAPAN), 2: NIPPON SPORT SCIENCE UNIVERSITY (TOKYO, JAPAN)

**Introduction** The previous study have shown that repeated sprint cycling training effectively improve muscle oxidative potential and cycle endurance capacity (Burgomaster et al., 2005). We speculated that this exercise in hypoxia may provide more stimuli especially to local muscle. So, the purpose of this study was to examine whether acute hypoxia affects muscle oxygenation and neuromuscular activity during repeated sprint cycling. **Methods** Seven cyclists performed five, 30-s sprints with 240 s of rest under normoxic (21%O<sub>2</sub>, 79%N<sub>2</sub>) and acute hypoxic (16%O<sub>2</sub>, 84%N<sub>2</sub>) conditions. Mean power output was recorded by cycle ergometer, and arterial O<sub>2</sub> saturation (SpO<sub>2</sub>) was estimated via pulse oxymeter with adhesive optodes placed on the forehead. The relative concentrations of oxy-hemoglobin (O<sub>2</sub>Hb) in the right vastus lateralis (VL) muscle were monitored continuously by near-infrared spectroscopy. In the present study, the resting level of O<sub>2</sub>Hb was defined as 100% (baseline) of oxygenation, and the minimum plateau level of O<sub>2</sub>Hb was obtained by arterial occlusion and was defined as 0% of oxygenation. Surface electromyogram (EMG) of VL was also recorded. Root mean square (RMS) was utilized to quantify EMG activity. For each sprint, the RMS was normalized to the first sprint value, which was assigned the value of 100%. Results SpO<sub>2</sub> under hypoxic condition was significantly lower than that under normoxic condition ( $p < 0.05$ ) while mean power output was not different in both conditions. During exercise, significant differences were not observed in oxygenation level of VL in both conditions. However oxygenation level of VL in hypoxia was significantly lower than that in normoxia immediately after exercise. Normalized RMS values were significantly decreased over the five sprints in normoxia ( $p < 0.05$ ) while no change was observed in hypoxia. As a result, RMS in hypoxia was significantly higher than that in normoxia in third, fourth and fifth sprint ( $p < 0.05$ ). Conclusion These findings suggest that repeated sprint cycling in hypoxia require greater neuromuscular activity and cause delay in muscle re-oxygenation after exercise. References Burgomaster, K. A., Hughes, S. C., Heigenhauser, G. J., Bradwell, S. N., Gibala, M. J. (2005). *J Appl Physiol*, 98(6), 1985-90.

**Poster presentations****PP-PM65 Physiology: Jumping Performance****THE RELATIONSHIP BETWEEN 1 RM BACK SQUAT AND VERTICAL JUMPING IN YOUNG WOMEN**

FERUNAJ, P.

UNIVERSITY OF SPORTS OF TIRANA

Ferunaj, P., Erindi, A. Derveni, A University of Sports, Tirana (Albania) **Introduction** In today's fitness industry, strength and power, in addition of cardiovascular fitness, flexibility and body composition, are key components. One study (1) reported that double leg press power was related to vertical jump performance in young women. Other studies have shown improvement in explosive jumping actions (2,3) produced by combination of both maximal and explosive strength development. Therefore, we hypothesized that the maximal strength for lower extremities would lead to higher vertical jump in young women. **Methods** Eighteen young women in Tirana, participated in this investigation and were divided into 2 groups based on 1-repetition maximum (1-RM) back full squat exercise adjusted to body mass (4): an Active group (AG; age 19  $\pm$  0.3 years) and a non active group (NAG; age 19  $\pm$  0.5 years). Weight and height were measured using standard methods. Peak power for both squat jump (SJ) and counter movement jump (CMJ) was measured using the ergo jump. Results Back squat 1RM was  $74.76 \pm 4.88$  kg for the active group and  $65.72 \pm 1.91$  kg for non active group. Squat jump (SJ) and counter movement jump (CMJ) were respectively  $30.24 \text{ cm} \pm 3.29$  and  $41.19 \text{ cm} \pm 7.19$  for AG and  $29.29 \pm 4.54$  and  $34.55 \pm 9.03$  for NAG. **Discussion** Our

results suggest that 1RM full squat does not influence the SJ, but has better correlation with CMJ in AG. In contrast, the data gathered in NAG showed that 1 RM back squat can significantly influence the power, expressed in vertical Jump for both SJ and CMJ. Consequently, the 1RM back squat is an easily applied, inexpensive test and can provide fitness instructors and strength and condition coaches with relevant information concerning the maximal strength and power of lower extremities in young women. ### **HIGH-IMPACT LOW-REPETITION JUMP TRAINING IS EFFECTIVE IN PREVENTING THE REDUCTION MID-DIAPHYSEAL FEMORAL BONE GEOMETRY SEEN IN POST-MENOPAUSAL WOMEN**

KATO, T.1, YAMASHITA, T.1, MATUMOTO, M.2, YAMAMOTO, H.3, TAKAMI, K.4, HONDA, A.5, UMEMURA, Y.2

1/SUZUKA UNIVERSITY OF MEDICAL SCIENCE, (SUZUKA, JAPAN), 2/CHUKYO UNIVERSITY (TOYOTA, JAPAN), 3/IASAHI UNIVERSITY (GIFU, JAPAN), 4/HOSEI UNIVERSITY (TOKYO, JAPAN), 5/JAPAN INSTITUTE OF SPORTS SCIENCES,

**Objective** The hypothesis of the present study was that low-repetition high-impact jump training would be effective for enhancing bone cross-sectional geometry rather than increasing DXA measured BMC and aBMD in post-menopausal women. **Methods** Thirty-three middle-aged post-menopausal women (mean age,  $61.2 \pm 5.6$  years; range, 53-74 years) were divided into two groups: jump training group and control group. The Jump group jumped 20 times per day, twice a week for 12 months on a shock absorbing pad. Main outcome measures Dual energy X-ray absorptiometry (DXA) was used to measure BMC and aBMD in the lumbar spine and proximal femur. Magnetic resonance imaging (MRI) determined bone geometric characteristics in the mid-femur, such as femoral mid-diaphyseal cross-sectional area, periosteal and endosteal perimeters and maximum and minimum second moment of area. **Results** The postmenopausal middle-aged women who undertook the jump training intervention displayed a significantly greater femoral mid-diaphyseal maximum second moment of area than the control group after 12 months. Although, no significant differences were found after 12 months for the DXA measured BMC and aBMD at the lumbar spine, total proximal femur and femoral neck between the jump training and control groups. **Conclusions** In middle-aged postmenopausal women, aBMD measures were not related to jump training effects which supports the notion that long bones tend to change their size and geometry rather than amount of mineral in order to meet the increased functional demands associated with low-repetition high-impact loading.

### **EFFECTS OF LANDING TRAINING ON JUMP HEIGHT, KINETICS AND KINEMATICS DURING LANDING-TO-JUMP MOVEMENT**

IIDA, Y., KANEHISA, H., INABA, Y., NAKAZAWA, K.

UNIVERSITY OF TOKYO

**Introduction** In landing-to-jump movement (L-J), the technique in not only jumping movement but also landing movement is an important factor influencing jump performance. Hewett et al. (1996) demonstrated that jump training program intended to decrease landing impact (peak of vertical ground reaction force) decreased landing impact and increased jump height. Furthermore, Iida et al. (2009) showed that the jump height of L-J has a significant negative correlation with the magnitude of landing impact. These findings indicate that technique for absorbing landing impact may be associated with the performance of the latter jump movement. The purpose of this study was to clarify the effects of landing training (without jumping movement) on jump performance of L-J. We hypothesized that landing training decreases the landing impact in L-J and increases the jump height of L-J. **Methods** Twenty-one healthy young adults were randomly assigned to control group (CG: n=11) or training group (TG: n=10). TG performed landing training intended to decrease impact force for 2 weeks (6 sessions). Ground reaction forces (GRFs) and kinematic data were obtained in landing (LAND) and L-J from 35 cm-high, and squat jumps (SJ) before and after the intervention. **Results** In TG, the peak vertical GRF up to 100 ms after ground contact relative to body weight (impact index) significantly decreased (Pre:  $3.04 \pm 0.74$  vs. Post:  $2.41 \pm 0.42$ ,  $P < 0.05$ ), and L-J height significantly increased (Pre:  $46.1 \pm 5.8$  [cm] vs. Post:  $47.8 \pm 5.8$  [cm],  $P < 0.05$ ). Ground contact time in L-J and the SJ height unchanged in both groups. For TG, the maximal flexion angle of hip, and joint torque, power and work of hip joint in propulsive phase significantly ( $P < 0.01$ ) increased after training. **Discussion** Previous studies showed that landing training decreased landing impact (McNair et al., 2000; Onate et al., 2001; Prapavessis et al., 2003), but it is unknown that whether landing training improves jump performance of L-J. The current finding shows that the landing training improves not only technique for absorbing landing impact but also L-J performance itself, and supports our hypothesis. The increase of L-J height may be due to an increase in force generation around the hip joint, rather than improve jump ability. **Reference** Hewett TE., Stroupe AL., Nance TA., Noyes FR. ### **DIFFERENCES IN THE BILATERAL DEFICIT IN VERTICAL JUMPING BETWEEN BOYS AND GIRLS**

VELIGEKAS, P., BOGDANIS, G.C., TSOUKOS, T., SELIMA, E.

UNIVERSITY OF ATHENS, GREECE

**Introduction** The bilateral deficit in vertical jumping occurs when the summed unilateral jump height is greater than the bilateral jump height. This phenomenon has been described mainly for muscle strength in adult populations, while there is a lack of information in very young individuals and especially females. Therefore, the aim of this study was to examine whether a bilateral deficit in jumping exists in children and to compare boys and girls of the same age and training background. **Methods** One hundred and twenty-five schoolchildren (59 boys and 66 girls, aged  $10.6 \pm 0.1$  y, height:  $144 \pm 1$  cm, body mass:  $41.2 \pm 0.9$  kg) performed one-leg and two-leg counter movement jumps (CMJ) without arm swing on a contact mat. Jumps were performed after full familiarization and the best of three efforts was recorded. The bilateral jump deficit index was calculated as:  $1 - (\text{right} + \text{left leg jump height}) / \text{two-leg jump height} \times 100$ . Peak leg power output during jumping was calculated using the equation of Sayers et al. (1999) and was scaled with body mass. Differences between boys and girls were analyzed using analysis of variance (ANOVA) with repeated measures on one factor or unpaired t-tests, whenever it was appropriate ( $p < 0.05$ ). **Results** are mean  $\pm$  standard error. **Results** Jump height and leg peak power were similar in boys and girls

( $21.8 \pm 0.7$  vs.  $20.1 \pm 0.5$  cm and  $59.1 \pm 2.2$  vs.  $56.1 \pm 1.9$  W, respectively). The two-leg CMJ was significantly higher than the sum of the right and left leg jumps only in boys ( $P < 0.01$ ), as shown by the positive bilateral index of  $9.2\% \pm 2.2\%$ . In contrast, girls showed neither bilateral deficit nor facilitation, since the bilateral index was not different from zero ( $1.7 \pm 2.2\%$ ), indicating equal two-leg and sum of two legs jumps. The bilateral indices of boys and girls were significantly different ( $p < 0.02$ ). Discussion The main finding of the present study was the lack of a bilateral deficit (negative bilateral index) in both boys and girls around 11 years old. The fact that the summed unilateral jump height was not greater than the bilateral jump height in both groups may be due to a decreased ability to activate motor units during pre-puberty (Paasuke et al., 2000). Differences in the bilateral index between the two genders have been previously observed during sprint cycling (Dunstheimer et al., 2001) and may be explained by a possibly superior motor skill ability (i.e. balance on one leg and jump) of girls over boys in that age. ## THE RELATIONSHIP BETWEEN KNEE EXTENSOR MUSCLE STRENGTH AND VERTICAL JUMP PERFORMANCE: EFFECT OF LOAD

VUK, S., MARKOVIC, G.

UNIVERSITY OF ZAGREB

Introduction One of the fundamental mechanical properties of skeletal muscles is the force-velocity-power (FVP) relationship. Power output of a skeletal muscle depends on both muscle force and a velocity of shortening. Since they are inversely related, power output at higher external loads should be dependent on muscle strength and vice versa. Accordingly, the heavier the load that has to be overcome during movement, the more important is muscle strength for power production and performance. In this study we examined the relationship between knee extensor muscle strength and vertical jump performance with different loads. Methods Sixty-six young and healthy men volunteered in the study. After standardized warm up, each subject performed countermovement jumps (CMJ) under 5 loading conditions: no load (1BW), negative loads (0.85 and 0.7BW), and positive loads (1.15 and 1.3BW) on a force plate. CMJ was followed by the measurement of subject's maximal concentric knee extension torque at 60 deg/sec on an isokinetic dynamometer. The relationship between strength and jumping performance with various loads was assessed by Pearson's correlation coefficients (CC) and partial CC after controlling for body mass. Results Knee extensor muscle strength correlated significantly ( $r = 0.78-0.79$ ; all  $p < 0.01$ ) with peak power output during CMJ at all loading conditions. When controlled for body mass, the corresponding CC were reduced but still remained highly significant ( $r = 0.62-0.65$ ; all  $p < 0.01$ ). Considerably lower CC ( $r = 0.18-0.43$ ;  $p = 0.01-0.15$ ) were observed between knee extensor muscle strength and CMJ height at all loading conditions. Removing the effect of body mass increased the CC at all loading conditions ( $r = 0.37-0.51$ ; all  $p < 0.01$ ). We have also observed that subjects changed their depth of countermovement during performance of CMJ with different loads. Discussion The first main finding is that there are no significant changes in CC between knee extensor muscle strength and CMJ peak power under different loads applied. The lower body power output during CMJ with various loads depends not only on the FV relationship, but also on changes in leverage of leg extensors and muscle's force-length relation. As subjects changed their movement kinematic pattern during CMJ with different loads, the relationship between leg extensors muscle strength and power output during CMJ didn't behave as expected from FVP relationship. The second main finding is an increase of the CC between knee extensor muscle strength and jump height after removing the effect of body size. This is in line with our previous study (1) which suggests that CMJ height could be a body size independent measure of a muscle power. ## RELATIVE FATIGUE IN REPEATED SPRINT ABILITY IS RELATED TO JUMP AND FULL SQUAT MAXIMAL POWER IN SOCCER PLAYERS

LÓPEZ SEGOVIA, M., PALAO, J.M., GONZÁLEZ-BADILLO, J.J.

FEDERACIÓN DE FÚTBOL DE LA REGIÓN DE MURCIA

RELATIVE FATIGUE IN REPEATED SPRINT ABILITY IS RELATED TO JUMP AND FULL SQUAT MAXIMAL POWER IN SOCCER PLAYERS López-Segovia, M.1, Palao, JM.2, González-Badillo, JJ.3 1: Research Center of Murcia Soccer Federation (Murcia, Spain), 2: University of Murcia (Murcia, Spain), 3: University of Pablo de Olavide (Seville, Spain). Introduction The ability to execute repeated sprints (RSA) is important for a soccer player's performance (Impellizzeri, et al, 2008). This capacity is influenced by aerobic aspects such as the maximum oxygen consumption (Meckel et al, 2009) as well as anaerobic aspects such as phosphocreatine degradation (Gaitanos et al, 1993) and muscle buffer capacity (Edge et al, 2006). However, the relationship between RSA and lower-body power exercises done by the soccer player in training sessions (full squat (FS) and countermovement jump (CMJ)) is not known. The objective of the present study was to assess the relationship between RSA and lower-body power in FS and CMJ for the soccer player. Methods Eighteen field players from a soccer team from the Spanish Third Division were analyzed. The RSA protocol consisted of executing 40m series (with photoelectric cells placed at 0m and 40m) with 2' of recovery between series, until 3% of the speed from the best series of each player is lost. The number of series executed was recorded as the indicator of RSA. One week later each player completed both a countermovement jump (CMJ) and progressive full squat test with loads (FSL) (López-Segovia et al, 2010). The maximum average power generated in the concentric phase with each load until the maximum power was achieved was recorded for both exercises. For data analysis, Pearson correlation and t-test were used. The alpha level was set at  $p < 0.05$ . Results RSA was significantly related to the average maximum power per kg of weight for FS ( $r = 0.539$ ,  $p \leq 0.05$ ) as well as with the profile of maximum power for each player (sum of the average power in 20, 30, and 40kg) for the CMJ ( $r = 0.577$ ,  $p \leq 0.05$ ). Discussion The results found indicate that the power obtained in the FS and CMJ partially explain the loss of performance in RSA. The relationship found constitutes a starting point for the relationship between RSA and power in soccer players. Future studies should assess the level of contribution of aspects that affect RSA and determine how much a specific strength conditioning program affects RSA. ## CHANGES OF POWER-VELOCITY RELATIONSHIP IN FEMALE VOLLEYBALL PLAYERS

BUŠKO, K.1,2, LIPÍŃSKA, M.1, MICHALSKI, R.2, LEWANDOWSKA, J.1, PASTUSZAK, A.1

1: JOSEF PILSUDSKI UNIVERSITY OF PHYSICAL EDUCATION (WARSAW, POLAND), 2: INSTITUTE OF SPORT (WARSAW, POLAND)

**Introduction** Volleyball players' fitness relies on their strength, power output and jumping ability (Smith et al., 1992). The players' power output is often measured on a cycloergometer (Buško, 2009). In the literature, there is no publication for changes on the force-velocity and power-velocity relationship in female volleyball players during the training. The aim of the study was to follow the changes of power-velocity relationship in female volleyball players during training. **Methods** Twelve female volleyball players (age  $21.6 \pm 1.6$  years, body height  $177.2 \pm 6.1$  cm, body mass  $71.6 \pm 6.4$  kg, and training experience  $8.9 \pm 3.3$  years) volunteered to participate. Force-velocity and power-velocity (P-v) relationship were determined from five maximal cycle ergometer exercise tests, 10 s each, with increasing external loads amounting to 2.5, 5.0, 7.5, 10.0, 12.5% of body weight (BW). There were 2-min breaks between the tests. The measurements were performed before the preparatory period (I), after the end of preparatory period (II) and after the end of first competitive season (III). The results were statistically processed using analysis of variance (ANOVA) with repeated measures (post-hoc Scheffé test). **Results** The relative power output at the load of 2.5% and 5.0% BW significant increased between the measurements I and II by 8.2% and 6.1%, respectively. The relative power output at the load of 7.5% BW increased from  $8.85 \pm 0.46$  W/kg (I) to  $8.98 \pm 0.65$  W/kg (II) and  $9.42 \pm 0.84$  W/kg (III,  $p < 0.05$ ). The relative power output at the load of 10.0% BW was observed from  $8.31 \pm 1.11$  W/kg (I) to  $9.26 \pm 1.17$  W/kg (II,  $p < 0.05$ ) and  $9.64 \pm 0.96$  W/kg (III,  $p < 0.05$ ). The relative power output at the load of 12.5% BW insignificant increased between the measurements I and II by 10.0%, and I and III by 16.0%. **Discussion** Training of motor skills in volleyball players has its principal place during the preparatory period. In the competitive season the main emphasis is on improving the technique and tactics, and training of motor skills are reduced (Häkkinen, 1993). In this paper, volleyball training insignificant improved the female players' P-v characteristics during the preparatory period. After the first phase of the competitive season significant, "parallel" shift of P-v curves was observed. Busko (2009) described similar changes of the P-v relationship in male volleyball players during one years training. **Acknowledgements** The study was supported by Ministry of Science and Higher Education (Grant No. AWF - Ds.-150). **References** Buško K. (2009). Human Movement, 10(2), 149-152. Häkkinen K. (1993). Sports Med Phys Fitness, 33, 323-332. Smith DJ, Roberts D, Watson B. (1992). Sports Sci, 10(2), 131-138.

## A RELIABILITY ANALYSIS OF THE VERTICAL COUNTERMOVEMENT JUMP TEST

DINSDALE, A.J., BISSAS, A.

LEEDS METROPOLITAN UNIVERSITY (LEEDS, UK)

**Introduction** The vertical countermovement jump (CMJ) test has been reported as a highly reliable measure of functional power output with Intraclass Correlation Coefficients (ICC) ranging from 0.78 to 0.98 (Robbins & Docherty, 2005). However, absolute measurement statistics are not usually included in CMJ reliability analysis; this is a significant limitation when attempting to identify small performance changes between conditions [e.g. in Post-Activation Potentiation (PAP) research]. Therefore, this study aimed to identify the degree of random error, due to performance variation, in the CMJ test. **Methods** Five trained males (age:  $20.8 \pm 1.1$  years, height:  $1.79 \pm 0.06$  m, mass:  $81.5 \pm 6.5$  kg) who regularly took part in jumping activities were recruited. The design of the study comprised one familiarisation and two identical testing sessions separated by 48 hours. The testing sessions consisted of: a 15-min warm-up, 2 practice CMJs and 5 tested CMJs performed on a Kistler force plate (1000Hz). The jump height was calculated from the force-time curves using two different methods: the take-off velocity method (TOV) and the flight time method (FT). Three statistical methods for assessing reliability were used after the data were assessed for heteroscedasticity: 95% Limits of Agreement (LOA), Coefficient of Variation (CV) and ICC (3, 1) consistency. Reliability results were obtained as follows: a) reliability based on the average score of the 5 jumps (R5); b) reliability based on the best jump performance (RB). **Results** Both methods, TOV and FT, produced almost perfect ICC values of 0.99 and 1.00 ( $p < 0.001$ ) respectively for both R5 and RB. However, the TOV method for R5 demonstrated a random error of 10% of the grand mean with LOA (Bias  $\pm$  Random Error):  $0.00 \pm 0.04$  m, whereas the FT method demonstrated a lower relative random error of 6.5% with LOA:  $-0.01 \pm 0.03$  m. Interestingly, when the best score was used for the analysis the relative random error for TOV increased to 12.5% with LOA:  $0.00 \pm 0.05$  m, whereas the FT method produced a relative random error of 2% with LOA:  $-0.01 \pm 0.01$  m. The CV values based on the R5 data were 2.6% for TOV and 2% for FT while the respective values for RB were 3.2% and 0.9%. **Discussions** The ICC results demonstrate a very high reliability between the sessions; however the measures of absolute reliability suggest that the random error could reach noteworthy levels (4-5 cm). It appears that when the calculations involve the best trial analysed by the FT method the random error is reduced considerably. The estimation of the random error is of high importance particularly in PAP studies where changes in jump performance range from 2-8% (Tillin & Bishop, 2009). **References** Robbins D, Docherty D. (2005) J Strength Cond Res, 19(4), 898-902. Tillin N, Bishop D. (2009) Sports med, 39(2), 147-166.

## DETERMINANTS OF STANDING LONG JUMP PERFORMANCE IN CHILDREN

BOGDANIS, G., VELIGEAS, P., TSOUKOS, T., KOSTIKIADIS, J.

UNIVERSITY OF ATHENS

**Introduction** Standing long jump (SLJ) is commonly used test to assess explosive leg power. It is often employed for talent selection and prediction of potential in different sports (Burr et al. 2008). However, body dimensions of the jumper may have implications in leg power assessment, since taller persons may jump longer (Chamari et al., 2008). Also, individuals with different body masses may have the same SLJ performance, while leg power generated may be widely different. Therefore, the aim of this study was to identify the most significant variables that contribute to SLJ performance in young boys and girls. **Methods** One hundred and nineteen schoolchildren (58 boys and 61 girls, aged  $10.7 \pm 0.1$  y, height:  $144 \pm 1$  cm, body mass:  $41.2 \pm 0.9$  kg) were tested on two separate occasions following full familiarization. Testing included measurement of SLJ, 10 m and 30 m sprint times with photocells, vertical counter movement jump (CMJ) without arm swing on a contact mat and anthropometric measurements. To assess the influence of technique during the SLJ, an experienced investigator rated technique in each SLJ by giving a mark from 1 to 10. Differences between boys and girls were analyzed using unpaired t-tests. After bivariate correlation analysis, multiple linear stepwise regression analysis was performed with SLJ performance as the dependent variable. **Results** No differences were found in all variables measured between boys and girls and therefore all subsequent analyses were performed for the pooled data. SLJ performance was  $1.40 \pm 0.02$  m, CMJ was  $0.21 \pm 0.04$  m and 10 m and 30 m sprint times were  $2.21 \pm 0.01$  and  $5.72 \pm 0.04$  s, respectively. SLJ was significantly correlated with 10 m time ( $r = -0.66$ ,  $p < 0.01$ ), 30 m time ( $r = -0.68$ ,  $p < 0.01$ ) and CMJ ( $r = -0.58$ ,  $p < 0.01$ ). Stepwise multiple linear regression analysis revealed that the most significant predictors of SLJ were 30 m time, CMJ, age and the mark for jump technique (adjusted  $R^2 = 0.77$ ,  $SEE = 0.09$ ,  $p < 0.001$ ). **Discussion** This study showed that per-

formance in SJL in young boys and girls can be predicted by sprint ability, vertical jump performance and technique level. Height and weight did not play a significant role in performance of the SJL in this relatively homogeneous group of individuals. It is important to note that vertical jump performance explains only a small part of the variance in performance of SJL. This may be because SJL is a more complex motor task that requires combination of vertical and horizontal leg power in combination with a full-body coordinated movement. #### THE INFLUENCE OF EXERCISE ON SENSORY PERCEPTIONS OF SPORTS DRINKS

ALI, A., DUIZER, L., FOSTER, K., GRIGOR, J., WEI, W.

MASSEY UNIVERSITY

Background: So as to enable efficient delivery of both water and energy, most sports drinks contain approximately 6-9% CHO. However, in more recent years 'flavoured-water' drinks, with reduced energy (1-3% CHO) content, have become available on the market. Anecdotal information from competitive runners and triathletes suggests these beverages, or simply water, are preferred during exercise relative to traditional sports drinks. Purpose: The aim of this study was to examine perception of the sensory properties of different formulations of sports drinks when consumed before, at various points during, and following exercise in recreational runners. Methods: Following familiarisation, 14 recreational runners underwent four trials in a single blind counterbalanced design. Each trial utilised one of four different solutions: 7.5% carbohydrate, 421 mg/L electrolyte (HiC-HiE); 7.5% carbohydrate, 140 mg/L electrolyte (HiC-LoE); 1.3% carbohydrate, 421 mg/L electrolyte (LoC-HiE) and water. Subjects were provided with 50-ml samples to ingest and then rate (using a 100-mm line scale) the intensity of sweetness, saltiness, thirst-quenching ability and overall liking before (-30 min), during (0, 30 and 60 min) and following (90 and 120 min) treadmill running exercise. Exercise was performed at 70-80% of age-predicted maximum heart rate; subjects were seated for the pre- and post-exercise sampling periods. Results: Ratings of sweetness for all energy-containing drinks were higher during exercise relative to pre- and post-exercise conditions ( $P < 0.05$ ); ratings also increased with duration of exercise ( $P < 0.001$ ). Sweetness ratings for LoC-HiE increased during exercise ( $P < 0.05$ ) but remained the same for other beverages. Ratings of saltiness decreased for all energy-containing drinks during exercise relative to pre-exercise ( $P < 0.05$ ); ratings decreased with duration of exercise in these drinks ( $P < 0.05$ ). Ratings of thirst quenching ability ( $P = 0.106$ ) and overall liking ( $P = 0.077$ ) showed a trend to be higher during exercise than non-exercise conditions; thirst-quenching ability ( $P = 0.039$ ) and overall liking ( $P = 0.013$ ) increased with duration of exercise with all beverages. Conclusions: Significant changes in sensory perception occur when consuming various formulations of sports drinks during exercise relative to non-exercise conditions. Temporal changes also occur during exercise itself which leads to enhanced liking of all beverages. The low-carbohydrate solution showed the greatest changes in sensory perceptions between non-exercise and exercise conditions indicating that what is preferred at rest may not be true during exercise.

#### NUTRITIONAL STATUS OF MAGNESIUM IN RATS SUBMITTED TO MAGNESIUM DIETARY DEFICIENCY AND PHYSICAL ACTIVITY

AMORIM, A.T., TIRAPEGUI, J.2

(1) FEDERAL UNIVERSITY OF MARANHÃO; (2) UNIVERSITY OF SÃO PAULO

INTRODUCTION: Marginal dietary magnesium (Mg) deficiency is a common problem worldwide. The importance of Mg in physical activity is also recognized. However, there is little information about Mg deficiency in regular physical activity. OBJECTIVE: To evaluate serum, erythrocyte and tissue concentrations of magnesium in animals submitted to physical activity and dietary Mg deficiency. MATERIALS AND METHODS: Male Wistar rats (initial weight of 280 g) were divided into control (CON,  $n=9$ ), exercised control (CONEX,  $n=9$ ), sedentary Mg deficient (DEF,  $n=9$ ) and exercise Mg deficient (DEFEX,  $n=9$ ). The control diet contained 500 mg of Mg/Kg diet and the Mg deficient diet contained 200 mg of Mg/Kg diet. The animals were fed ad libitum during 6 weeks of experiment and swam 1 hour per day during 5 days every week. The removal of the tissues took place 24 hours after the last exercise session. Total Mg concentration in the serum, erythrocyte, gastrocnemius and soleus muscles, liver, brain and kidneys was determined by atomic absorption spectrophotometry. RESULTS: Mg concentration in the serum of animals in the DEFEX group was significantly lower ( $p < 0.05$ ) than in the EX group ( $2.3 \pm 0.4$  ug Mg /mL and  $3.1 \pm 0.07$  ug Mg /mL, respectively). In the erythrocyte, Mg concentration in the SED group presented values 30% higher than in the other groups ( $p < 0.05$ ). In the gastrocnemius muscle, Mg concentration was higher ( $p < 0.05$ ) in the EX group compared to the DEFEX group ( $120.9 \pm 48.0$  ug Mg /mg dry matter and  $63.3 \pm 14.5$  ug Mg /mg dry matter, respectively), whereas in the soleus muscle no significant differences between the EX and DEFEX groups were found ( $154.5 \pm 30.3$  ug Mg /mg dry matter and  $156.7 \pm 30.2$  ug Mg /mg dry matter, respectively). In the liver, no significant differences were found. Mg concentration in the kidneys of exercised animals was significantly higher ( $p < 0.05$ ) in comparison to SED and MARG groups. Concerning the brain, Mg concentration was higher ( $p < 0.05$ ) in the EX group compared to the DEFEX group ( $67.9 \pm 7.5$  ug Mg /mg dry matter and  $48.7 \pm 12.3$  ug Mg /mg dry matter, respectively). CONCLUSIONS: The dietary consumption of Mg below the recommended levels reduced the concentration of the mineral in serum, brain and tissues toughly demanded during physical activity like the gastrocnemius muscle. Mg concentration in the soleus muscle and in the kidneys was maintained in animals of the DEFEX group. ACKNOWLEDGEMENTS: CAPES for financial support

#### POST-EXERCISE WATER IMMERSION INCREASES SHORT TERM FOOD INTAKE IN ACTIVE MEN

HALSE, R., WALLMAN, K., GUELF, K.

THE UNIVERSITY OF WESTERN AUSTRALIA, PERTH, WESTERN AUSTRALIA

Introduction The performance of exercise while immersed in cold water has been shown to influence energy intake in the subsequent meal (White et al., 2005). In addition, cold water immersion has been shown to reduce the concentration of the hormone leptin, high concentrations of which signal satiety (Zeyl et al., 2004). Taken together, these findings raise the question of whether the common practice of post-exercise cold water immersion (CWI) by athletes acutely affects energy intake. Hence, this study investigated the acute effect of CWI following exercise on subsequent energy intake and macronutrient preferences, as well as the circulating levels of a range of appe-

title-related hormones. **Methods** Ten physically active men participated in three randomised, counterbalanced trials each consisting of 40 min of treadmill running (70% VO<sub>2</sub>peak), followed by 20 min of either cold water immersion (CWI: 15°C); neutral water immersion (NWI: 33°C) or a resting control with no immersion post-exercise (CON). Participants were then given 30 min access to a buffet-type breakfast of precisely known quantity and nutrient composition from which they could consume ad libitum. Blood samples were collected pre-exercise; post-exercise; post-immersion and post-breakfast to determine the response of leptin, insulin, active ghrelin, pancreatic polypeptide and peptide tyrosine tyrosine. **Results** Participants consumed significantly more energy in the post-exercise meal following both CWI (4893 ± 1554 kJ, *p* = 0.006) and NWI (5167 ± 1975 kJ, *p* = 0.010) compared to CON (4089 ± 1585 kJ). However, there was no significant difference in total energy intake between the CWI and NWI trials (*p* = 0.595). Absolute carbohydrate and protein intake were significantly higher following both CWI and NWI compared to CON (*p* < 0.05), with no difference between the two immersion protocols (*p* > 0.05). These changes were associated with a significant interaction effect of time and trial on the circulating concentrations of both leptin (*p* = 0.045) and active ghrelin (*p* = 0.046). **Discussion** Post-exercise water immersion is associated with higher energy intake in the subsequent meal compared to a resting control. This is an important consideration for athletes using water immersion as a method of recovery from exercise. **References** White LJ, Dressendorfer RH, Holland E, McCoy SC, Ferguson MA. ## HYDRATION STATUS AND FLUID INTAKE HABITS IN SKI TOURERS DURING A SKI TOUR

HAUDUM, J., HAUDUM, A., MÜLLER, E.

UNIVERSITY OF SALZBURG

**Introduction** Dehydration (i.e., a decrease in body fluid from euhydrated state) and hypohydration may result in a decrease in performance, decrease in overall health as well as death (1). It is well known that many athletes finish a race with a fluid deficit of more than 2% of their body weight because they do not drink enough to compensate the fluid loss (2). High-intensity exercise and hot conditions, and especially in winter sports such as ski touring, clothing and altitude may contribute to higher sweat rates (1). **Purpose** The purpose of this study was to determine the hydration status in ski tourers before and after a physically demanding (ascending and descending) ski tour. **Methods** 15 ski tour racers (14 males, 1 female, age 36.8 yrs ± 7.6 yrs, body mass 74.7 kg ± 13.7 kg) volunteered to participate in this study after providing written informed consent. Subjects completed a diet record the day before the testing session and on test day to control their fluid intake. They were instructed to follow their usual pre-race diet and to abstain from heavy exercise the 24h before the trial. Subjects provided a urine sample before and after the ski tour (distance 8.8 km, elevation gain 760 m) in order to determine urine specific gravity (Usg) and pH. Usg ≥ 1.020 was used as the cut-off point for dehydration. Additionally, body mass (on a digital scale in dry underwear or without clothes), total body water (TBW), lactate (La) and rate of perceived exertion (RPE) were evaluated before and after exercise. During the trial, ingestion of fluids was at will. However, the volume ingested was recorded to correct post-exercise body mass. **Results** 6 Subjects (40%) appeared to be inadequately hydrated pre-exercise. Results showed statistically significant differences in weight (*p* < .001, ES = .73), TBW (*p* < .05, ES = .25), La (*p* < .001, ES = .50), pH (*p* < .05, ES = .32) and RPE (*p* < .001, ES = .87). Mean values for Usg showed no statistical significance between pre- and post-trial values. **Conclusion** More than one third of ski tourers started exercise dehydrated and no subject consumed enough to match fluid losses, and only two consumed fluids during the trial. Given that races in ski touring are usually longer than the 8.8 km distance of this trial, these results highlight the need to provide more information about proper hydration pre-, as well as during exercise since performance will be affected even more by dehydration during longer races. 1. ## ENERGY EXPENDITURE AND DIETARY INTAKE DURING HIGH- AND LOW VOLUME TRAINING PERIODS AMONG ENDURANCE ATHLETES

DRENOWATZ, C.

MICHIGAN STATE UNIVERSITY

**Energy Expenditure and Dietary Intake during High- and Low Volume Training Periods among Endurance Athletes** Drenowatz C. 1, Eisenmann JC. 1, Carlson JJ. 2 1 Human Energy Research Laboratory, Michigan State University (USA) 2 Radiology & Osteopathic Medicine, Michigan State University (USA) **Introduction** Energy balance and appropriate nutritional intake are established contributors to athletic performance. Previous research, however, has not evaluated differences in energy expenditure in response to different training regimens or only assessed exercise energy expenditure (EEE), rather than considering total daily energy expenditure (TDEE) when examining dietary intake. The purpose of this study was to examine dietary intake in endurance trained athletes during a week of high-volume (HV) and low-volume (LV) training while measuring EEE, resting metabolic rate (RMR) and non-exercise energy expenditure (NEAT) and to evaluate if endurance athletes meet current nutrition recommendations. **Methods** Energy expenditure and dietary intake was measured in 15 male endurance athletes (age 23.6 ± 2.4) during non-consecutive weeks of HV and LV training. Anthropometric measurements including %fat via BodPod were taken according to standard procedures at the beginning and end of each week. TDEE was calculated by summing RMR, measured via indirect calorimetry, NEAT, measured with the SenseWear Armband, and EEE, using heart rate telemetry. Dietary intake was assessed with an online food frequency questionnaire which was completed at the end of the HV and LV week. **Results** No change in body composition was observed during either week of training, which suggests that athletes maintained energy balance. While TDEE was significantly higher during the HV week (4824 ± 773 vs. 4080 ± 637 kcal/day) no differences in energy intake were observed (2662 ± 1299 vs. 2487 ± 1213 kcal/day). Macronutrient composition of the diet also remained unchanged with carbohydrates (CHO), fat, and protein contributing 51%, 33%, and 16%, respectively. With respect to recommendations for endurance athletes the reported CHO intake of 4.5 g/kg body weight was well below recommendations, while fat intake (1.3 g/kg) was above, and protein met recommendations. Key micronutrients met or exceeded recommendations with the exception of potassium. **Discussion** Dietary intake was not altered in response to changes in training volume or TDEE. The reported dietary intake was significantly lower than TDEE. This discrepancy was attributed to underreporting rather than an energy deficit. The high fat intake, low fiber consumption, and high sodium intake suggests that these athletes were generally consuming a typical Western diet. Nevertheless, micronutrient intake exceeded current recommendations supporting that endurance athletes are able to meet recommendations without the utilization of supplements. Overall, these endurance athletes may not pay sufficient attention to their dietary intake in order to optimize their performance.

**EFFECT OF SPICES ON GASTRIC MOTILITY AND APPETITE SENSATIONS**

NAGAI, N.1, WAKISAKA, S.1, TAKAGI, A.1, YAMAGUCHI, M.1, MORITANI, T.2

1: UNIVERSITY OF HYOGO, 2: KYOTO UNIVERSITY

**EFFECT OF SPICES ON GASTRIC MOTILITY AND APPETITE SENSATIONS** Nagai, N.1, Wakisaka, S.1, Takagi, A.1, Yamaguchi, M.1, Moritani, T.2 1: Graduate School of Human Science and Environment, University of Hyogo (Hyogo, Japan) 2: Graduate School of Human and Environmental Studies, Kyoto University (Kyoto, Japan) **Introduction** The gastric electrical activity paces the contractions of the stomach and can be measured noninvasively using surface electrodes placed on the abdomen (Verhagen 1999, Parkman et al. 2003). Our previous studies (Wakisaka et al. 2009, 2011) have clearly demonstrated that gastric motility was transiently increased after water ingestion, while hot water (>150 ml, 65 °C) accelerated the pace of the normal range of gastric motility (normogastria). By means of our newly developed electrogastrography (EGG) recording and analysis methods, we investigated the response of the gastric motility and appetite sensations (feeling of hunger, fullness, desire to eat, and satiety) to spice (yellow curry powder)-containing soup or isoenergetic, flavorless placebo soup (43kcal, 150 ml, 65 °C) in 12 healthy female volunteers (19-23 yrs). **Methods** Each subject was tested on two separate days in a randomized order at 9 a.m. after overnight fast. The gastric motility, eardrum temperature, and heart rate were measured for 20 min in the fasting state and 40 min after consuming the soup in sitting-up position. Appetite sensations were measured 3 times (fasting, right after and 40 min after). To determine the gastric motility, we assessed the component of bradygastria (1-2 cpm), normogastria (2-4 cpm), tachygastria (4-9 cpm), and each power ratio (post/pre) of EGG frequency power spectrum. **Results** Each EGG power ratio tended to increase following spice-containing soup as compared with placebo soup (bradygastria,  $4.1 \pm 0.6$  vs.  $2.2 \pm 0.7$  times; normogastria,  $6.5 \pm 1.9$  vs.  $2.3 \pm 0.5$  times; tachygastria,  $7.6 \pm 2.7$  vs.  $2.5 \pm 0.8$  times, mean  $\pm$  S.E.). As to the appetite sensations, fullness ( $p < 0.05$ ) and satiety ( $p < 0.01$ ) scores significantly increased after spice-containing soup with different time courses ( $p < 0.001$ ). Delta-increase in eardrum temperature right after consuming the spice-containing soup was significantly greater than that of placebo soup ( $0.40 \pm 0.05$  vs.  $-0.05 \pm 0.17$  °C,  $p < 0.05$ ), while similar increase in heart rate ( $7.9 \pm 0.9$  vs.  $8.4 \pm 1.3$  bpm, NS) was observed after both soups. **Discussion** The present results suggest that the spices contained in curry powder enhances gastric motility and fullness and satiety feelings while increasing eardrum temperature when compared with placebo soup trial. **References** Verhagen MAMT, Van Schelven LJ, Samsom M, Smout AJPM. **EFFECTS OF EATING BREAKFAST ON HEART RATE AND ORAL TEMPERATURE AFTER EATING LUNCH**

NOSE, Y.1, NISHIMURA, K.2, YAMAGUCHI, H.3, ONODERA, S.4

1. GRADUATE SCHOOL, KUMW 2. HIT 3. KIU 4. KUMW

**Introduction:** In the subjects who ate breakfast every day (breakfast group), the heart rate increased for duration of one hour after eating lunch. The heart rate of subjects who ate breakfast only two times or less during the week (skipping group), however, showed no significant difference between the rates before and after lunch. Eating is accompanied by increased blood flow to facilitate digestion. These results suggest that the increase of blood flow for the skipping group is low even after lunch. The purpose of this study was to determine the effects of eating breakfast on heart rate, cardiac parasympathetic reactivation and oral temperature after eating lunch in the skipping group. **Method:** There were two regimens. One was the regimen of skipping breakfast (C group) and the other was the regime of eating breakfast no later than 9:00AM (SB group). All subjects ate lunch between 11:45AM and 12:15PM. All subjects ate the same diets. Oral temperatures were measured before lunch and once every hour for four hours after lunch. Cardiac autonomic nervous system activity was calculated using Maximum Entropy Calculation Methodology (MemCalc) and evaluated by using high frequency (HF; 0.15-0.4Hz) in R-R intervals. Heart rate and HF were measured for five minutes before lunch and immediately, at 20min, at 40min, at one hour, at two hours, at three hours and at four hours after lunch. **Results:** The difference in oral temperature before and after lunch of the SB group was greater than that of the C group (ANOVA:  $p < 0.05$ ). In the C group, oral temperatures at one and three hours after lunch were lower than before lunch ( $p < 0.05$  before  $36.84 \pm 0.18$ °C, 1 hour  $36.71 \pm 0.18$ °C, 3 hours  $36.66 \pm 0.21$ °C) and the temperatures of half of the subjects fell at four hours after lunch. Heart rate of the SB group increased significantly for two hours after lunch ( $p < 0.05$ : before  $66.4 \pm 13.2$ bpm, immediately  $74.4 \pm 15.9$ bpm, 20min  $74.2 \pm 14.1$ bpm, 40min  $73.9 \pm 12.9$ bpm, 1 hour  $70.41 \pm 11.7$ bpm, 2hour  $70.4 \pm 11.7$ bpm), and the heart rate of C group showed no significant differences between measurements before and after eating. **Discussion:** Diet-induced thermogenesis (DIT) which increases core body temperature, is generated by eating. These study results suggest that the DIT of C group is low and therefore unable to induce a rise in oral temperature. These results suggest that eating breakfast prevented hypothermia in persons in the skipping group. When subjects ate breakfast only one day, blood flow increased. It is possible that increase of blood flow could be induced post-prandial hypotension. So it is necessary to study further the differences between results in a group regularly eating breakfast and a group eating breakfast only once.

**DOES HIGH CARDIORESPIRATORY FITNESS ASSOCIATED WITH HEALTHY DIETARY INTAKE IN EUROPEAN ADOLESCENTS: THE HELENA STUDY?**

CUENCA-GARCIA, M.1, ORTEGA, F.B.1,2, RUIZ, J.R.3, HUYBRECHTS, I.4, SJÖSTRÖM, M.2, GONZÁLEZ-CROSS, M.5, MORENO, L.A.6, DE HENAUW, S.4, KERSTING, M.7, CASTILLO, M.J.1, ET AL

1:FM-UGR (GRANADA, SPAIN), 2:PREVNUT-KI (HUDDINGE, SWEDEN), 3:FCAFD-UGR (GRANADA, SPAIN), 4:UZ (GHENT, BELGIUM), 5:CTAN/CSIC (MADRID, SPAIN), 6:UNIZA (ZARAGOZA, SPAIN), 7:FKE (BONN, GERMANY)

**Does high cardiorespiratory fitness associated with healthy dietary intake in European adolescents: The HELENA study?** Cuenca-Garcia, M.1, Ortega, F.B.1,2, Ruiz, J.R.3, Huybrechts, I.4, Diaz, L.E.5, Ciarapica, D.6, Molnar, D.7, Sjöström, M.2, Gotthard, F.8, Widhalm, K.9, González-Cross, M.10, Moreno, L.A.10, De Henauw, S.4, Kersting, M.12, Castillo, M.J.1 1:FM-UGR (Granada, Spain), 2:PREVNUT-KI (Huddinge, Sweden), 3:FCAFD-UGR (Granada, Spain), 4:UZ (Ghent, Belgium), 5:CTAN/CSIC (Madrid, Spain), 6:INRAN (Rome, Italy), 7:AOK (Pécs, Hungary), 8:FACHRU (Lille, France), 9:MEDUNIWIEN (Vienna, Austria), 10:PUM (Madrid, Spain), 11:UNIZA (Zaragoza, Spain), 12:FKE (Bonn, Germany) **Introduction:** Cardiorespiratory fitness (CRF) and diet have been related to healthier cardiovascular profile. Despite the importance of these two factors, little is known about the relationship between them. The aim of this study was to study the relationship between CRF and diet in European adolescents. We also examined whether having a high CRF is associated with compliance to the recommendations. **Methods:** The study comprised 1492 adolescents (770 female) from eight European cities participating in the HELENA (Healthy Lifestyle in Europe by Nutrition in Adolescence) study. Dietary intake was self-registered by the adolescents using a computer-based tool

24-h dietary recalls (HELENA-DIAT) on 2 non-consecutive days. CRF was assessed by the 20-meter shuttle run test. Weight and height were measured, and body mass index (BMI) was calculated. The adolescents were grouped by low and high CRF levels according to the FITNESSGRAM Standards. Multilevel analyses and logistic regression analyses adjusted by center, age and BMI were performed. Results: Higher CRF was related to higher total energy intake in boys ( $p=0.003$ ). No association was found between CRF and macronutrients, yet some positive associations were found with daily intake of bread/cereal in boys and milk products in both boys and girls (all  $p<0.003$ ), regardless of center, age, and BMI. CRF was inversely related to sweet beverage consumption in girls. These findings were overall consistent when CRF was analyzed according to the FITNESSGRAM categories (high/low CRF). CRF was not related to compliance of dietary guidelines/recommendations, except for sweet beverages which was lower in girls with high CRF. Discussion: Overall, the associations between CRF and diet was weak and non-consistent, yet participants with higher CRF showed higher intake of some healthy foods, i.e. more bread/cereal, milk products and less sweet beverage. Funding: The HELENA Study was carried out with the financial support of the European Community Sixth RTD Framework Programme (Contract FOOD-CT-2005-007034). ### PP-PM67 Cardiovascular Health 2

#### BLOOD PRESSURE OF UNMEDICATED HYPERTENSIVE WORKERS AND PHYSICAL TRAINING

MELLO, A., SERRA, R., SIMÃO, R.

UFRJ - UNIVERSIDADE FEDERAL DO RIO DE JANEIRO

**Introduction** The employees' health is the concern of large corporations. A Brazilian company has been promoting a fitness program for six years oriented by the School of Physical Education at Universidade Federal do Rio de Janeiro, Brazil. As part of the risk factors control for non-transmissible chronic diseases, physical exercises are recommended for the prevention, treatment and control of blood pressure (BP). The aim of this study was to investigate the BP behavior after four months of training in unmedicated hypertensive subjects. **Methods** Fifty-seven sedentary subjects participated in the program (time  $\geq 1$  year), divided into a training group (TG) and a control group (CG). All were physically assessed and the TG had three sessions per week, totaling 48 sessions, each lasting 60 minutes. They performed a 25-minute aerobic training between 50 to 70% of heart rate reserve, a strength training in two series ranging from 8 to 12 repetitions, and a flexibility training applying the static stretching method. BP was measured by auscultation at pre- and post training and data were processed by two-way ANOVA using the Scheffé post hoc when needed ( $p < 0.05$ ) for intragroup and intergroup comparison. **Results** The intragroup outcome for the TG showed an 11.4% reduction in systolic BP (SBP) ( $P < 0.05$ ) and 5.3% in diastolic BP (DBP) ( $P > 0.05$ ). The CG showed no changes in BP ( $P > 0.05$ ). Comparing CG and GT, there was a significant difference in SBP in post-training situation, but this did not occur in other measurements. **Discussion** Studies confirm the hypotensive effect after aerobic work (Pescatello et al., 2004), but few have investigated the post-exercise strength hypotension. Martins et al. (2004) followed medicated hypertensives subjected to strength, aerobic and flexibility sessions and after eight weeks they found no significant differences regarding the resting values in both groups; however the BP in the TG showed a tendency to reduction. Despite the methodological differences between our experiment and Martins and co-workers', we found higher reductions in BP, probably because our sample was not medicated and training lasted 16 weeks. With measurements taken 48 hours after the last session aiming to decrease the acute hypotensive effect immediately after exertion, we found a clinically significant reduction in BP at rest. **References** Pescatello LS, Franklin BA, Fagar R, Farquhar WB, Kelley GA, Ray CA. **Introduction** The volume and intensity of exercise has significant acute effects on the relative concentration of erythrocytes, haematocrite and haemoglobin through changes in plasma volume, and also on the absolute concentration and function of some leukocyte subsets via cell movement circulation and lymphatic organs. The aim of this study was to monitor the response to training load on haematological markers in elite canoeists during a training season. **Methods** This study took place during the training season that culminated with the participation in the 2008 Olympic Games. The sample was composed by 11 canoeists athletes 22,0 $\pm$ 4,3 years old, 66,2 $\pm$ 4,4Kg and 164,5 $\pm$ 4,2cm. Initial VO<sub>2</sub>max was 64,9 $\pm$ 4,8 ml.Kg.min<sup>-1</sup>. Blood samples were collected by venopuncture. For the blood collection a time lapse of 48 hours of rest after the last training session was respected. The moments controlled were: the beginning of the season, after an off training period of 6 weeks (t1), the 11th week after the application of high weekly training volumes (t2), week 26 after a cycle of intense training (t3), the 31th week of the training season and the end of this tapering phase (t4). Leukocyte, monocyte, granulocytes, erythrocyte, platelet concentration (Plt), haematocrite, haemoglobin (Hb) and mean corpuscular haemoglobin (MCHC) were measured with a full blood count. **Results** After the increase in volume training (t2), a reduction in the number of leukocytes, lymphocytes and platelets was observed, while the number of granulocytes increased. Small increases in MCHC, hemoglobin, hematocrite were also observed. After the intense training period (t3) leukocytes continued to decrease, as well as lymphocytes. Unlike the observed in t2, the number of granulocytes was reduced below the baseline. Erythrocytes, platelets and MCHC increased. Before the competition period (t4), values returned to the initial ones. **Discussion** Cross-sectional studies that have compared leukocyte numbers and functions in blood samples taken from athletes more than 24 h after their last training session with those of sedentary individuals have generally report very few differences (Gleeson, 2007). Other have found that Ironman triathletes showed significantly lower Hb, MCHC and Plt than untrained men most of the year, and that there were significant differences month-to-month for both groups in these parameters (Broadbente, 2011). Our research verifies that the volume and intensity chronic training cause hematologic change. Reducing load and intensity similar values than the baseline one were founded again. **References** Broadbente S. (2011). Eur J Appl Physiol, 111,93-100. Gleeson M. (2007). **Introduction** The Human Animal Bond (HAB) is a mutually beneficial and dynamic relationship between people and animals that is influenced by behaviors. Each influences the psychological and physiological state of the other. The positive association between pet ownership and various physiological and psychological health outcomes was reported (Dembicki D et al., 1996; DeMello LR, 1996; Oka et al., 2009). Dog is the most popular pet. There were invasive and non-invasive method in the measurement of dog heart rate. In HAB studies, invasive method couldn't use for pet. And common non-invasive method could not use for various size dogs. The objective of this study was to measure non-invasively heart rate from various size dogs. **Methods** Dog heart rate was measured using the sport heart rate monitor (Polar) designed for use in human. This monitor was consisted of an electrode belt with built-in transmitter and remote monitoring receiver. Various size dogs (small, medium, big) were measured. Dog heart rate was measured during 35 min. This 35 min consisted of 5 sections and the 5 sections were as follows: walking time (5 min), relax time (5 min), playing time with a toy (5 min), relax time (5 min), in house (15 min). Measurements were made on the 1 min setting. Attachment of the electrode belt was performed at least 30 min before recording. The receiver contained in a wristband was strapped to the dog lead. **Results** In each size dog, heart rate could be measured. The important points to measure dog heart rate using human heart rate monitor were five. 1 Before the electrode attachment, skin site was exposed using the comb. 2 The gel for the ultrasonography was spread between the electrode and the skin. 3 There was no space between the electrode and skin. 4 The electrode was attached on the left dorsal. 5 The electrode and transmitter was secured by a self-adherent wrap (Coban, 3M) or an elasticated band (Stockinet plus, 3M). **Discussion** In dogs, thick hair disturbed contact of the skin and the electrode. And movement of the chest with respiration made space between the electrode and the skin. This method resolved these problems. Without shaving the hair, heart rate of various size dogs could be measured non-invasively by this method. In HAB studies, this method would be useful. **References** Dembicki D, Anderson J (1996) J Nutr Elder, 15, 15-31 DeMello LR (1999) Psychol Health, 14, 859-868 Oka K, Shibata A (2009) J Phys Act Health, 6, 412-418

## TRENDS OF ELEVATED SYSTOLIC BLOOD PRESSURE LEVELS IN A SAMPLE OF YOUTH. RELATIONSHIP WITH CARDIO-RESPIRATORY FITNESS, BODY MASS INDEX AND PHYSICAL ACTIVITY

GAYA, A.R., GAYA, A., MARTINS, C., AIRES, L., MOTA, J.

FEDERAL UNIVERSITY OF SOUTH OF BRAZIL. FACULTY OF PHYSICAL EDUCATION

**Objective:** To analyse the association of being assigned to a high blood pressure (HBP) group with changes in body mass index (BMI), physical activity index (PAI) and cardiorespiratory fitness (CRF) for one year in a sample of youth. **Methods:** Longitudinal study with 221 youth aged 8-17 (85 boys and 136 girls). Blood pressure (BP) was assessed in fasting state using an automated oscilometric sphygmomanometer. Students were invited to measure anthropometric variables, sexual maturation and perform 20m Shuttle and Run Test (Fitnessgram Battery Test). PAI was assessed using a standard questionnaire. Changes over time were calculated:  $\Delta = T1 - T0$ . Subjects were classified in a high level of BP if their values were above percentile 75, adjusted by gender and age. **Results:** For one year, approximately 6.5% of the subjects moved from normal to HBP group, while 4.3% moved from HBP group to normal. The risk of being assigned for the group of HBP for one year was associated with being male (OR: 4.33; 95% CI: 1.74; 10.79) and overweight/obese at baseline (OR: 8.16; 95% CI: 3.40; 19.58). High levels of CRF at baseline were inversely associated with risk of HBP values (OR: 0.31; 95%CI: 0.11; 0.88) when BMI was included on the model. The differences of BMI, CRF and PAI between time 1 and time 0 did not show significant association with the risk of being in HBP group. **Conclusions:** Our results suggest that number of children which moved from normal to HBP group was higher than the number of subjects that left the HBP group. Overweight/obese seems to be the main risk associated with early development of HBP values in children and adolescents

## CARDIORESPIRATORY FITNESS AND FATNESS ARE ASSOCIATED WITH POSITIVE HEALTH IN CHILDREN AND ADOLESCENTS

CASTRO-PIÑERO, J.1,2, PADILLA-MOLEDO, C.1,2, ORTEGA, F.B.2, MORA, J.1, MÁRQUEZ, S.3, SJÖSTRÖM, M.2, RUIZ, J.R.2,4

1: UCA (PUERTO REAL, SPAIN), 2: KI (HUDDINGE, SWEDEN), 3: ULEONLEÓN, SPAIN), 4: UGR (GRANADA, SPAIN)

**Introduction** Positive health is likely a buffer against physical and mental illness. Positive health may explain some of the health benefits associated with increasing cardiorespiratory fitness and decreasing fatness in youth. We examined the association of cardiorespiratory fitness and fatness with positive health indicators in 684 (365 boys and 319 girls) Spanish children aged 6 to 17.9 years. **Methods** Positive health indicators were self-reported using items of the Health Behavior in School-aged Children questionnaire. The study health indicators were: perceived health status, life satisfaction, quality of family relationships, quality of peer relationships and academic performance. Weight and height were measured and body mass index was computed. We also measured triceps and calf skinfolds thickness and body fat percentage was estimated. Cardiorespiratory fitness was measured by the 20m shuttle-run test. **Results** Cardiorespiratory fitness was positively associated with life satisfaction in children and adolescents. Fatness was inversely associated with perceived health status in children and adolescents, whereas fatness was inversely associated with life satisfaction, quality of family relationships and academic performance only in children. **Conclusion** These findings suggest a link between cardiorespiratory fitness and fatness and positive health indicators, suggesting that improving both fitness and fatness could exert a favorable effect on positive health during childhood and adolescence.

## CARDIORESPIRATORY FITNESS, FATNESS, HEALTH COMPLAINTS AND HEALTH RISK BEHAVIORS IN YOUTH

CASTRO-PIÑERO, J.1,2, PADILLA-MOLEDO, C.1,2, ORTEGA, F.B.2, MOLINER-URDIALES, D.3, KEATING, X.D.4, MORA, J.1, RUIZ, J.R.2,5

1: UCA (PUERTO REAL, SPAIN), 2: KI (HUDDINGE, SWEDEN), 3: UJI (CASTELLÓN, SPAIN), 4: UTA (AUSTIN, USA), 5: UGR (GRANADA, SPAIN)

**Introduction** Less is known whether cardiorespiratory fitness is associated with health complaints and health risk factors in youth. Likewise, studies examining the association of fatness with health complaints and health risk factors in youth are scarce and the results

contradictory. Therefore, the aim of the present study was to examine the association of cardiorespiratory fitness and fatness with health complaints and health risk behaviors in 691 (323 girls) Spanish children aged 6-17.9. Methods Health complaints and health risk behaviors were self-reported using items of the Health Behavior in School-aged Children questionnaire. Weight and height were measured and body mass index was computed. Body fat percentage was estimated from triceps and calf skinfolds thickness. Cardiorespiratory fitness was measured by the 20m shuttle-run test, and youth categorized as fit/unfit. Results Unfit children and adolescents were more likely to report health complaints sometime (OR: 2.556, 95% CI: 1.299-5.031; and OR: 1.997, 95% CI: 1.162-3.433, respectively) than their fit counterparts. Likewise, overweight-obese children and adolescents and those with high fat levels were more likely to report health complaints (OR: 1.732, 95% CI: 1.019-2.945; and OR: 1.983, 95% CI: 1.083-3.629, respectively). The analysis of the combined influence of fitness and fatness revealed that fit youth had lower health complaints index than the fat-unfit and unfat-unfit groups (all  $P < 0.05$ ). Conclusions Low fitness and overweight-obesity increased the risk of having health complaints in youth, yet high levels of cardiorespiratory fitness might overcome deleterious effects of overweight-obesity on health complaints.

## HEART RATE VARIABILITY AS A COMPREHENSIVE ASSESSMENT TOOL IN A PHYSICAL ACTIVITY PROGRAM FOR SCHIZOPHRENIA

BLASCO-LAFARGA, C.1, CAUS, N.2, TORTOSA-MARTÍNEZ, J.2, MUÑOZ-PÉREZ, M.3, MARTÍNEZ-NAVARRO, I.1

1: UNIVERSITY OF VALENCIA, SPAIN; 2: UNIVERSITY OF ALICANTE, SPAIN; 3: DR. ESQUERDO MENTAL HEALTH CENTRE, ALICANTE, SPAIN.

**Introduction** An Autonomic Nervous System (ANS) dysfunction mediated by sympathetic hyper-arousal and vagal withdrawal has been described in Schizophrenia (SCZ) independent of medication effects (Henry et al., 2010). Physical Activity (PA) has been proposed as a non-pharmacological strategy to improve the ANS functioning through a better coordination on the sympathetic afferent autonomic controls and the improvement in vagal responses (Negrao et al., 2008). Therefore, our purpose is to analyze some main HRV indices in order to consider them as previous control variables to classify participants in Experimental (E) or Control (C) Group within a three months Leisure-Time PA Program (PAP) held in Dr. Esquerdo Mental Health Centre. **Methods** 35 patients (16 male; 19 female; age:  $44.86 \pm 10.33$ ; years ill:  $23.29 \pm 8.87$ ; Smoking: Non-9, medium-5, heavy-20) were randomly distributed between Experimental (E=14) and Control (C=21) group. HRV data (Polar Electro RS800) were registered after shower, 10 min lying with no breathing control, before breakfast. Best central 5 min were retained for treatment (Kubios 2.0) and Statistical analysis (SPSS 15.0). After K-S test, (ln) was considered for skewed data. Results Mancova considering Gender, Group and Tobacco as co-factors; and RRI, Age and Years ill as Co-variables, showed no significant differences when comparing Gender or Groups for the linear indices. Meanwhile, the non-linear indices, now without the covariable RRI, revealed a strong and significant gender influence in SampEn, and a trend in  $\alpha 1$  (male vs. female; SDNN:  $21.76 \pm 4.34$ ,  $22.77 \pm 3.26$ ; pNN50:  $3.57 \pm 3.52$ ,  $5.83 \pm 2.640$ ; lnRMSSD:  $2.60 \pm 0.23$ ,  $2.80 \pm 0.17$ ; lnHF:  $3.81 \pm 0.45$ ,  $4.63 \pm 0.34$ ; lnLF/HF:  $1.18 \pm 0.42$ ,  $0.46 \pm 0.31$ ; SampEn:  $1.03 \pm 0.13$ ,  $1.55 \pm 0.97$ ;  $p < 0.05$ ;  $\alpha 1$ :  $1.41 \pm 0.13$ ,  $1.10 \pm 0.95$ ;  $p = 0.067$ .) **Discussion** Our results matched to the already described autonomic impairment with markers of very high cardiovascular risk. Also, they point to a better capacity of non-linear approaches to detect subtle changes, as much as gender influence. The absence of significant Group differences may allow to analyze the changes in HRV along the Leisure-time PAP. There is still great lack of information about the awaited benefits of PAP for SCZ and about training variables like doses, frequency, etc. The multimodal origin of the above mentioned ANS dysfunction and the direct relation between cardiac functioning improvement and Exercise, suggests the feasibility of HRV as a comprehensive and complementary tool in PAP. **References** Henry BL, Minassian A, Paulus MP, Geyer MA & Perry W. (2010). J Psychiatr Res, 44(3), 168-176. Negrao CE & Middlekauff HR. (2008). Heart Fail Rev, 13(1), 51-60.

## CORRELATIONS BETWEEN STRENGTH AND HEART RATE VARIABILITY AFTER 16 WEEKS OF CONCURRENT TRAINING IN MIDDLE-AGED MEN

GASPARI, A., FERRARI, S., LEITE, S., LIBARDI, C., SOUZA, G., ANTUNES, M., MADRUGA, V.A., CHACON-MIKAHIL, M.T.

STATE UNIVERSITY OF CAMPINAS - BRAZIL

**Introduction** Heart rate variability (HRV) is a risk marker for cardiovascular disease (Heffernan et al., 2007) and has been recently used for measurement of physical training improvement of the cardiovascular system. High fitness level can minimize physiological changes in vagal modulation related to aging process, regardless of gender (De Meersman, Stein 2007). Concurrent training (CT) has shown the same benefits as isolated training, although to a lesser magnitude (Leveritt et al., 1999). This research has the goal of verifying the effects of CT on correlations between strength and HRV. **Methods** Ten healthy and non-physically active men were analyzed ( $48 \pm 4.1$  years). The CT proposed consists of 16-training weeks (3 d.wk-1), 3 sets of 10 maximal repetitions (RM) with 60 sec of rest between sets, 6 exercises, followed 30 min jogging at 55-85%  $VO_{2peak}$ . Maximal upper-body (UBS) and lower-body strengths (LBS) were measured by 1-RM test, involving two exercises that were part of the training routine (bench press and leg press). The RR intervals were recorded for 20 min at rest in supine position using the Polar® S810, the data was analyzed using FFT algorithm by Polar Precision Performance and were calculated the variables pNN50, RMSSD, High Frequency (HF) Hz, Low Frequency (LF) Hz were calculated. Results Maximal UBS ( $69.5 \pm 8.4$  to  $85.9 \pm 9.6$  kg) and LBS ( $196.2 \pm 29.5$  to  $315.2 \pm 62.6$  kg) improved ( $p < 0.05$ ) after the training program. There were no changes at the HRV markers analyzed. The significant correlation coefficients between UBS, LBS and HRV were:  $r = 0.58$  ( $p = 0.04$ ) UBS vs. LF (Hz), and  $r = 0.70$  ( $p = 0.01$ ) LBS vs. LF (Hz), both after training. **Discussion** Before training no correlations were found between UBS, LBS and HRV variables suggesting a preserved heart rate autonomic control in this population. After 16wk of CT, strength levels increased without any modification in the autonomic markers. Moreover, the correlation after training between UBS and LBS with LF could indicate negative influence of the strength improvement above the autonomic control. Perhaps some peripheral changes can have changed some central control structure that is reflected in the heart. **References** Leveritt, M; et al. (1999) Sports med, 28, (6), 413-427. Heffernan, KS; et al. (2007) Am J Physiol Heart Circ Physiol, 293, 3180-3186. De Meersman, RE; Stein, PK. (2007) Biol Psych, 74, 165-173.

## EFFECTS OF CARDIORESPIRATORY FITNESS OVER CARDIOVASCULAR RISK FACTORS CONTROLLING FOR OBJECTIVELY MEASURED PHYSICAL ACTIVITY IN YOUTHS

SILVA, G., AIRES, L., PIZARRO, A., SANTOS, M.P., MOTA, J., OLIVEIRA, J., RIBEIRO, J.C.

FACULTY OF SPORT - UNIVERSITY OF PORTO

**INTRODUCTION:** This study aimed to verify the effects of cardiorespiratory fitness levels over a set of cardiovascular risk factors, controlling for sex and physical activity (PA) of moderate (MPA), vigorous (VPA) and very vigorous (VVPA) intensities in children and adolescents. **METHODS:** Students aged 10-19 years (51 boys and 90 girls) completed measurements to participate in the study. Measured cardiovascu-

lar risk factors were: waist circumference (WC), body mass index (BMI), total cholesterol (TC), high-density cholesterol (HDL), low-density cholesterol (LDL), triglycerides (TRI), fasting glucose (GLU), systolic blood pressure (SBP), diastolic blood pressure (DBP) and mean arterial pressure (MAP). A metabolic syndrome risk score (MRS) was computed from the standardized z-score of WC, HDL, TRI, GLU and MAP. The 20-meter shuttle run test (SR) was used to assess CRF. FITNESSGRAM reference standards for SR laps were considered to classify participants in low-fit and fit. PA was measured by accelerometers (7164 MTI, Actigraph) during 7 consecutive days. PA was expressed as the time (min/day) expended in MPA (2000-2999 counts/min), VPA (3000-4499 counts/min) and VVPA (>4500 counts/min). A Multivariate Analysis of Covariance (MANCOVA) was used assuming CRF levels as the independent factor. Cardiovascular risk factors and MRS were assumed as dependent variables. Sex, MPA, VPA and VVPA were included in the model as covariates. Analyses were carried out in SPSS 19.0 with a significance level set at 0.05. RESULTS: A preliminary analysis indicated that there were no significant interactions between factors and covariates. For the definitive model, the strength of the relationship between CRF levels and the set of cardiovascular risk factors was strong (multivariate  $\eta^2 > 0.25$ ). Forty four percent of the variance in cardiovascular risk factors is accounted for differences in CRF levels, holding constant sex and PA. Sex differences explained 18,6% of the variance in dependent variables, controlling for the differences in CRF and PA. Only VPA showed a significant effect ( $p < 0.05$ ) over the set of cardiovascular risk factors, explaining 17,9% of their variance, when CRF, sex and PA were controlled. CONCLUSIONS: Results indicate that CRF levels have a significant effect over a set of cardiovascular risk factors, independent of sex and PA. Furthermore, VPA also has a significant effect over cardiovascular risk factors, independent of sex and CRF levels. This study was supported by FCT (Projects: PTDC-DES-7242-2006 and PTDC/DES/099018/2008; PhD grant: SFRH/BD/45090/2008).

## AEROBIC AND RESISTANCE TRAINING IN CHRONIC HEART FAILURE AND TYPE 2 DIABETES

TARPERI, C., BACCHI, E., ZANOLLA, L., BARALDO, A., MILANESE, C., MOGHETTI, P., CEVESE, A.

UNIVERSITY OF VERONA

Introduction Aerobic and strength training specifically improve, respectively, central and peripheral limiting factors of skeletal muscle performance, also in the elderly healthy population. Type 2 Diabetes patients (DM2) suffer peripheral and metabolic limitations to skeletal muscle performance, while Chronic Heart Failure (CHF) patients are mainly limited by cardiovascular factors. Therefore, the aim of the present research was to compare and characterize the effects of the two types of exercise on DM2 and CHF. Methods 26 DM2 male patients ( $57 \pm 7.2$  yrs,  $HbA1c$   $7.3 \pm 0.7\%$ ) and 20 CHF male patients (NYHA Class II-III, ICD implanted: age  $67 \pm 5.0$  yrs, EF 28.9%) were randomized to aerobic or resistance training. Supervised exercise sessions were performed 3 times weekly following the Recommendations for exercise prescriptions in DM2 (ACSM and ADA, 2010) and in CHF (ACSM and NYHA). The following variables were assessed before and after 4 month treatments: BMI, body composition (by Total Body DEXA); peak oxygen uptake ( $VO_{2peak}$ ); muscle 1RM indirect tests (Brzycki method, chest press and leg press). Results At baseline, DM2 and CHF respectively showed the following values: BMI  $29 \pm 4.4$  and  $26 \pm 3.6$   $kg \cdot m^{-2}$  ( $p = 0.008$ ), FAT  $24 \pm 7.7$  and  $20 \pm 5.4$   $kg$  ( $p = 0.05$ ),  $VO_{2peak} \cdot kg^{-1}$   $27 \pm 4.0$  and  $18 \pm 2.6$   $ml \cdot kg^{-1} \cdot min^{-1}$  ( $p < 0.05$ ), 1RM at chest press  $48 \pm 9.8$  and  $34 \pm 6.6$   $kg$  ( $p < 0.0001$ ), at leg press  $257 \pm 55$  and  $203 \pm 32$   $kg$  ( $p < 0.001$ ). The anthropometric values did not change after any training in both groups. After aerobic training,  $VO_{2peak} \cdot kg^{-1}$  equally increased by 19% both in DM2 and CHF ( $P < 0.001$ ), while after resistance training it increased by 17% in CHF only ( $P = 0.001$ ). After resistance training, 1RM increased by 23% in DM2 and by 52% in CHF with chest press; by 17% in DM2 and by 44% in CHF with leg press. In addition, after aerobic training, a statistically significant increase by 12% and 22% at chest press and at leg press, respectively, was found in CHF. Discussion Both treatments achieved health related benefits in CHF and DM2 populations. Despite the different effects of the underlying pathology, the percent increase in  $VO_{2peak}$  elicited by aerobic training was identical in the two groups, suggesting the ability of the human body to specifically enhance damaged mechanisms as a result of a systematic physiological stimulation. The efficacy of resistance training in enhancing  $VO_{2peak}$  in CHF must be related to the impaired state of skeletal muscles caused by a long lasting condition of circulatory insufficiency. Also the larger effects of resistance training on muscle performance (1RM) in CHF points to more serious muscle deterioration in CHF, as it is known that the gain in muscle force is indirectly related to the starting condition.

## CARDIOVASCULAR RISK REDUCTION IN OLDER ADULTS BY PHYSICAL EXERCISE

MARTINS, R., TEIXEIRA, A.M., COELHO E SILVA, M.J., VERÍSSIMO, M.T.

UNIVERSITY OF COIMBRA, FACULTY OF SPORT SCIENCES AND PHYSICAL EDUCATION

Introduction Deterioration of the cardiovascular system and the metabolic profile tends to accompany aging. Although the effects of aerobic versus resistance training on cardiovascular risk factors have been compared, there is a need to further investigate the effects of the aerobic-based exercise versus strength-based exercise on body weight (BW), body mass index (BMI), waist circumference (WC), lipids, blood pressure, and walking distance in older women and men. In the current study we hypothesized that moderate intensity, progressive aerobic-based and strength-based training would improve metabolic health of older women and men. Methods Sixty three sedentary women and men (65-95 years old) volunteered to the study. Participants were randomized into two training groups and one control group. Venous blood samples were collected into EDTA containing tubes, after 12 hours fasting. Differences between evaluations were analyzed with an ANOVA for repeated measures. Bonferroni's tests were used for multiple comparisons. Statistical significance was accepted at the  $p < 0.05$  level. Results The exercising group attained after treatment significant differences on BW, WC, BMI, DBP, TG, TC, HDL-C, LDL-C, TC/HDL-C relationship, and 6-minute walk distance. The control group only had significant differences on WC. At baseline, BMI correlated with TC ( $r = 0.35$ ), and TG ( $r = 0.38$ ); WC correlated with TC ( $r = 0.30$ ), TG ( $r = 0.35$ ), and TC/HDL-C ( $r = 0.38$ ); BW also correlated with TC ( $r = 0.33$ ), TG ( $r = 0.27$ ), and TC/HDL-C ( $r = 0.33$ ). Discussion Our finding that TC, LDL-C, TG, and TC/HDL-C diminish with exercise is consistent with previous research [1] even some have failed to attain gains after strength training in women [2] and in men [3]. A dose-response relationship between serum lipid levels (TC, TG, HDL-C, and TC/HDL-C) and levels of physical activity have been pointed to explain this absence of gains [4]. Independent of the mechanism underlying lipid changes, a reduction of 1% on TC has been shown to reduce the risk for coronary artery disease by 2% [5], which implies that our exercising participants have reduced about 12% their risk. A 1% reduction in LDL-C reduces the risk of major coronary events by approximately 2% [6], which means that we have about a 26% gain. Moreover, a decrease of 1% on HDL-C has been associated with a 2-3% increase in the risk for CHD [7], and assuming that the reverse is true, the 5% increase observed in our both programs should decrease CHD by 10-15%. ## COMPARISON OF SYSTEMIC ARTERIAL STIFFNESS OF MEN AND WOMEN IN A JUNIOR HIGH SCHOOL STUDENT

ONODERA, S.1, MATSUMOTO, N.2, YOSHIOKA, A.3, TAKAHARA, T.4, NOSE, Y.4, TAKAGI, Y.4, SAITO, T.4, ARAKANE, K.4, YAMAGUCHI, H.5, IEMITSU, M.6, TAKAHASHI, K.7, MIYACHI, M.8

1) KUMW, 2) SHUJITSU UNIV., 3) KAGAWA UNIV., 4) GRADUATE SCHOOL, KUMW, 5) KIBI INTERNATIONAL UNIV., 6) RITSUMEIKAN UNIV., 7) TAU, 8) NATIONAL INSTITUTE OF HEALTH AND NUTRITION

**INTRODUCTION;** The purpose of the present study was to investigate the changes in the systemic arterial stiffness of men and women while junior high school student. **METHODS;** Four hundred eighty-seven subjects voluntarily participated in this study (age: 13.4±1.0 years, height: 159.0±8.8 cm, weight: 51.9±7.1 kg, % body fat: 20.5±7.7%). They were divided into the light body weight, standard body weight and over body weight of groups using the Ministry of Education, Culture, Sports, Science and Technology-Japan method. In addition, according to the guideline for children of the Japanese Society of Hypertension, all subjects were assigned into the normal group and high level of normal group of blood pressure. We have informed consent for subjects according to the Declaration of Helsinki. The systemic arterial stiffness was measured by the pulse wave velocity between brachial and ankle arteries (baPWV). **RESULTS;** The baPWV was 955±135 cm/s in the light body weight of group, 965±133 cm/s in the standard weight of group and 989±136 cm/s in the over body weight of group. The differences between over body weight of group and others were statistically significant ( $p<0.05$ ). The baPWV was 943±127 cm/s in the normal group of blood pressure and 1059±137 cm/s in the high level of normal group of blood pressure. The difference between normal group and high level of normal group was statistically significant ( $p<0.05$ ). The baPWV was 956±133 cm/s in the normal group of blood pressure and body weight, 981±122 cm/s in the one risk factor group (over body weight of group or high level of normal group of blood pressure) and 1083±141 cm/s in the both risk factors group (over body weight of group and high level of normal group of blood pressure). The baPWV of the both risk factors group was significantly higher rather than the other two groups ( $p<0.05$ ). **DISCUSSION;** We suspect that the systemic arterial stiffness of obese children is higher than the non-obese children. This is because the baPWV is increased by adiposity. Therefore, the findings of the study indicate that risk factor such as over body weight increases baPWV while the growth period; those would imply an important suggestion that the baPWV is affected by the growth period's lifestyle. #### KINEMATICS OF THE SWING PHASE DURING RACE WALKING

SMITH, L.C.1, HANLEY, B.2

1: UNIVERSITY OF SALFORD, 2: LEEDS METROPOLITAN UNIVERSITY

**Introduction** Race walking is an abnormal gait with rules which state that no visible loss of contact should occur and that the knee should be straightened from initial contact until the vertical upright position. While these rules may predominantly affect the leg's motion during the stance phase, it is possible that they also have an effect during swing. The swing phase is governed by a number of variables, including joint angles and inertial properties of the segments (Mena et al., 1981). The aim of this study was to measure swing characteristics of the leg during race walking. **Methods** Ten international male race walkers (stature: 1.83 m ( $\pm$  0.07); mass: 69.0 kg ( $\pm$  9.3)) walked on a treadmill (Gaitway, Traunstein) at 12.72 km/hr ( $\pm$  .69). The treadmill incorporated two in-dwelling force plates (Kistler, Winterthur) providing values for step length and cadence. The sampling rate was 1000 Hz and data were recorded for 30 s after 2,500 m of walking. Simultaneous video data were recorded using a high-speed camera (RedLake, Tucson). The video data were digitised at 125 Hz (SIMI, Munich) and filtered using a Butterworth 2nd order low-pass filter of 10 Hz. De Leva's (1996) body segment parameter model was applied. Moment of inertia (MOI) was calculated using the parallel axis theorem. Pearson's  $r$  was used to find associations with a confidence level of 5%. **Results** The mean step length for the walkers was 1.14 m ( $\pm$  .05) and cadence 3.06 Hz ( $\pm$  .12). The swing time of 0.36 s ( $\pm$  .01) represented 56% ( $\pm$  1.3) of total step time. At toe-off, the mean knee angle was 152° ( $\pm$  8); the knee then flexed to a minimum of 100° ( $\pm$  6) with extension to 181° ( $\pm$  3) at heel-strike. The minimum MOI for the whole leg was 0.067 kg•m ( $\pm$  .007), which combined the values for the thigh (0.014 kg•m  $\pm$  .001), shank (0.023 kg•m  $\pm$  .003) and foot (0.030 kg•m  $\pm$  .004). Minimum knee angle was correlated positively with minimum whole leg MOI ( $p = .010$ ), minimum shank MOI ( $p = .028$ ) and minimum foot MOI ( $p = .008$ ). No correlations between either minimum knee angle or MOI values with speed or swing time were found. **Discussion** The athletes in this study had a mean minimum knee angle of 100°; this is much greater than for distance running (Williams et al, 1991) and resulted from the need to straighten the knee to 181° by heel-strike. The correlations between minimum knee angle and the moments of inertia show that the negative effect of this technique is a greater inertial resistance to swing. However, the lack of association with speed suggests this may not be a critical factor in success and maintaining a technique that eases knee extension at heel-strike is more important. **References** De Leva P. **Introduction** The biomechanical characteristics of human locomotion, i.e. walking and running at different speeds and slopes, were plenty documented in the literature in conjunction with the mechanical efficiency of the gait (Minetti et al. 2002). No study have been carried out, at least in our knowledge, in which basic kinematical variables were measured when the running speeds vary, as it may happens during a marathon race at increasing slopes. Therefore the aim of this study was to investigate how step length, step frequency, contact and fly time are influenced when running with different constant speeds, performed at 2% and 7% slope inclination. **Methods** Eight elite marathon runners RE and eight amateur marathon runners RA, performed various tests on treadmill at 0%, 2%, 7% slope inclination, at constant speed: 14,15,16,17 and 18 km•h<sup>-1</sup>. High-speed digital cameras 210 Hz were used to record; Dartfish 5.5Pro was used to perform a 2D video analysis. **Result** Step length SL, step frequency SF, fly time FT and contact time CT were measured and ana-

lyzed for comparison. ST, SF and FT increased, CT decreased as a function of the increased speed at any grades with the exception of FT that decreased at 2 and 7% grades. At the same speed ST, CT and FT decreased and SF increased as a function of the increasing grade. Data fitted to the linear regression line ( $R^2 > 0.95$ ). The two groups were significantly different ( $p < 0.05$ ) in FT at every speed; in SL, SF at 15, 16, 17, 18 km•h<sup>-1</sup> in level running only. Significant differences between the two groups were found in FT at 2% and 7% grades in all speeds ( $p < 0.05$ ). Discussion Alterations in percentage for all variables were greater in group RA. It can be concluded that not only the running speed but also the gradient influence the selection of optimum step length and frequency with which efficient running can be maintained. The elite runners can acutely adapt to the altered circumstances more efficiently than amateur runners who have less experience. References Minetti AE, Moia C, Roi GS, Susta D, Ferretti G. ## SLOPES AND SPEED RELATED EFFECTS ON KINEMATIC AND EMG PATTERNS IN ELITE RACE WALKING

PADULO, J.1, ANNINO, G.1, LEBONE, P.1, VERNILLO, G.2, LA TORRE, A.2, TIHANYI, J.3, D'OTTAVIO, S.1.

1: UNIVERSITY "TOR VERGATA" (ROME ITALY), 2: UNIVERSITY (MILANO ITALY), 3: UNIVERSITY, (BUDAPEST HUNGARY)

Introduction In human locomotion every external condition generates a strategy. The aim of this study is to analyze the kinematics parameters and to identify the changes in movement pattern and muscle activity of race-walkers (RW). Methods Twelve elite RW have race walking on a treadmill for 5 minutes each slope (0, 2 and 7%) in iso-efficiency speed (IES1) with heart rate and sEMG on leg muscles constantly monitored. Digital cameras (210 Hz) were used to record; Dartfish 5.5Pro was used to perform a 2D video analysis, while for statistical analysis was used Anova. (I) The IES (km/h) for each subject at 0% grade was the average speed during the best performance in the 10000 m race, minus 1 km/h, which corresponds to the ~50% Vo2MAX and requires an energy cost (Cw0) of 5.0 J/m/kg according to previous studies (Di Prampero 1986). Moreover, according to previous data (Minetti et al. 2002) the increase of Cw as a function of ground slope is:  $0.15 \cdot \text{slope} (\%) + Cw0$ . We calculated for each ground slope the IES at which the Vo2 was equal to the oxygen consumption during level race walking using the following equation:  $Vo2 = (Cw0/21(J/m)) \cdot (IES0/0.06 (m/min))$   $IES = (Vo2 \cdot 21 \cdot 0.06)/(0.15(Cw) \cdot \text{slope} (\%) + (Cw0))$  Results IES, step length (SL) and frequency (SF) decrease as a function of the increasing slope: IES0 12.5 – IES2 11.8 – IES7 10.3; SL= (0-2%= -3.71%, n.s.; 0-7%= -12.23%,  $p < 0.001$ ); SF= (0-2%= -2.38%, n.s.; 0-7%= -6.07%,  $p < 0.01$ ). The contact time (CT) and heart rate (HR) increase at the increasing slope: CT= (0-2%= 2.46%, n.s.; 0-7%= 6.56%,  $p < 0.01$ ); HR= (0-2%= 0.62%, n.s.; 0-7%= 3.25%,  $p < 0.05$ ). The sEMG activity was reduced at the increasing slope in: tibialis anterior (0-2%= 22.49%,  $p < 0.0001$ ; 0-7%= 41.18%,  $p < 0.0001$ ); rectus femoris (0-2%= 15.35%,  $p < 0.0001$ ; 0-7%= 29.13%,  $p < 0.0001$ ). While the sEMG activity was increased in this muscles: vastus lateralis (0-2%= 22.95%,  $p < 0.0001$ ; 0-7%= 31.15%,  $p < 0.0001$ ); gastrocnemius medialis (0-2%= 21.40%,  $p < 0.001$ ; 0-7%= 48.37%,  $p < 0.0001$ ); biceps femoris (0-2%= 190.78%,  $p < 0.0001$ ; 0-7%= 201.37%,  $p < 0.0001$ ). Discussion These results provide the resultant of the real mechanical work in different slopes without increasing energetic cost, validating the equation to calculate the speed in RW only at IES between zero and 2% gradient. While for higher gradient levels the procedure used in this study seems to overestimate the speed, probably due to the different biomechanics between walking (Minetti et al., 2002) and race walking. ## KINEMATICS OF THE SWING PHASE IN DISTANCE RUNNING

SMITH, L.C.1, HANLEY, B.2

1: UNIVERSITY OF SALFORD, 2: LEEDS METROPOLITAN UNIVERSITY

Introduction The motion of the swing leg is a key component in distance running. More acute knee angles are associated with more economical runners (e.g. Williams and Cavanagh, 1987). This may be due to a decrease in the moment of inertia (MOI) of the leg, although it is unclear if other variables are affected by this decrease in MOI. The aim of this study was to measure swing characteristics of the leg during distance running. Methods Ten competitive male distance runners (stature: 1.80 m ( $\pm 0.07$ ); mass: 66.6 kg ( $\pm 5.4$ )) ran on a treadmill (Gaitway, Traunstein) at 17.56 km/hr ( $\pm .57$ ). Running pace was calculated by 10 km race time  $\times 1.03$ . The treadmill incorporated two in-dwelling force plates (Kistler, Winterthur) providing values for step length and cadence. The sampling rate was 1000 Hz and data were recorded for 30 s after 1,500 m of running. Simultaneous video data were recorded using a high-speed camera (RedLake, Tucson). The video data were digitised at 125 Hz (SIMI, Munich) and filtered using a Butterworth 2nd order low-pass filter of 10 Hz. De Leva's (1996) body segment parameter model was applied. Moment of inertia was calculated using the parallel axis theorem. Pearson's r was used to find associations with a confidence level of 5%. Results The mean step length for the runners was 1.62 m ( $\pm .12$ ) and cadence 3.04 Hz ( $\pm .18$ ). The swing time of 0.45 s ( $\pm .03$ ) represented 69% ( $\pm 1.2$ ) of total step time and was correlated positively with step length ( $p = .026$ ) and negatively with cadence ( $p = .001$ ). At toe-off, the mean knee angle was  $161^\circ$  ( $\pm 5$ ), which flexed to a minimum of  $56^\circ$  ( $\pm 6$ ) with extension to  $158^\circ$  ( $\pm 5$ ) at heel-strike. The minimum MOI for the whole leg was  $0.048 \text{ kg}\cdot\text{m}^2$  ( $\pm .008$ ), which combined the values for the thigh ( $0.016 \text{ kg}\cdot\text{m}^2 \pm .002$ ), shank ( $0.015 \text{ kg}\cdot\text{m}^2 \pm .003$ ) and foot ( $0.017 \text{ kg}\cdot\text{m}^2 \pm .003$ ). Minimum knee angle was correlated positively with minimum whole leg MOI ( $p = .011$ ), minimum shank MOI ( $p = .024$ ) and minimum foot MOI ( $p = .001$ ). Running speed was correlated with the minimum whole leg MOI ( $p = .040$ ), but no other correlations were found. Discussion A more acute knee angle led to a decrease in the MOI of the leg during distance running. The reduction in whole leg MOI was in turn correlated with speed and is thus an indicator of faster runners. The acute knee angles were achieved by knee flexion of  $105^\circ$  from toe-off and then extension by  $100^\circ$  to heel-strike. Maintaining this range of motion during a distance race requires both strength endurance and flexibility. Therefore, distance runners are advised to improve the strength of the hamstring muscles as well as increasing the mobility of the knee joint in order to make knee flexion easier during swing and increase running speed. ## METHODS OF QUANTIFYING LOWER EXTREMITY KINEMATICS DURING RUNNING

SINCLAIR, J., EDMUNDSON, C., HOBBS, S.J.

UNIVERSITY OF CENTRAL LANCASHIRE

Introduction Both cardan and helical angles are popular methods of calculating angular kinematics. Cardan angles are sequence dependent and can influence the angular calculations. The International Society of Biomechanics recommends an XYZ sequence of rotations. However, the dominance of sagittal plane motion during gait can result in planar cross talk, causing greater than expected coronal/transverse plane profiles (Thewlis et al 2008). As such the XYZ sequence may not be the most suitable method. Helical angles

define a position and orientation vector, and motion from a reference position is expressed in terms of rotation along a single projected axis (Woltring et al 1985). This study investigates the influence of the helical method and 6 cardan sequences on lower extremity joint kinematics in the sagittal, coronal and transverse planes. Methods Eleven participants took part in this investigation. Kinematic data was obtained at 350Hz via an eight camera motion analysis system as participants ran at 4.0ms; angles were created using the helical method and the XYZ, ZXY, XZY, YXZ, YZX and YXZ sequences. Differences in peak angles and range's of motion were examined using repeated measures ANOVA's. Results Hip Main effects were found. Post-hoc analyses found that peak angles using the ZXY sequence in the coronal (ZXY=15.67 XYZ=9.08) and transverse planes (ZXY=13.60 XYZ=-21.38) were significantly greater than the others. Knee Main effects were found. Post-hoc analyses revealed that peak values using the YXZ sequence were significantly greater for the coronal (YXZ=-33.10 XYZ=-3.09) and transverse planes (YXZ=31.14 XYZ=10.79) than the others. Ankle Main effects were found. Post-hoc analyses revealed that ROM in the coronal (YXZ=26.41 XYZ=5.72) and transverse planes (YXZ=28.48 XYZ=4.42) and peak values using the YXZ sequence in the coronal (YXZ=67.65 XYZ=-9.46) and transverse (YXZ=-71.06 XYZ=-2.66) planes were significantly greater than the others. Discussion The results show that when investigating running in the sagittal plane the method used has no significant affect on angular kinematics. However, this was not the case when examining angular kinematics in the coronal and transverse planes. The results of this study with respect to lower extremity joint kinematics found that the ZXY and YXZ sequences produced anatomically unrealistic angular values and as such their use is discouraged. It appears that the ISB recommended XYZ sequence is sufficiently robust for the 3-D representation of lower extremity joint kinematics during running thus its use is encouraged. ### 3-D KINEMATIC COMPARISON OF OVERGROUND AND TREADMILL RUNNING

SINCLAIR, J., EDMUNDSON, C.J., HOBBS, S.J.

UNIVERSITY OF CENTRAL LANCASHIRE

Introduction A number of studies investigating the mechanics of human movement have been conducted using the treadmill. The treadmill is an attractive device for the analysis of human gait, whereby velocity and gradient can be maintained and repeated (Schache et al 2001). However, to what extent the treadmill is able to mimic the kinematics of overground motion remains a controversial topic within the literature (Alton et al 1998). The aim of this study was to compare the 3-D angular kinematics of the lower extremities during overground and treadmill locomotion in order to determine the extent to which the two modalities are similar. Methods Twelve participants (Age 22.5 + 5.2 years, Height 171.2 + 5.5 cm and mass 75.4 + 8.4 kg) ran at 4.0ms in both treadmill and overground conditions. Lower extremity 3-D angular kinematic parameters during the stance phase were obtained at 500Hz using an eight camera motion analysis system. Kinematics from the hip, knee and ankle joints in the sagittal, coronal and transverse planes were collected and compared using paired samples t-tests with significance set at  $p < 0.05$ . Results Hip Significant differences in range of motion (Overground=47.61+10.42, Treadmill=31.63+10.46) and angle at heel strike (Overground=47.10+13.45 Treadmill= 35.11+12.65) were observed in the sagittal plane. Furthermore significant differences in range of motion (Overground=8.40+5.38 Treadmill= 0.41+13.51) were observed between the two conditions in the transverse plane. Knee Significant differences between the two conditions were observed in the sagittal plane for the magnitude of peak flexion (Overground=39.48+5.20 Treadmill=34.46+5.69). Ankle Significant differences between the two conditions were observed in the sagittal plane for the magnitude of motion from heelstrike to peak dorsi-flexion (Overground=18.32+7.40 Treadmill=13.94+7.24). Furthermore significant differences were also found in the coronal plane at heelstrike, toe-off and for the magnitude of peak eversion (Overground=18.32+7.40 Treadmill=13.94+7.24). Discussion Differences between the two conditions, suggest that the mechanics of treadmill locomotion cannot be generalized to overground locomotion. Thus leading to the conclusion that the treadmill should be utilized with caution within clinical and research settings in terms of its ability to mimic the kinematics of overground running. References Alton F, Baldey L, Caplan S, and Morrissey MC (1998) A kinematic comparison of overground and treadmill walking. *Clinical Biomechanics*, 13, 434-440. ### YOUNG AND ELDERLY JOINT STIFFNESS IN DIFFERENT GAIT CONDITIONS

GONÇALVES, M., MARQUES, N.R., HALLAL, C.Z., CROZARA, L.F.

SÃO PAULO STATE UNIVERSITY

Introduction Falls are a very common event in elderly population, principally during the gait. Findings in the literature shows that gait is an activity which requires high levels of attention to estimate, plan and execute its regulation. Thus, cognitive tasks performed with motor tasks could modify the elderly postural control and improve the risk of falls in this population. The present study had the goal to evaluate the influence of a cognitive daily task on muscular stiffness of elderly and young women during the gait. Methods Participated of this study 17 young and 18 elderly, physically fit women. The volunteers walked on a treadmill in two different conditions: normal gait and dual task gait. Electromyography signal were recorded on the muscles rectus femoris (RF), vastus medialis (VM), vastus lateralis (VL), biceps femoris (BF), tibialis anterior (TA), gastrocnemius lateralis (GL) and soleo (SO). For the EMG signal analysis it was used 10 initial gait cycles for each conditions. Then the co-contraction between RF and BF, VM and BF, VL and BF, TA and GL and TA and SO were calculated by common area method (Winter, 2005). For the statistic data analysis it was used the one sample test t for the comparison between different gait condition in a same group and test t for independent samples to compare both gait conditions between the groups. Results For the cocontraction percent between RF and BF, VM and BF, VL and BF were not found significant difference in all comparisons. The cocontraction percent between TA and GL and between TA and SO were significant higher for elderly people than young volunteers in normal and dual task conditions. Discussion/ Conclusion The improve of stiffness is cited in the literature as an inefficient muscular pattern during the movement, due the high activation of agonist and antagonist muscles (Candotti et al., 2009). In line of this, high cocontraction percent also should be a mechanical disadvantage in elderly people, because it contributes for fatigue instalation consequently improve the risk of falls (Hortobágyi e De Vita, 2000). Thus, we conclude that challenge cognitive situations during gait could alterate the neuromuscular behaviour and improve the risk of falls. References Winter DA. New Jersey: John Wiley & Sons, Inc., Hoboken; 2005. ## SOLEUS ACTIVITY IN POST-STROKE SUBJECTS MOVEMENT SEQUENCE FROM STANDING TO SITTING

SILVA, A.1, SANTOS, R.1, SOUSA, F.2

1: SCHOOL OF ALLIED HEALTH SCIENCES OF OPORTO 2: FACULTY OF SPORTS, UNIVERSITY OF PORTO, PORTUGAL

The beginning of the sequence of movement, from standing to sitting, requires the modulation of the plantar flexors activity, including soleus muscle, to allow the tibia's movement on the foot, preserving its antigravity function (Silva et al., 2011). Analyze whether in the 4 sample subjects of the study by Silva et al. (2011), the soleus muscle in the contra-lateral limb to the committed hemisphere maintains the trend towards higher in the electromyographic (EMG) activity when compared to the ipsilateral limb. It is also intended to verify the behavior of these muscles in terms of electromyographic activation time (in percentage) in the analyzed movement. The same sample of individuals, mean age 54.2 ( $\pm 7.9$ ) years, with hemiparesis following stroke was recruited. The EMG data was recorded using the Biopac MP 150 and the correspondent analysis was performed off-line with the Acqknowledge 3.9.0. To identify movement sequence phases a force platform connected to a Bertec AM6300 amplifier was used. The electrodes placement followed the recommendations of SENIAM. The study phase was recognized using the force platform at which anterior displacement of the center of pressure was distinguished, corresponding to the beginning of the sitting. On the other hand the beginning of the posterior shift of the center of pressure matched the final phase of the studied sequence. The soleus temporal activity as well as its magnitude was recorded during the time set. The duration of the activity was subsequently normalized to the duration of the analyzed phase and converted into a percentage. The muscle's aEMG was quantified using the indicator root mean square (RMS) after curve's rectification and signal smoothing. Comparing the EMG activity of the two soleus muscle, there was a trend in three subjects to a higher register in the more affected limb when compared to the less affected, although the lowest proportion activation time of the movement sequence studied was found in this leg. ## COMPARATIVE ANALYSIS OF SHOT PUT BETWEEN SPIN AND GLIDE TECHNIQUE IN THE RELEASE ACTION

AOYAMA, S., FUKUDA, S., AOYAMA, T., TSUNODA, N.

KOKUSHIKAN UNIVERSITY

**Introduction** In recent years it has been increase in number of athletes who use the spin technique in shot put. The shot put technique involves extremely complex movements performed at high speed in the limited space. However, no study has focused on for same subject of using spin technique and glide technique related performance. Therefore the purpose of this study was established the modality of the shot put of two different technique especially release action. **Methods** The subjects were seven male Japanese right-handed elite shot put throwers who can use spin technique and glide technique (age: 22.7 $\pm$ 2.3yrs, height: 176.6 $\pm$ 6.8cm, body weight: 107.6 $\pm$ 15.1kg, spin throw: 14.1 $\pm$ 1.3m, glide throw: 13.4 $\pm$ 1.5m). All the subjects performed total six throws that three spin throws and three glide throws same as a competition rule with recorded best throw from both techniques. Throwing movements were measured by 3-D analysis (APAS) that was calculated release speed and body movement velocities (angular velocity in the right elbow: EV, right greater trochanter velocity: TV, right knee velocity: KV). Throwing movement was defined by the divided turn-phase and release-phase with two positions. **Results** The results of this study were as follows: EV of spin technique was significantly higher than glide technique ( $p < 0.05$ ). Shot put performance was significantly related in release speed (spin technique:  $r = 0.501$ , glide technique:  $r = 0.579$ ) and EV (spin technique:  $r = 0.845$ , glide technique:  $r = 0.709$ ). However, shot put performance was not significantly correlations between TV and KV. Also, release speed was closely related to EV (spin technique:  $r = 0.928$ , glide technique:  $r = 0.808$ ). On the other hand, TV and KV were unrelated to release speed of both techniques. **Discussion** In this study, centrifugal force of the spin technique is produced more extension and smoothly in right elbow than the glide technique. In addition, only EV is correlative between shot put performance and release speed. This means that the one of the big factors in relationship to release speed was elbow extension movement of the release arm. From these results, it was suggested that it is important factor to consideration for training method to improve more release speed and explosive power of elbow extension can be expectation of better shot put performance. **References** Luhtanen P, Blomqvist M, Vanttinen T. ## ELECTROMYOGRAPHIC ANALYSIS OF TRUNK MUSCLES DURING THE DIFFERENT PHASES OF THE GOLF SWING

SILVA, L., MARTA, S., VAZ, J., PAULA, A., BRUNO, P., PEZARAT-CORREIA, P.

FACULTY OF HUMAN KINETICS

**Objective:** The aim of this study is to describe and compare the activity of different trunk muscles during swing phases. **Methods:** Ten male golfers (handicap: 5-20) performed 5 swing shots with the pitching wedge and 5 swings with the 4-iron, in a random sequence. Surface EMG was recorded from trunk muscles of both sides: rectus abdominis (RA), external oblique (EO), internal oblique (IO), erector spinae (ES) and gluteus maximus (GM). EMG signals were normalized using the maximal voluntary contraction (MVC). The average EMG signal during each phase of the golf swing was determined. Four high speed video cameras (100 Hz) were used for delimitation of swing phases. Descriptive statistics were reported as mean  $\pm$  SD. Data were tested for normality with Shapiro-Wilk test. Repeated measures one-way ANOVA were used with swing phases as fixed factor, followed by Bonferroni post-hoc analysis if necessary. The significance level was set at 5%. **Results:** The comparison between different phases through ANOVA showed a significant effect of swing phases in muscle activation level. Bonferroni pairwise comparisons showed similar pattern for both clubs, in what refers to significant differences between swing phases. The RA muscle showed, in both sides and with both clubs, its maximum activation during the Forward Swing phase (24-39% MVC). The EO muscle showed peak activity during the Forward Swing (39-63% MVC) in both sides and with both clubs. The difference between Forward Swing and the other phases were higher in the right EO (55-63% MVC). The left IO showed higher activity in the Forward Swing phase (80-84% MVC). In the right IO the peak EMG activity was observed during the Acceleration phase (48-54% MVC). The right ES showed maximum level of EMG activity in the Forward Swing phase (38-40% MVC). The left ES presented the highest EMG activity during the Acceleration phase (35-39% MVC). The right GM muscle presented greater level of EMG activity in the Forward Swing phase (62-72% MVC). The higher EMG activity of left GM was observed during the Acceleration phase (52-67% MVC) with significant differences when compared with all the other phases in both clubs (range  $p = .001-.047$ ). **Conclusion:** All muscles reached their maximum level of activity during Forward Swing and Acceleration phases. The higher activation was found in the trunk rotators to the left. Strong activations were also found in the right gluteus maximum during the Forward Swing phase and in the left gluteus maximum during the Acceleration phase. This pattern is probably related with the hip extension and to the weight transfer from the trailing to the lead leg. During the Backswing and Follow-Through phases, all muscles were recruited with low to moderate activity.

## EMG RESPONSE DURING THE SLOW COMPONENT PHASE DEPENDS ON LOCAL MUSCLE ENVIRONMENT

PATRAS, K., ZIOGAS, G., RISTANIS, S., TSEPIS, E., GEORGIOULIS, A.D.

ORTHOPAEDIC SPORTS MEDICINE CENTER, UNIVERSITY OF IOANNINA

EMG RESPONSE DURING THE SLOW COMPONENT PHASE DEPENDS ON LOCAL MUSCLE ENVIRONMENT Kostas Patras<sup>1</sup>, Giorgos Ziogas<sup>1</sup>, Stavros Ristanis<sup>1</sup>, Elias Tsepis<sup>1,2</sup>, Anastasios D. Georgoulis<sup>1</sup> 1Orthopaedic Sports Medicine Center, School of Medicine, University of Ioannina, Greece 2Physical Therapy School, Technological Educational Institution of Patra at Aigion, Greece INTRODUCTION: The development of an "additional" slow component on the oxygen cost of heavy "submaximal" exercise may be attributable to enhanced motor unit recruitment resulting in increased EMG amplitude [1]. However, it has recently been demonstrated that task specificity may alter the EMG response during the slow component phase [2]. We hypothesized that chronic muscle perturbations that alter the expected response to fatiguing exercise [3] may also influence the EMG response. METHODS: Fourteen healthy male amateur soccer players and fourteen amateur soccer players having undergone unilateral anterior cruciate ligament reconstruction (18.5 months post-operatively) participated in the study. Athletes underwent a GXT test to volitional exhaustion and two 10-min bouts, one at a moderate (80%LT) and one at a heavy intensity (40%D). During the 10-min bouts, blood lactate was measured at baseline and at end-exercise. EMG data were recorded at the 3rd, 5th, 7th, and 10th minute from vastus lateralis bilaterally using a telemetric EMG system. Repeated measures ANOVA's were used to compare the time course of the EMG amplitude between legs and exercise intensities. RESULTS: VO<sub>2</sub> values increased until the 9th minute of the heavy bout for both groups (F=54.4, p<0.001). End-exercise blood lactate values for the heavy bout averaged 7.9 (1.6) and 7.6 (1.7) mM for the healthy and the reconstructed group respectively. EMG amplitude increased during the heavy bout for the intact but not the operated leg of the reconstructed group (F=4.82, p<0.01). Furthermore, EMG amplitude increased during the heavy bout for both the control leg of the healthy group and the intact leg of the reconstructed group (F=5.78, p<0.01). Finally, EMG amplitude increased during the heavy bout (F=5.76, p<0.01) for the control leg of the healthy group but not for the operated leg of the reconstructed group (F=3.34, p<0.05). DISCUSSION: The VO<sub>2</sub> slow component during heavy intensity exercise is associated with increased EMG amplitude of vastus lateralis. However, our results indicate that although the development of the slow component may at least be partly attributed to additional recruitment of motor units, the EMG response is susceptible to alterations due to chronic local muscle adaptations [4, 5]. ## ELECTROMYOGRAPHIC STUDY OF THE GLUTEUS MAXIMUS MUSCLE BY USING AN ERGOMETRIC TREADMILL BASED ON BRUCE AND NAUGHTON PROTOCOLS: A COMPARATIVE STUDY AMONG THE PROTOCOL STAGES

BANKOFF, A.

UNIVERSIDADE ESTADUAL DE CAMPINAS

Introduction Electromyography (EMG) is a technique to monitor the electrical activity of excitable membranes, and they are applied in striated skeletal muscles. It represents the extent of action potentials for sarcolemmal membrane of striated skeletal muscle cell. By using such technique, one can record an action potential, e.g. voltage event in the time. The basis of knowledge and of understanding for EMG is the drive motor (BANKOFF, 2007). Methods For this study, we used an Lynix® electromyograph (PS6040), containing six channels, acquired from the FAPESP support 1996/5708-4. To acquire the EMG recordings, we established the frequency of 1199.760 Hz. The instrument was calibrated with 2000 HZ gain, low-pass filter of 600 Hz and high-pass filter of 10Hz. Setting input signal limits was established in 3000 uV (upper limit), -3000 uV (upper limit), and input range from -5 V to +5 V. The test parameter was simple type, and the graphics mode was calibrated in x+y+z+w.t, allowing to demonstrate records simultaneously for each experiment. The recordings were made in the last 10 seconds for each protocol stage, noting that the Naughton protocol model II has eight stages. Results Table 01. Distribution of overall means in Root Means Square (RMS) and Standard Deviation (SD) for the GMM of 15 male subjects on an ergometric treadmill by using the Bruce's and Naughton's protocol. STAGES BRUCE PROTOCOL NAUGHTON PROTOCOL RMS SD RMS SD 1 72.95 62.24 58.32 47.96 2 102.35 75.77 62.51 47.71 3 135.68 121.92 109.47 81.12 4 203.86 189.47 124.0 100.0 5 240.20 226.06 135.74 115.06 6 272.0 261.0 169.46 165.75 7 335.0 332.0 195.02 185.61 8 - 232.24 201.25 Discussion Was evident that the action potentials were higher for the ergometric treadmill by using the Bruce protocol. We found that action potentials have already started when they were higher, from the first stage, when compared with the Naughton protocol. It is interesting to observe that the action potentials organised in ascending way, according to the stages. The biggest growing difference, however, is between stage 6 and stage 7, i.e. when the speed is roughly from 5.5 mph to 6.0 mph and the inclination from 20 % to 22 %. ## HOW DO HUMANS ACCELERATE WHILE RUNNING?

VAN CAEKENBERGHE, I., SEGERS, V., AERTS, P., DE CLERCQ, D.

GHEENT UNIVERSITY

Introduction Steady-state running and maximal sprint accelerations (ACC) have been widely studied, yet unsteady running has only gained limited interest. We study ground reaction forces (GRF, as a first outcome of motor behavior) during submaximal running ACC. In contrast to steady-state running, when accelerating an imbalance in braking and propulsive impulses must be generated. Theoretically, three strategies can be followed to create this positive impulse: decreasing peak braking GRF, enlarging peak propulsive GRF, and a larger relative duration of the propulsive phase. High sprint ACC are obtained by adapting the running movement to all three strategies, avoiding braking impulses (Hunter et al., 2005). It is hypothesized that in a submaximal ACC range, running kinetics gradually change to this type as ACC rises (Kugler et al., 2010). Methods 740 stances of 6 subjects (3M, 3F, 70±11kg) running at varying ACC over a series of force platforms are studied using intrasubject linear regressions. The independent variable is the ACC during stance. Dependents are the negative braking and positive propulsive impulses normalized to body mass, the according negative and positive GRF amplitudes (% of body weight) and proportional duration of propulsion. Slopes (mean±sd) of linear regression, positive values confirming the hypotheses, average explained variance and significance of regression were calculated. Wilcoxon tests indicate significances between variables (<0.05=\*). Results Non-linearity between acc and subimpulses was observed, resulting in a zone of submaximal (0-1.3m/s<sup>2</sup>) and higher

ACC (1.3-3.9m/s<sup>2</sup>). For submaximal ACC mainly (\*) a less negative braking impulse (slope:0.13±0.02) than a more positive accelerating (0.09±0.01) impulse is found. Relative propulsion duration increases (0.13±0.04). Peak braking GRF become less negative (0.12±0.04) and peak propulsive GRF more positive (0.12±0.01). Higher ACC are mainly (\*) realized by an increased propulsive impulse (0.19±0.04), whereas the braking impulse approaches zero (0.03±0.02). Proportional propulsion duration increases (0.13±0.03), peak braking GRF become less negative (0.14±0.05) and peak propulsive GRF more positive (0.10±0.03). 44 of 60 regressions were significant (p<0.05) with a mean R<sup>2</sup> of 0.42±0.20. Over subjects and variables R<sup>2</sup> are low as no correction was yet made for the large speed range and also during submaximal ACC some clearly differing more sprint-like purely propulsive contacts are observed. Discussion For submaximal ACC all substrategies are used, mainly resulting in a decrease in braking and a lesser increase in propulsive impulse. They are also used during higher ACC, mainly resulting in an increased propulsive impulse and a sprint-like almost purely propulsive type of running. #### THE COMPARISON SOME PARAMETERS ON ELECTROMYOGRAPHY DURING TREADMILL RUNNING IN RUNNERS AND NON-ATHLETICS

SHIRPOUR, S., AZARBAIJANI, M., SALEK ZAMANI, Y.

ISLAMIC AZAD UNIVERSITY, BUSHEHR BRANCH

The aim of this study was comparison some parameters on electromyography during treadmill running in runners and non-athletic subjects. This research contain of 17 healthy male runners, (age 23 / 44 ± 4/30 years, weight 70 / 33 ± 9/30 kg, height 172 / 77 ± 6/35 cm, body mass index(BMI) 23 / 50 ± 2/46 kg/ m<sup>2</sup>) and 8 non-athletes (age 23 / 5 ± 4 /10 years, weight 70 / 18 ± 6/95 kg, height 173 / 75 ± 4/68 cm, body mass index 23 / 22 ± 1/85 kg/ m<sup>2</sup>) completed running on a treadmill with speed 6 kilometers per hour for data entry electromyography from vastus medialis and Gastrocnemius (GCS) muscles. calculated electromyography index was including the percentage of muscle activity in a step cycle, ratio time to reach the peak the total time activity, speed increased activity from the beginning to reach peak and Speed reduce activity from peak until the end of the muscle activity. Data analysis using multivariate analysis of variance and t- test for independent groups level 0/05 ≥ p were performed. The preliminary assessment don't show any significant difference in morphology athlete and non-athlete groups (p>0/05). survey results don't show any significant difference between amount of activity, ratio time to reach the peak, the rate of increase and decrease the speed of muscle activity vastus medialis in athlete and non-athletel(p>0/05). Similarly, there is no difference between activity rate and increase muscle activity of Gastrocnemius in athlete and non-athletes. But the average time to reach peak muscle activity GCS in athlete group was significantly 0/081 higher than non-athlete group (p<0/05). Also reduce the speed of neural activity in the GCS muscle in athletes groups was significantly 2/65ml watt per second higher than non-athlete groups (p<0/05). Generally, this study showed that when there are no differences in morphology between athletes and non-athlete group, electromyography variables are not different in running with speed 6 km between athletes and non-athletes. But in athletes the ratio time to reach the peak the total time activity and reduced speed of neural activity in GCS muscle is more. Results of the research support to hypothesis of the effect of sports participation on neuromuscular function, but to be seems that in low work load Compatibility of electromyography be less observed.

#### EFFECTS OF DYNAMIC ELECTROMYOSTIMULATION OF THE UPPER BODY ON ISOMETRIC AND ISOINERTIAL STRENGTH PARAMETERS AND THROWING PERFORMANCE

DOERMANN, U., MOEBIUS, M., NZEOCHA, S., WIRTZ, N., NOWAK, S., KLEINOEDER, H., MESTER, J.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Elite throwing performance of baseball or handball players should be characterized by both high velocity and accuracy. One possible approach for this is electromyostimulation (EMS). Training effects of EMS are mainly explained by a synchronous activation and a higher frequentation of motor units as well as a greater recruitment of fast muscle fibres. Although one study (Pichon et al. 1995) reveals an improvement of swimming sprint performance by static EMS, there are no data for effects of dynamic EMS training on the upper body. The aim of this study was to investigate the effects of EMS supported dynamic training forms on strength, power and throwing performance. Methods: 20 strength trained subjects (22.5 ± 2.0 yrs; 177.0 ± 6.2 cm; 71.3 ± 9.5 kg) were randomized in an EMS (EMS-G) and a bodyweight group (BW-G). The training period lasted 4 weeks (2x/week). Push ups, dips, crunches and one-handed throwing movements with a rubber band (Thera-Band) were the exercises for both groups (3 sets, 10 rep., 1 min rest). The temporal distribution of contraction modes for a single repetition was 2s con, 0.5s iso and 2s ecc. The difference between the 2 groups was given in the additional application of EMS by a surface electrode vest (miha bodytec) during the exercises (individually 70% intensity; impulse: frequency 85Hz, width 350µs, type bipolar/rectangle; duty cycle 6/4). The pre- and post-test were conducted before and after the training period. The strength diagnostics were carried out with a Lat- (LM) and a Twister-Machine (TM) as well as with a Bench- (BP) and an Abdominal-Press (AP) (gym80; 3 isometric and 3 isoinertial tests with 40% additional load). Throwing performance was tested by a medicine ball toss (MBT) (one-/two-handed, 500g/2kg) and by a throwing speed test (TST) (handball, 7m) measured by a radar device (Outerlimits Sports). Results: Sign. increases of maximal isometric force (Fmax) and isoinertial power (Pmax) were shown for the BW-G: Fmax improved at BP (6%), LM (8%) and TM (6-7%). Pmax increased at TM (11-12%), AP (8%) and BP (7%). No sign. results were given for the EMS-G and between the groups (p ≤ 0.05). The EMS-G showed a significantly higher throwing performance for the TST (4%) and the one-handed MBT (3-5%). There were no sign. results for the BW-G and between the groups (p ≤ 0.05). Conclusion: There are specific effects within groups indicating that bodyweight training improves strength and power of muscle groups. Dynamic EMS training supported the coordination of these by improving throwing performance. Most advantageous combinations of both training methods (bodyweight exercises with additional application of EMS) have to be tested in further investigations by using different training stimuli (e.g. additional load, individually current intensity, time under tension etc.). Pichon, F., Chatard, J. C., Martin, A., & Cometti, G. (1995). Electrical stimulation and swimming performance. Med Sci Sports Exerc, 27, 1671-1676.

## THE EFFECT OF SUSPENSION FORKS ON UPPER BODY MUSCLE ACTIVATION DURING A SIMULATED MOUNTAIN BIKE DROP-OFF.

HURST, H.T., SINCLAIR, J., EDMUNDSON, C.J., BROOKS, D., MELLOR, P.J.

UNIVERSITY OF CENTRAL LANCASHIRE

**Introduction** Mountain biking (MTB) requires racers to compete over varied terrain, including rocky paths, technical single-track and open forestry roads. Courses also include frequent obstacles such as jumps and vertical drops. Previous studies (Seifert et al., 1997; MacRae et al., 2000) have investigated the use of suspension systems on performance and energy expenditure during MTB. However, no studies have examined the influence of these systems on muscle activation. The purpose of this study was therefore to investigate the influence of suspension forks on muscle electromyographical (EMG) activity. **Methods** Ten male participants (age:  $26.6 \pm 6.74$ , mass:  $76.07 \pm 6.92$ , height:  $183.73 \pm 4.55$ ) took part in this investigation. Participants rode a mountain bike (Scott Scale 40), fitted with front suspension forks (Rock Shox Tora XC SL with 100mm travel), at  $2.5\text{ms}^{-1} \pm 10\%$  off a ramp with a 30cm vertical drop off. Three trials were performed by each participant with the fork in lock out mode and three in open mode. Surface EMG information was obtained at 1000Hz from the Anterior Deltoid, Pectoralis major, Triceps Branchii and Brachioradialis muscles. Following full wave rectification and filtering at 20Hz using a low pass filter, peak and mean amplitudes from 1000ms pre and post impact were obtained and compared using paired t-tests with significance at  $p < 0.05$ . **Results** Significantly lower  $p < 0.05$  peak activation magnitudes were observed for the Anterior Deltoid (open= $0.318\text{mV}$  and lock out= $0.403\text{mV}$ ) and the Pectoralis Major (open= $0.094\text{mV}$  and closed= $0.109\text{mV}$ ). Furthermore, significantly lower  $p < 0.05$  magnitudes for the mean activation were observed for the Tricep Branchii (open= $0.114\text{mV}$  and closed= $0.134\text{mV}$ ) and Brachioradialis (open= $0.089\text{mV}$  and closed= $0.111\text{mV}$ ). **Discussion** The findings indicate that suspension forks results in significantly lower upper body muscle activation. This suggests that suspension forks are effective in reducing the landing forces encountered when riding off drop offs. When repeated drops are performed, as is typical of MTB racing, the reduced muscle activation may lead to reductions in muscular stress and ultimately result in improved performance over a longer period of the race. **References** MacRae, H. ## TWO DIFFERENT METHODS FOR IDENTIFICATION OF THE ELECTROMYOGRAPHIC FATIGUE THRESHOLD IN FUTSAL PLAYERS

CARDOZO, A.C., ALMEIDA NETO, A.F., CASTRO, A., CROZARA, L.

SÃO PAULO STATE UNIVERSITY

**Introduction** Performance limitations, particularly those related to neuromuscular fatigue may be reflected by electromyographic fatigue threshold (EMGFT). However, different methods, exercises and procedures used in researches commits data applicability. In this context, the aim of this study was determine the EMGFT of rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF) and gastrocnemius lateralis (GL) muscles obtained by two different methods. **Methods** Ten amateur futsal players performed 5 minutes warm up at  $5\text{ km.h}^{-1}$ , followed by an incremental protocol at  $8\text{ km.h}^{-1}$ , with increments of  $1\text{ km.h}^{-1}$  every 3 minute, until voluntary exhaustion. Surface electrodes were placed on the bellies of the RF, VL, BF and GL muscles from the right lower limb. For the determination of EMGFT it was considered the methodologies proposed by Devries et al., (1982) (EMGFT 1) and Candotti et al., (2008) (EMGFT 2). Two-way analysis of variance (ANOVA) was used ( $p < 0.05$ ). **Results** The mean values of the EMGFT from the RF, VL, BF and GL muscles were, respectively,  $11.17 \pm 1.03$ ,  $11.21 \pm 1.31$ ,  $10.85 \pm 0.85$ ,  $11.51 \pm 0.98$  for EMGFT 1 and  $11.13 \pm 2.10$ ,  $11.35 \pm 2.33$ ,  $12.87 \pm 1.83$ ,  $11.25 \pm 1.99$  for EMGFT 2. No differences between the EMGFT 1 and EMGFT 2 and between the muscles were found. The relative speeds of the EMGFT 1 from the RF, VL, BF, and GL muscles were respectively, 77.12%, 78.78%, 73.36% and 81.06% of the maximal speed achieved, while the relative speeds from the EMGFT 2 were 73.48%, 79.91%, 91.30% and 74.97%, also showing similar values. **Discussion** The results confirm the proposal that the neuromuscular fatigue threshold can be identified by the analysis of the EMG signal. The mean values of the EMGFT 1 and EMGFT 2 (RF, VL, BF and GL) relatives to the maximal intensity achieved on the test (77.12%-81.06%) were similar to the ones from preview studies (HUG et al., 2006; HANON et al., 1998), except for the BF in the EMGFT 2 (91.30%). The occurrence of EMGFT 1 and 2 were also similar with the lactate threshold (74.6%) and lower than anaerobic threshold (87.3%), except for the BF in the EMGFT 2 (91.30%) (FRAGA, SILVA, GONÇALVES, 2009). **References** Devries, H.A.; Moritani, T.; Nagata, A.; Magnussen, K. *Ergonomics*, London, (1982), 25(9), 783-791. ## THE EFFECTS OF INCREASED MUSCLE ACTIVATIONS ON SPRINT START KINEMATICS, A THEORETICAL APPROACH

JESSOP, D., PAIN, M.T.G.

SOUTHAMPTON SOLENT UNIVERSITY

**The Effects of Increased Muscle Activations on Sprint Start Kinematics, a Theoretical Approach** Jessop, D. M.1 and Pain, M.T.G.2 1: Southampton Solent University (Southampton, UK), 2: Loughborough University (Loughborough, UK) **Introduction** The aim of this study was to analyse the influence of increased muscle activations on sprint start performance using a four segment torque driven computer simulation model. Increased muscle activation in the sprint start has been previously examined experimentally but the findings were relatively inconclusive (Gutiérrez-Dávila et al., 2006). It was considered that a theoretical approach would enable greater control over variables such as the initial position of the athlete. **Methods** One elite male subject performed a series of maximal effort sprint starts. Data were collected for three dimensional joint kinematics and muscle activations. The two dimensional computer model was created using Matlab 7 and Simulink and comprised of a head and trunk, thigh, shank and foot. Torque generators were inserted at the hip, knee and ankle, and horizontal and vertical non-linear spring dampers were used to represent ground contact. The kinematic data provided initial joint orientations, after which, the model was driven using the EMG data combined with joint torque/ angle/ angular velocity data. The model started on movement onset and stopped on take-off from the starting block. Model inputs were optimised, using DIRECT optimisation (Finkel, 2003), to give the maximum horizontal velocity of the centre of mass on takeoff (OPTVEL). Following this, the start was re-optimised but the initial joint activations were forced to be >14% above the previous initial levels (OPTACT). **Results** Data for OPTVEL were: contact time = 0.27 s, horizontal velocity =  $2.61\text{ ms}^{-1}$ , vertical velocity =  $0.64\text{ ms}^{-1}$ , horizontal acceleration =  $9.54\text{ ms}^{-2}$ . Data for OPTACT were: contact time = 0.18 s horizontal velocity =  $1.84\text{ ms}^{-1}$ , vertical velocity =  $1.29\text{ ms}^{-1}$ , horizontal acceleration =  $10.20\text{ ms}^{-2}$ . **Discussion** Despite

its simplicity, the torque driven model was successfully used to represent and investigate the sprint start. Increasing activations did not increase horizontal velocity but did reduce contact time and increase horizontal acceleration. It should be considered that the criterion used to define sprint start performance can influence the results found (Bezodis et al., 2010). To investigate further, more sophisticated computer simulation models are needed. These should include a greater number of body segments, and simulate the start further into the race. ## MECHANICS OF DOUBLET FIRINGS IN SIMULATED MOTOR UNIT POOLS

HELLER, M.

UNIVERSITY OF VIENNA

Motor unit double discharges, or doublet firings, have been described as two consecutive motor unit discharges that occur with short interspike intervals. By the use of electrical stimulation protocols, short interspike intervals inserted at the beginning of a stimulation train have been shown to increase both the peak force and the rate of rise of force production (Garland and Griffin, 1999). The aim of this article is to estimate possible mechanical effects of simulated motor unit doublets in selected motor unit pools (MUPs) during the initial isometric contractions. Five different MUPs with varying ranges were simulated considering important nonlinearities in the force response to pairs of stimuli according to Thomas et al. (1999). The results support the hypothesis that double discharges represent a functional entity: expected increases depend on the properties of the MUP as a whole. Relative timing of the doublet discharges occurs, but has only little effect.

## VARIABILITY IN VASTUS LATERALIS, RECTUS FEMORIS AND BICEPS FEMORIS MUSCLES ACTIVITY DURING ELECTRICAL AND MAGNETIC FEMORAL NERVE STIMULATION

NOORKOIV, M., PENAILILLO, L., NOSAKA, K., BLAZEVIČ, A.J.

EDITH COWAN UNIVERSITY

**Introduction** Magnetic nerve stimulation (MS) has a lower focality than electrical stimulation so coactivation of nearby nerves and muscles can result in a lesser ability to stimulate specific muscles. The aim of this pilot study was to determine the specificity with which MS activates quadriceps and hamstring muscles and whether this activation pattern affects torque magnitude. Since electromyography cannot be used to assess muscle activity during tetanic MS, near-infrared spectroscopy (NIRS) was used to estimate it. The change in total haemoglobin (tHb) during knee extension was examined in vastus lateralis (VL), biceps femoris (BF), and rectus femoris (RF) during (1) maximal voluntary contraction (MVC), (2) electrical supramaximal doublet twitch stimulation (TW) and (3) tetanic MS, at 40° and 80° knee angles. **Methods** Three men (27-31 y) participated. MS (2-s, 90% of max power at 25Hz) was applied through a 50-mm double coil. Electrical stimulation and MS were delivered to the femoral nerve. Changes in VL, BF and RF tHb were continuously monitored using NIRS and change in tHb was calculated as a difference from baseline to contraction. **Results** The relative MS torques were similar in subjects 1 and 2 (78% and 75% of MVC, respectively); TW was 32% and 20%, respectively. Subjects 1 and 2 showed identical changes in VL, BF and RF tHb during TW, MS and MVC, where the absolute decrease in VL tHb mirrored the increase in the torque magnitude. However, MS torque in subject 3 was low (25% of MVC); TW was 30.2% of MVC, VL tHb decreased less than RF at 40°, and BF and RF tHb decreased with the same pattern, but with lesser magnitude. At 80°, the change in tHb of VL, BF and RF was the same as at 40° during TW and MVC but there was an increase in VL tHb, no change in BF, and a substantial decrease in RF tHb during the MS. After normalizing tHb to torque, the pattern of change in tHb was consistent across all contractions, except that the decrease in VL tHb during TW was the largest in all subjects despite eliciting the smallest torque value; that decrease was larger at 40° ( $P = 0.04$ ). **Discussion** High torque generation during MS was associated with substantial decreases in VL (and to a lesser degree RF) tHb (i.e. blood flow), whereas the lower torque in subject 3 was associated with minimal decreases in VL but greater decreases in RF. Thus, low torques might result from preferential activation of RF, indicating that the placement precision of the coil on the nerve significantly impacts muscle activation and torque magnitude. The higher relative decrease in tHb during TW suggests a lesser efficiency of contractile force transmission when compared to MS or MVC. Examination of more subjects is clearly warranted.

## PERIPHERAL MUSCLE STIMULATION WITH PULSED MAGNETIC FIELDS: RELIABILITY OF ED NEUROMUSCULAR PARAMETERS

CREUZNACHER, U.1,3, SCHULZ, A.1, KÖHLING, R.2,3, ZSCHORLICH, V.1,3

UNIVERSITY OF ROSTOCK

[1] Institute of Sport Science [2] Institute of Physiology [3] Department Aging Science and Humanities **Introduction** Compared to electrical muscle stimulation (EMS), human skeletal muscles can be stimulated relatively painlessly by pulsed magnetic fields (magnetic nerve stimulation, MNS) even at high intensities and frequencies. The aim of the study was to examine the reliability of magnetically evoked twitch and tetanic muscle contractions. **Methods** 18 healthy men ( $26 \pm 4$  years) took part in the test-retest study. In a first experiment single twitch contractions (magnetic gradient: 159 A/μs; impulse width: 280 μs) were applied to the quadriceps femoris muscle (QF). After a short resting the QF was stimulated at 50 Hz for one second (magnetic gradient: 90 A/μs). To minimise the movement of the racetrack coil an extra load was applied to the QF, which could be kept constant at 13.9 kPa. The "peak torque" (PT), "rate of torque development" (RTD), "half relaxation time" (HRT) and "rate of torque relaxation" (RTR) were tested for reliability using the intraclass correlation coefficient (ICC) and the coefficient of variation (CV). **Results** All parameters of evoked single twitch contractions (PT: ICC = 0.97 (0.91 - 0.99), CV =  $2.5 \pm 2.4$  %; RTD: ICC = 0.88 (0.70 - 0.95), CV =  $7.2 \pm 4.3$  %; HRT: ICC = 0.89 (0.74 - 0.96), CV =  $4.1 \pm 3.4$  %; RTR: ICC = 0.81 (0.55 - 0.92), CV =  $6.7 \pm 5.8$  %) and tetanic contractions of 50 Hz (PT: ICC = 0.96 (0.90 - 0.99), CV =  $4.4 \pm 3.0$  %; RTD: ICC = 0.86 (0.68 - 0.95), CV =  $9.7 \pm 5.2$  %; HRT: ICC = 0.81 (0.57 - 0.93), CV =  $7.6 \pm 9.3$  %; RTR: ICC = 0.95 (0.86 - 0.98), CV =  $5.8 \pm 4.7$  %) showed high correlations (ICC) and less day-to-day variabilities (CV). **Discussion** Both the relative (ICC) and absolute reliability indices (CV) suggest a highly reliable method of twitch and tetanic muscle stimulation (50 Hz) with pulsed magnetic fields. Gerrits et al. (2001) reported a larger CV for PT (9 %) of a tetanic 50 Hz EMS. Additionally, they found CVs for HRT (7 %) and RTD (13 %), but only at a frequency of 100 Hz. Polkey et al. (1996) observed a CV for PT of 8.5 % for single twitch contractions while stimulating the femoral nerve magnetically. In a recent study Cannon et al. (2008) observed lower ICC values for PT (0.81), RTD (0.81), HRT (0.81) and RTR (0.82) for electrically evoked single twitch contractions via the femoral nerve. **References** Cannon J, Kay D, Tarpenning KM, Marino FE (2008). ## ANALYSIS OF ELECTROMYOGRAPHIC SIGNAL AND KINEMATIC PARAMETERS DURING INCREMENTAL RUNNING PROTOCOL

GONÇALVES, M., CASTRO, A.

SÃO PAULO STATE UNIVERSITY

**Introduction** Incremental Running protocols are often used to determine specific exercise intensities, which are widely used for the application of training protocols. In this context, the biomechanical evaluation is an important tool for understanding the factors related to performance in running. Therefore, the aim of this study was to analyze the effect of running with increasing speed on the electromyographic signal (EMG) amplitude of the iliocostalis lumborum (IC), rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), tibialis anterior (TA), biceps femoris (BF) and gastrocnemius lateralis (GL) muscles, stride length (SL) and stride frequency (SF), and the inter-stride variation coefficient (VC) of these parameters during treadmill running protocol. **Methods** Nine runners performed five minutes at run speed of 9 km.h<sup>-1</sup>, followed by incremental protocol with initial velocity of 10 km.h<sup>-1</sup> and an increment of 1 km.h<sup>-1</sup> every 3 minutes until exhaustion. The EMG signal (Root Mean Square - RMS) of each muscles, SL and SF was calculated from the average of the last ten stride cycles, at 60%, 80% and 100% maximum velocity (Vmax) reached during the incremental protocol. The VC inter-stride was used to analyze the variability these variables. After that, the one-way repeated measures ANOVA was used for comparison of values of SL, SF, RMS and VC between speeds examined. The significant level was set at  $p < 0.05$ . **Results** The SL, SF and RMS values of the RF and GL increased with the running speed increment, while for the muscles VL and VM was verified and increase only at the 60% in relation to 100% from the Vmax. The higher VC variability was occurred in SL and the EMG signal of the BF and TA during the sub-maximal intensities (80% e 60% Vmax) and higher variability was from SF and the EMG signals from the IC, BF, GL and TA during the maximal intensity (100% Vmax). **Discussion** The EMG signal, the SF and the SL increased concomitantly to the speed increment, indicating the exigency of the recruitment of new motor units which intensify their firing rate provide greater joint stability (CARDOZO and GONÇALVES). Besides, the SL presented contribution to the four times increase of speed in relation to the SF. These results suggests that the muscular activity increases in function of the running intensity in a distinct way to the lower limb muscles and could be associated to the greater variability of the neuromuscular responses and the adjusts promoted in the stride cycles as the speed increases (FRAGA, Da SILVA and GONÇALVES, 2009). **REFERENCES** Cardozo AC, Gonçalves M. (2003). Electromyography and Clinical Neurophysiology, 43(6), 377-380. Fraga CHW, Silva SRD, Gonçalves M. (2009). Motriz, 15(4), 911-918.

## DOES FATIGUE CHANGE MUSCULAR ACTIVATION STRATEGIES IN RECURVE ARCHERY?

ERTAN, H.

ANADOLU UNIVERSITY

**DOES FATIGUE CHANGE MUSCULAR ACTIVATION STRATEGIES IN RECURVE ARCHERY?** Eroğlu K. 1.1, Ertan, H.2, Knicker, A.J.3, Soyulu, R. 4 1: Sakarya University, Sakarya/Turkey, 2: Anadolu University, Eskisehir/Turkey, 3: German Sports University, Cologne, 4: Hacettepe University, Ankara/Turkey. **Introduction** In an archery competition, the archer is sustained to shoot in difficult conditions as stress, wind, etc. The pulling weight is approximately 20 kg. of a bow, and the archer 144 times pull his bow in a competition. If stress or weather conditions block shooting, the archer can hold down the bow but must pull again in order to shoot his arrow in a given period. When considering of the pulling weight of the bow, to shoot arrow will be difficult for the archer. According to some studies elite archers develop a specific forearm and pull finger muscle activation strategy by active contraction of the forearm extensors with the fall of the clicker. Because of these conditions, the aim of this study was to analyse the effects of fatigue on drawing hand forearm muscular activity. **Methods** 6 Female (Age: 16,66±3,44; Training age: 5,88±2,92) and 10 male (Age: 22,33±12,95; Training age: 4,11±2,80) subject were involved in the study. Each subject participated in double test session and each archer shoot 12 arrows before and later fatigue protocol and drawing hand forearm flexors and forearm extensors EMG activities has been measured in each tests. In fatigue protocol, the subject has repeated sets of drawings (each set included 6 drawings without arrow and shooting). The subject was asked to rate her fatigue level by looking at the Borg Scale. The subject has repeated the drawing set 11 times. EMG recordings 1 s prior and 1 s after the fall of clicker has been analysed and their mf values has been calculated in Matlab. Differences between two test session was analysed in Wilcoxon statistical tests. **Results** According to the results of the study, there were not significant differences in forearm flexors and extensors in drawing arm between two test session ( $p > 0.05$ ). However, median frequencies of EMG values has shown significant differences of some of the drawing arm muscles before and after fatigue protocol according to 3 arrows ( $p < 0.05$ ). **Discussion** As a result, any differences was observed with the effect of fatigue in the archers forearm extensors and forearm flexors in drawing arm. P-value was 0,0676 in forearm flexor. It can be thought that with more subjects the results may be show significant differences especially in forearm extensors and also effects of the fatigue can be searched any other muscles in bow arm or drawing arm. **References** Ertan, H., Kentel, B., Tumer, S. ## RELATIONSHIP BETWEEN EMG ACTIVITY OF QUADRICEPS MUSCLE AND SKIN COLD STIMULATION OF THE DERMATOME AREA

SUGAWARA, H.1, TADANO, C.1, SHIMOSE, R.1, YONA, M.2, NAITO, Y.3, SEKI, H.4, KOGA, H.1, MACDONALD, G.1, MURO, M.1  
1: TOHO UNIVERSITY(TOKYO, JAPAN), 2: TOKYO UNIVERSITY OF PHARMACY AND LIFE SCIENCES(TOKYO, JAPAN), 3: KOKUSIKAN UNIVERSITY(TOKYO, JAPAN), 4: NIIGATA UNIVERSITY OF MANAGEMENT(NIIGATA, JAPAN).

**Introduction** It is well known that facilitation and inhibition of spinal motoneurons takes place markedly with electrical stimulation of cutaneous nerves, with skin brushing, and with skin anesthesia. In a previous study, we found that skin cold stimulation (SCS) recruits fast motor units at low tension (Yona, 1997). This result was obtained with SCS applied directly above the working muscles. However, it is unclear whether EMG activity of quadriceps muscle results in the same changes in facilitation induced by SCS of the dermatome area at rest in lower limb muscles. The purpose of this study was to examine the change of EMG activity, during dynamic contraction, of the three superficial quadriceps muscles with SCS on vastus lateralis (VL) and L4 dermatome area on the medial side in lower limb. **Methods** Seventeen healthy male subjects (age 21-42) voluntarily participated in the present study. Unilateral dynamic knee extension was performed for

one sec at 15% MVC. Force was measured using a torque transducer. Subjects randomly performed 5 repetitions of the task under 4 conditions: (1) direct SCS of VL (SCS), (2) non-SCS of VL(non-SCS), (3) SCS of L4 dermatome(SCS-L4) in lower limb(Keegan and Garrett.,1948), (4) non-SCS of L4 dermatome. SCS condition was achieved by cooling the skin to 25°C using a gel cooling pad (Alcare Co. Ltd). Surface EMG from the muscle belly of the RF, VL and VM were recorded using miniature electrodes. The root mean square of the EMG (rmsEMG) and mean power frequency (MPF), using the wavelet method, were analyzed on computer. Results The rmsEMG in VL with SCS was significantly greater than activation without SCS but the rmsEMG decreased in SCS-L4. However, RF and VM did not change in all conditions. VL also changed significantly in comparison with SCS / non-SCS ratio of rmsEMG. On the other hand, MPF did not change in all conditions. Discussion SCS increased rmsEMG in VL, but in contrast SCS-L4 rmsEMG decreased. This signifies the linkage of the L4 dermatome to VL motoneurons because SCS-L4 projects motoneuron inhibition to VL. Therefore, we suggest that SCS-L4 during dynamic contraction inhibits VL motoneurons in the presence of sensory-motor linkage. These results suggest that the influence of cutaneous input can demonstrably modulate muscle activation with transmission across interneurons. References Yona M. (1997). *Jpn J Physiol*, 47(4):341-348. Keegan, Garrett. (1948). *Anat Rec* 102:409-437.

#### **DYNAMICAL SYSTEM APPROACH IN ANALYSIS OF DISCRETE MOVEMENTS IN SOCCER. WHAT HAPPENS WHEN THERE ARE FOUR CHOICES IN ORDER PARAMETER WITH SUBJECTS REPRESENTING BOTH ENDS OF THE SKILL CONTINUUM?**

NILSEN, A., INGVALDSEN, R.P.

*BERGEN UNIVERSITY COLLEGE*

Dynamical System Approach as methodology in analysis of discrete movements in soccer. What happens when there are four choices in order parameter with subjects representing both ends of the skill continuum? Nilsen AK<sup>1</sup>, Ingvaldsen RP<sup>2</sup> <sup>1</sup>Department of Sport and Physical Education, Bergen University College, Bergen Norway <sup>2</sup>Departement of Sport and Physical Education, Nord-Trøndelag University College, Levanger Norway Introduction Two studies explore the application of a dynamical system approach in the analysis of discrete hand movements (Sørensen et al., 2001, Rostoft et al., 2002). Both studies demonstrate that the spatial position of an approaching ball function as a control parameter in the shift between two different techniques, i.e. order parameters. The aim of the present study was to use the same procedures, but now with subjects shifting between four different techniques in receiving and passing a ball in soccer. The spatial position of an approaching ball was used as a control parameter, the combination of inner or outer left or right foot represented the four choices in order parameter. Methods Sixteen female subjects participated in this study in a specialist group with highly skilled soccer players, and in a normal group of subjects with no experience from soccer. Under three different experimental conditions the subjects were required to receive balls from nine different spatial locations, and rapidly pass the balls towards a target. 1) The control parameter was scaled systematic with balls from the right side of the subject to the left side, and vice versa. 2) The spatial location of the ball direction varied randomly. 3) The control parameter was scaled systematic while simultaneously inducing stress by giving the subjects simple mathematical tasks. Results In Condition 1 and 2, the specialist group showed greater variation in use of receiving and passing techniques compared to the normal group. For the latter group the right foot dominated. Overall, the specialists used the same techniques in the same position whether the scaling went from the right to the left or the opposite scaling direction. The normal group used one solution for one way and another for the opposite direction. In Condition 3, the group differences in technical choices were even more significant. Discussion The present study has demonstrated the possibility of using four choices in order parameter with spatial localisation as a control parameter in a study of a discrete movement. The results also favour a view that motor preferences interact with task demand, as emphasized in the study by Rostoft et al. (2002). Rostoft, M.S., Sigmundsson, H., Whiting, H.T.A. Ingvaldsen R.P. #### **VISUAL SEARCH STRATEGIES AND VISUAL CUES OF BASEBALL BATTERS BEFORE THE PITCHER'S WIND-UP AND RELEASE**

TAKEUCHI, T., INOMATA, K.

*DIVISION OF SPORT COGNITIVE AND BEHAVIORAL SCIENCE*

Introduction Hitting a baseball requires a batter to process information accurately because a pitcher throws the ball very fast. Researchers have tried to identify the important sources of visual information used by baseball batters during the preparatory phase of a pitch. The main purposes of the present study were to examine the differences in visual search strategies and visual cues between expert and non-expert hitters before the pitcher's wind-up and release. Methods Seven of these subjects were members of the Chukyo University baseball team (Expert group), and the other seven subjects were ordinary university students (Non-expert group). The subjects were asked to observe pitches thrown by a pitcher on a screen and to push a switch button when they made a decision to swing the bat. The pitches were edited to occlude and present selectively specific pitcher's body parts. Subject's eye movements, reaction times and accuracies in judging were measured and analyzed. Results Expert hitters shifted their fixation point from the proximal part of the pitcher's body, such as the head, chest and trunk, to the pitching arm and the release point before pitcher release, while the gaze point of the non-expert group visually focused on the head and the face. Moreover, when the pitcher's wrist or elbow was selectively presented, the response time was significantly delayed compared with when the pitcher's upper body was shown. Moreover when the pitcher's release point, wrist and elbow were selectively presented, the response time of an expert hitter was significantly delayed compared with when the pitcher's arm, upper body, and under body was shown for expert group. No such differences the response time of a non-expert hitter were observed for any or all conditions. Discussion These results of eye movements were consistent with the previous results of Shank and Haywood (1987), Kato and Fukuda (2002), and Takeuchi and Inomata (2009). Moreover, these results of visual cues were consistent with the previous results of Muller, Abernethy, and Farrow (2006). These results suggested that Expert baseball hitters used visual search strategies to gaze at specific cues (the pitcher's arm including the whole body) during the pitcher's motion. References Kato, T., & Fukuda, T. (2002) Visual search strategies of baseball batters: eye movements during the preparatory phase of batting. *Perceptual and Motor Skills*, 94, 380-386. ### APPLICATION OF THE REVERSING FUNCTION ON SENSUOUS CONSCIOUSNESS TO MOTOR LEARNING

SATO, M.

NUMAZU COLLEGE OF TECHNOLOGY

**Introduction** In motor learning, learners accomplish the acquisition of a technique in sports by awakening and selecting their sensuous consciousness and making an appropriate sensory schema by means of their selected sensuous consciousness. In brief, it is important to awaken to one's own sensuous consciousness for the acquisition of a technique in sports. However, this task is difficult for beginners and learners who have only a limited ability of self observation. During a movement, we can direct our consciousness to two different directions. The first is to our own movement (own sensuous consciousness), the other direction is to the external environment. These two directions of the consciousness possess a reversing function. As an example, we consider walking in a crowd. In this case, we can direct our consciousness to our own walking form and also to other people's action in order to evade other people. Therefore, the aim of this study is to clear the effectiveness of directing one's own consciousness to an external environment in an acquisition of techniques in sports. **Method** In order to achieve this aim, the movement form of two assignments were compared (learner's consciousness is directed to one's own sensuous consciousness in the first assignment and it is directed to the external environment in the second assignment). As the research object, the movement in artistic gymnastics is selected because an acquisition of a motor technique is the main aim in artistic gymnastic. Beginners of artistic gymnastics are selected as the research subjects. **Result** The following became apparent by comparing these two assignments. The assignment that is directed to an external environment, worked more effectively for the acquisition of a motor technique than the other one. **Conclusion** Through this study clear evidence was discovered that an application of the reversing function on sensuous consciousness works very effectively for beginners. Henceforth, training methods like this should take into consideration the study of various other movements. However, the setting of a training situation influences training results in case of using this reversing function. The ability of trainers to provide such a setting should also be disclosed in the future.

### VISUAL REACTION TIME IN THE TWO SPECIALITIES OF KARATE: KUMITE COMBAT AND KATA FORM.

MARTÍNEZ DE QUEL, Ó.1, SAUCEDO, F.2, LÓPEZ, E.2

1: UCM (MADRID, SPAIN), 2: UPM (MADRID, SPAIN)

**INTRODUCTION** Reaction time seems to be an important feature of the practitioners in some combat sports. In karate, choice reaction time (CRT) seems to differentiate between athletes and sedentary people (Mori et al., 2002). Karate has two sports modalities. Kumite is the combat competition where an athlete must interact with the adversary and reacts to his/her actions. In the kata competition, the karateka does his/her actions without the adversary opposition. In kumite, athletes have to react to frequent visual stimulus; for example, punches or kicks must be defended to avoid being scored. The hypothesis of this study is that kumite athletes have a shorter visual CRT than kata athletes. **METHODS** After signing an informed consent, 169 karate athletes (70 women) participated in the study. They were divided into 2 groups according to their competition specialities. CRT was measured using the software SuperLab Pro 2.0. It was designed and validated a non-specific protocol with visual stimulus and manual responses. Each participant performed 4 blocks of 25 trials. The whole first block and the first trial of each block were excluded from the statistical analysis. Two variables were calculated: CRT in milisec (mean of 72 the trials) and efficiency in the test (number of correct responses divided by reaction time and multiplied by a constant to avoid decimals). Statistical package SPSS 15.0 was used. Analysis was performed separately by gender (male and female). After confirming the equality of variances with the Levene's test, a Student T-test was used to compare kata and kumite groups. **RESULTS** In the male groups, CRT and efficiency in the test were  $381,74\text{ms} \pm 51,54$  and  $246,85 \pm 30,58$  in kumite, and  $392,07\text{ms} \pm 72,86$  and  $238,92 \pm 39,82$  in kata. In the female groups, the results were  $409,64\text{ms} \pm 66,10$  and  $228,21 \pm 32,66$  in kumite and  $396,38\text{ms} \pm 70,14$  and  $231,78 \pm 28,23$  in kata. No differences between kata and kumite groups were found in CRT in male ( $t=,743$ ,  $p>,05$ ) nor in female ( $t=-,778$ ,  $p<,05$ ). The variable efficiency in the test shows also no differences between groups (male  $t=-,986$ ,  $p<,05$ ; female  $t=-,458$ ,  $p<,05$ ). **DISCUSSION** Some personal features can differentiate athletes of a specific speciality. These qualities could be used to predict if someone can reach a good performance in that sport. CRT is not a quality that can differentiate kata and kumite athletes. So, this variable can not be used in a talent selection process where an athlete goes to be recommended to training in a specific modality. In other combat sports, research showed that athletes are different than sedentary people in some RT tasks but not in others. For example, in fencing, athletes and sedentary people have the same simple RT and CRT in rest state but not during exercise (Mouelhi Guisan et al., 2006). In conclusion, there are no differences in CRT between kata and kumite athletes. **REFERENCES** Mori S, Ohtani Y, Imanaka K. (2002). Hum Mov Sc, 21, 213-230. ### WHAT KINESTHETIC DO THE COLLEGE SWIMMER BE AWARE OF DURING SWIM SKILL ENHANCEMENT?

SHIMOJO, H., TSUBAKIMOTO, S., TAKAGI, H.

UNIVERSITY OF TSUKUBA, GRADUATE SCHOOL OF COMPREHENSIVE HUMAN SCIENCES

**Introduction** In water exercise, human perceive buoyancy, hydraulic pressure and drag from water. Swimmer is aware of those water features and must swim fast. The skillful swimmer's motion has been conducted based on voluntary movement with the swimmer perceived and treated many kinesthetic feedbacks affected by water. If this kinesthetic that swimmer have been aware of during swim skill enhancement is revealed, we would suggest swimmers what kinesthetic should be concentrated during swim. The purpose of this study was investigated what kinesthetic feedbacks the college swimmer have been aware of during swim skill enhancement using psychological scale test. **Method** Questionnaire form gathered from the swimmers belonging college swim team in Japan. We choose 300 subjects data after exception error data. We asked the subjects twelve questions using a seven point Likert scale (1: Extremely disagree ~ 7: Extremely agree) what kinesthetic be aware of during swim skill enhancement. This scale meaning that if the point was raised, the swimmer has been very aware of the kinesthetic. The data were analyzed using factor analysis with promax rotation. **Result** We found three main factor named "somatic sense", "time perception" and "special sense". Mean of the score of somatic sense ( $5.57 \pm 0.85$ ) and time perception ( $5.84 \pm 0.87$ ) were high than special sense ( $3.87 \pm 1.16$ ). **Discussion** Our main findings were that the swimmer has been aware of somatic sense and time perception during swim skill enhancement. This result was confirmed that swimming skill was called "closed skill" requiring the swimmer concentrate somatic sense than special sense (Schmidt and Lee, 1999). Experienced swim skill has been

represented arm coordination or inter-limb coordination that requiring swimmer to control timing of movement (Seifert et al., 2010). Our result indicating that swimmer should concentrate time perception for keep controlling their coordination using somatic sense as time event during swim skill enhancement. References Schmidt R. A. and Lee T. D. (1999) Motor control and learning: A behavioral emphasis. 3rd ed. Champaign, Ill.; United States: Human Kinetics. Seifert L., Toussaint H. ### FACTOR PATTERNS OF MOTOR PERFORMANCE OF PRIMARY SCHOOL GIRLS ACCORDING TO BIRTH SEASON

SZABÓ, E.1, KECZELI, D.2, FARMOSI, I.1, GAÁL, S.3, KERESZTESI, K.2

1: SEMMELWEIS UNIVERSITY FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES (BUDAPEST, HUNGARY) 2: UNIVERSITY OF DEBRECEN AGTC GVK (DEBRECEN, HUNGARY) 3: SZENT ISTVÁN UNIVERSITY FACULTY OF EDUCATION (S)

**Introduction** The effect of season of birth on different health related traits is a current subject in medical research. However, there are details about the physiological process in literature of human biology, little information can be found for the effect of birth season on the motor performances of children. Only some publications show the relationship between birth season and performances of players (Dudink, 1994; Edwards, 1994; Rollin, 1992). Therefore, the aim of our research was to study the effect of birth season on development and sport accomplishment of young girls. **Methods** During the research 426 junior level primary school girls were studied for physical development and motor performances. The body height and body weight of them was taken, moreover 20 m dash, standing board jump, 6 minutes continuous running, throwing a stuffed ball and obstacle race-test were evaluated throughout the school Physical Education lessons. Univariate analysis of variance, correlation and factor analysis applying statistical programme package, SPSS, were used for data processing. **Results** Data of the variance analysis study results show that the children group included in the tests were quite homogenous in body height, but heterogeneous in body weight and motor performances. Physical development and four of the five evaluated sport skills were affected by the birth season. Development and motor performances of the summer and autumn born school girls was generally better than of those born in winter or spring. Differences are significant except the obstacle race-test. The results of factor analysis show similar factor patterns for different birth seasons. From data of winter-, summer- and autumn born girls two factors, while of spring born girls three factors could be separated. These factors explain 57-69 % of total variance. It was found for all birth season that age, body measurements and throwing a stuffed ball belonged to the first factor (anthropometric factor) with the highest factor weight. The second factor and in case of spring born girls the third factor contain the 20 m dash, 6 minutes continuous running, and obstacle race-test (running ability factors). **Discussion** The results call attention to the fact that the variation of motor performance of girls in the studied age period mostly depends on their development, body height and body weight. **References** Dudink, A. ### HOW PLASTIC SURGERY MODIFIES THE BODY SCHEMA: EVIDENCE FROM A LONGITUDINAL STUDY OF POSTURE

IODICE, P., PEZZULO, G., BELLOMO, R.G., SAGGINI, R.

UNIVERSITY OF CHIETI

Plastic surgery offers a quite unique window on abrupt and permanent modifications of a human's body schema. Its impact is comparable to amputations or other severe injuries, with the evident advantage from the experimenter's (and patient's) point of view that it is planned, allowing longitudinal studies and quantification of the weight and distribution of modified bodily masses (e.g., weight of the prosthesis). One potential drawback is that modifications due to (aesthetic) plastic surgery are often too little to be revealed by motor control tasks, making it difficult to measure the time course of body schema readaptation. The aim of our study is measuring the capability of the body schema to readapt to significant and abrupt changes, such as the distribution of mass centers, and in particular to assess what is the time course of such re-adaptation. For this reason, we have carried out a longitudinal study on postural modifications on a population of female patients (N = 30) who were subjected to additive or reductive plastic surgery. Posture and stabilometry evaluations were performed before surgery (T0), and after 1 month (T1), 4 months (T2), and 1 year (T3). Posture was reconstructed from spatial tracking system (Fastrack™ Polhemus) recordings. Stabilometry analysis was performed by force platform (Globus Italia). The results document a modification in posture and a significant increase in the sway area after body mass alterations. Posture and stabilometry data return to equilibrium after 1 year. Our data suggest that posture control relies on, at least in part, feedforward than only on feedback strategies.

### FUNDAMENTAL MOTOR SKILLS AND BODY COORDINATION OF PRESCHOOL GIRLS AND BOYS

IIVONEN, S., SÄÄKSLAHTI, A., MATILAINEN, P.

UNIVERSITY OF JYVÄSKYLÄ

**INTRODUCTION** Researchers emphasize that children should be encouraged to participate in diverse body coordination and Fundamental Motor Skills (FMS) activities, which children need in order to adapt their movements to different environments and be physically active in their daily lives (Stodden et al. 2008). This study aims to find out and compare differences in body coordination and FMS between preschool girls and boys. **METHODS** We measured preschool girls' and boys' body coordination using the KTK (Schilling 2000) and FMS using the APM-Inventory (Numminen 1995). We looked at three mean age groups: three years, 10 months (n = 9); five years, four months (n = 9); and six years, three months (n = 15). The Mann-Whitney test analyzed the differences between the two genders in body coordination activities – walking backwards on three balance beams 6.0, 4.5, 3.0 cm width, hopping over progressively higher foam hurdles (0–60 cm), jumping rapidly from side to side, stepping from platform to platform and moving the first platform to new position before stepping onto it again as fast as possible – and FMS – right foot static balance, left foot static balance, dynamic balance, walking speed (10 m), running speed (10 m), standing broad jump, sliding, galloping, somersault, throwing and catching combination, throwing at a target, kicking a ball at a target. **RESULTS** Significant differences were found between the genders when comparing the performances of the five-year-olds (U = 0; p = 0.044) and the six-year-olds (U = 8; p = 0.028) in walking backwards on three balance beams; the six-year-olds in hopping over progressively higher foam hurdles (U = 4; p = 0.005) and throwing at a target (U = 7; p = 0.019). The girls and boys performed equally on all the other test items. **DISCUSSION** An expected finding was that the differences in body coordination and FMS between the girls and boys were more common in the older rather than younger age groups of the children. Surprisingly, in the five-year-old age group, the boys showed better balance skills than the girls. This might be due to test-specific effects. On the other hand, this also might reflect changes in the preschool educational atmosphere: girls and boys are encouraged to be physically active in their play.

Based on the earlier research, logical findings were that in the oldest age group, the girls were more developed than the boys in their dynamic balance, and the boys showed better mastery than the girls in their manipulative skills, which might be due to typical free-time physical activities for boys, such as ball games. ## **MOTOR SKILLS DURING LANDING AND ITS RELATIONS TO PHYSICAL FITNESS AND PHYSICAL ACTIVITY OF ELEMENTARY SCHOOL CHILDREN**

KUNO-MIZUMURA, M.

OCHANOMIZU UNIVERSITY

**Introduction** Physical activity is critical to children's health and development. Recent studies have suggested that children with good object control skills are more likely to become fit adolescents. Fundamental motor skill development in childhood may also be an important component to promote long-term fitness (Bannett et al, 2008). On the other hand, some authors have speculated that altered neuromuscular control and strength of the lower extremity are responsible for the injury rates in children. Ground reaction force (GRF) may provide a surrogate measure for the strain experienced by musculo-skeletal system on landing. Better neuromuscular function may help to attenuate GRF on landing to reduce the injury risks during exercise, however, no studies have examined that motor skills during landing of children in relation to physical fitness development or physical activity (PA) level. The purpose of this study was to investigate motor skills during drop landing and its relation to physical fitness and pedometer-determined PA at school in Japanese elementary school children. **Methods** Subjects were children in grades 5 to 6 attending elementary school in Tokyo, Japan. Ninety-eight healthy children (48 for 5th grade and 50 for 6th grade) completed physical fitness battery tests such as broad jump, shuttle run, sit-and-reach, grip strength, side steps, sit-up, throwing a ball, and 50m run. The children also performed drop landing from 30 cm height block to investigate motor skills during landing. To determine shock attenuating ability, peak GRF on landing was measured by force platform (Kistler Inc., Switzerland) and normalized by subject's body weight (BW) for further analysis. The children wore pedometers (Life Coder EX, Suzuken, Japan) for two school days. **Results** Height and BW were significantly greater in 6th grade students compared with the 5th grade students. For physical fitness, grip strength, shuttle run, broad jump and 50 m run performance were also greater in 6th grade students. Peak GRF during landing produced  $5.2 \pm 1.1$  times BW for 5th grade students, while peak GRF during landing for 6th grade students produced significant smaller GRF ( $4.7 \pm 1.1$  times BW). There were significant positive correlations between PA at school and the results of shuttle run and that of sit-up. However, there was no significant correlation between peak GRF on drop landing and any of physical fitness measures or PA. **Discussion** These data indicate that motor skill during landing evaluated by peak GRF improved with age in elementary school children even. However, this difference in motor skill does not appear to be related to measures of physical fitness. Further studies are needed to elucidate neuromuscular development in children with respect to safety during exercise.

## **OBESE CHILDREN HAVE LOWER FINE MOTOR COMPETENCE THAN THEIR NORMAL-WEIGHT COUNTERPARTS**

GENTIER, I.1.2, D'HONDT, E.1.2, DEFORCHE, B.1.3, DE BOURDEAUDHUIJ, I.1, LENOIR, M.1

1: DEPARTMENT OF MOVEMENT AND SPORTS SCIENCES, UGENT, BELGIUM, 2: RESEARCH FOUNDATION - FLANDERS (FWO), 3: DEPARTMENT OF HUMAN BIOMETRICS AND BIOMECHANICS, VUB, BELGIUM

**Introduction** It is widely accepted that childhood obesity negative effects on medical, psychosocial, and fitness condition as well as on gross motor skill level. However, studies investigating fine motor skills in obese children are currently lacking, although they could provide insight in their perceptual-motor functioning. Therefore, this study aimed to investigate fine motor skills in obese compared to normal-weight children. **Methods** Thirty-six obese children were recruited, and 36 age- and gender-matched normal-weight children served as controls. Gross and fine motor skill competence was assessed by means of the Bruininks-Oseretsky Test of Motor Proficiency, Second Edition (Bruininks & Bruininks, 2005). **Results** Scores on manual control ( $p=0.05$ ), body coordination ( $p<0.001$ ), and strength and agility ( $p<0.001$ ) were significantly better in the normal-weight children compared to their obese counterparts, while a strong tendency was found for fine manual control ( $p=0.059$ ). A main effect of age ( $p<0.001$ ) revealed that the older age group obtained significant higher scores on all subtests. Furthermore, BMI related differences in manual control and body coordination varied according to age group indicating that the obese and normal-weight children belonging to the younger age group displayed more pronounced differences in their fine motor skill performance compared to the older age group. **Discussion** These findings confirm the detrimental effect of excess weight on gross motor skill performance. However, obese children's fine motor skills were also affected even though in these tasks the non-contributory mass that participates in the movement is restricted. This is in line with other studies which postulate that obese children have difficulties when sensory information is needed to plan and control movements (D'Hondt et al., 2008; Petrolini et al., 1995). A possible deficit in perceptual motor skills is therefore suggested. This study also indicates that differences between normal-weight and obese children in fine motor skill performance seem to become smaller with increasing age. This contradicts the findings of D'Hondt et al. (2010) which state that the negative impact of childhood obesity seem to deteriorate across developmental time. **References** Bruininks RH, Bruininks BD (2005). ## **COMPARISON OF RESPONSES MPF, IEMG, AND RMS BETWEEN KOREAN FOLK AND INTERNATIONAL TUG OF WAR OF KOREAN COLLEGE STUDENTS**

LEE, B.K.1, SHIN, J.M.1, LIM, W.K.2

1: SMU (CHEOAN, S. KOREA), 2: HUIJASAN, S. KOREA

**Introduction** International Tug of War was Olympic regular game from 1900, Paris to 1920, Antwerp. Tug of war International federation (TWIF) was established 1960, and hold International competition. Korea have a folk Tug of War, but the methods was different. The purpose of this study was to compare the EMG responses of MPF, IEMG, and RMS during international and Korean folk Tug of War, and to analyse the physiological characteristics of Tug of War. **Methods** The EMG signal were collected during Tug of War competition on 6 muscles for 1 minute, divided every 10 second, screened high quality signal, and accepted 5 second signals. This study used the data of Lee et al.(2009), and modified. The EMG variables including MPF, IEMG, and RMS were analyzed for muscle activities and fatigue. **Results**, **Discussion** MPF responses showed significant difference among times on 5 of 6 muscles, but there were no significant MPF shift. MPF responses of anterior tibialis only showed significant difference between 2 methods of Tug of War. IEMG of the Korean folk group on

triceps and rectus femoris were significant difference with those of international group. There were no significant difference on EMG responses among time and groups on 4 muscles during Korean folk and International of Tug of War. There were no significant difference among 1 minutes(time) and methods on most of the muscles during Tug of War on RMS. RMS of anterior tibialis showed significant difference among 60 seconds contraction only, and RMS of rectus femoris of Korean folk group were significant difference with those of international group. Korean Tug of War player might used more isotonic than isometric contraction. International Tug of War player might used mainly isometric contraction. The difference of methods, human race, intensity and duration of contraction(Dimitrova et al., 2009), and the direction of contraction(Kay et al., 2000) may different muscle and fatigue responses. Conclusion Muscle activity level of anterior tibialis, rectus femoris and triceps of folk groups significant difference with those of international groups on MPF, IEMG or RMS. Muscle activity level and fatigue were significantly different on some muscles between Korean folk and international methods. References Dimitrova NA, Arabadzhiev TI, Hogrel JY, & Dimitrov GV (2009). ### PP-SH16 Skill and Cognition

#### DOES CEREBRAL OXYGENATION AFFECT COGNITIVE FUNCTION DURING EXERCISE?

ANDO, S.

FUKUOKA UNIVERSITY

DOES CEREBRAL OXYGENATION AFFECT COGNITIVE FUNCTION DURING EXERCISE? Ando, S.1, Kokubu, M.2, Yamada, Y.1, Kimura, M.3 1: Fukuoka University, (Fukuoka, Japan), 2: Osaka University of Health Sport Sciences (Osaka, Japan), 3: Kyoto Prefectural University of Medicine (Kyoto, Japan) Introduction Cognitive function is fundamentally important to most human activities. The importance of cognitive function in sports has been emphasized (Williams and Ericsson 2005). Many sports require high-level cognitive functioning under conditions of physiological stress. Since cognitive function is likely to be associated with athletes' performance, it is crucial for cognitive function to be maintained during strenuous exercise for maximal sports performance. Multiple factors may affect cognitive function during exercise. However, to understand the way in which strenuous exercise affects cognitive function it is necessary to investigate the range of potential mechanisms individually, and to accumulate empirical evidence bearing on each. This study tested whether cerebral oxygenation affects cognitive function during exercise. Methods We measured reaction times (RT) of 12 participants while they performed a modified version of the Eriksen flanker task, at rest and while cycling. In the exercise condition, participants performed the cognitive task at rest and while cycling at three workloads [40, 60, and 80% of peak oxygen uptake (VO<sub>2</sub>)]. In the control condition, the workload was fixed at 20 W. RT was divided into premotor and motor components based on surface electromyographic recordings. The premotor component of RT (premotor time) was used to evaluate the effects of acute exercise on cognitive function. Cerebral oxygenation was monitored during the cognitive task over the right frontal cortex using near-infrared spectroscopy. Results In the exercise condition, we found that premotor time significantly decreased during exercise at 60% peak VO<sub>2</sub> relative to rest. However, this improvement was not observed during exercise at 80% peak VO<sub>2</sub>. In the control condition, premotor time did not change during exercise. Cerebral oxygenation during exercise at 60% peak VO<sub>2</sub> was not significantly different from that at rest, while cerebral oxygenation substantially decreased during exercise at 80% peak VO<sub>2</sub>. Discussion In the present study, premotor time significantly decreased during exercise at 60% peak VO<sub>2</sub>, in accord with previous reports (Brisswalter et al. 2002). However, despite an improvement in cognitive function during exercise at 60% peak VO<sub>2</sub>, cerebral oxygenation during exercise at 60% peak VO<sub>2</sub> was no different from that at rest. Error rate was not affected by exercise at 60% peak VO<sub>2</sub>. These results suggest that an improvement in cognitive function occurs during moderate exercise, independent of cerebral oxygenation. References Brisswalter J, Collardeau M, Arcelin R (2002) *Sports Med*, 32, 555-566 Williams AM, Ericsson KA (2005) *Hum Mov Sci*, 24, 283-307

#### PERCEPTUAL CUES VARIABILITY ON ANTICIPATING TENNIS SERVES. LEFT HANDED ARE MORE READABLE THAN RIGHT HANDED EX PROFESSIONALS PLAYERS

ZAWADZKI, P., ROCA, J.

BARCELONA UNIVERSITY

The aim of this study was compare perceptual cues variability of tennis serves, on right and left-handed players, to assist anticipation on devolution stroke. Eight ex professionals' players where analyzed in official matches at Barcelona Stage of Black Rock Circuit 2008, on clay court, in the course of the first round to semifinals of main draw. Two groups were formed by arm-racket laterality. Three left-handed players with top ATP career ranking 1st, 5th, and 14th position, and five right-handed players with 2nd, 3rd, 5th, 6th, and 10th best position. Bi-dimensional kinematics analysis where performed using a camera DCR-HC23E (Sony, Japan) to image capture, and software Utilius® EasyInspect to obtain spatial and temporal data of 187 serves. Forty-two variables were created from serve technique. Canonical correlation analysis was performed to verify relationships among serve technique variables, and serve result described thru bounce time-location. The main result shows three canonical correlation coefficients for each group:  $r = 0.976, 0.896$ , and  $0.848$  for left-handed group, and  $r = 0.921, 0.592$ , and  $0.529$  for right-handed group. All pairs of canonical coefficients are compound with the same variable of dependent set of variables, 'ball time between impact and bounce'. The first pair of canonical variate of left-handed group, means correlation with 'horizontal position of knee at body arc', what can be interpreted like when knee are more to the right side of body server, faster the ball came. In right-handed group corresponds to 'time of ball toss', interpreted like when ball toss get more time, slower ball serve came. Second and third coefficients correspond to the same pair of canonical variate for both groups, which is the 'horizontal position of knee and foot at racket-ball impact moment'. The main conclusion appoints to an important difference between groups, regarding second and third canonical correlation coefficients, can be observe that left-handed players are more regular in their actions during competition, through this information a returner can easier develop a response. The thematic relevance of Opponent Study in Sport is evident when the possibility of inform players when and how fit their responses allows coaches to enhance an intervention or plan a match.

## A DESCRIPTION ABOUT PERCEPTUAL CUES FOR ANTICIPATION OF TENNIS SERVES AT THE PROFESSIONAL LEVEL

ZAWADZKI, P., ROCA, J.  
BARCELONA UNIVERSITY

Four hypotheses of what a tennis serve returner must perceive to anticipate direction and velocity were appointed from literature: initial position of server, ball toss, body arc on knee bend, and angle between elbow-ball-shoulder before racquet ball contact. The aim of this study was to verify if these hypotheses could be related to stroke direction and velocity while competition. Eighteen right handed professionals' players were analyzed in official matches of Godò County Championship's 2008 - Barcelona, on clay court, in the course of the first round to quarter finals of main draw. Kinematics analysis were performed using a camera DCR-HC23E (Sony, Japan) to image capture of 306 serves, and software Utilius® EasyInspect (CCC, 2007) to extract spatial and temporal data. Forty-two variables were created from hypotheses, and canonical correlation analysis was performed to verify relationships among those variables and serve action result, described by bounce time-location. The most significant result shows to second serves  $R_c = 0.9725$ ,  $\lambda = 0.0056$ ,  $F = 4.6793$  ( $p < 0.001$ ), and  $x^2 = 303.4540$  ( $p < 0.001$ ), presenting horizontal oscillation of elbow when appears behind body movement as the most powerful predictor (canonical variate = -3.0795), associated with time from ball flight until bounce location (canonical variate = 14.436). That can be interpreted like when elbow appears close to the body ball comes slower. It is concluded that this information can be useful on training perception during practice and also on planning and preparing for a match. Provide players with information which allow fitted responses on fast technique actions reveal the thematic importance of perceptual cues in the field of Opponent Study in Sport.

## THE PATH OF ADOLESCENT ATHLETES TOWARD EXPERTISE

GONÇALVES, C.E., DIOGO, F.  
UNIVERSITY OF COIMBRA

Introduction Genetic factors in close interaction with the environment (practise/training), combined with the psychological characteristics of athletes, are all variables that will shape and influence the extent to which athletes reach expertise (Baker & Horton, 2004). The aim of the study is to analyze the development of excellence in youth sport, particularly the relationships between personal characteristics and contextual factors. Methods Forty-eight athletes sub-17 years of age ( $15.7 \pm 0.99$ ), from a soccer academy (20), a volleyball club (14) and an elite volleyball centre (14) participated in the study. A retrospective interview (Côté, Ericsson & Law, 2005) portuguese version from Barreiros & Fonseca (2007) was held to 48 athletes of soccer and volleyball. The interviews were applied individually, at the beginning of the season, by the principal researcher. Demographic and training loads information were also collected. Results Soccer players have a longer period of participation in sport than their volleyball peers, but elite volleyball players practice 2,5 more hours per week than the other athletes. The soccer players demonstrate higher values than volleyball players in the desire to become professionals in their sport. All the players prefer to train hard at the club or training center than playing with friends, just for fun. Discussion The high demands of expertise in professional soccer players leads young athletes to begin training at a very early age. The fact that the profession of footballer implies a high social recognition and provide significant financial income, compared to a professional volleyball career, probably have conditioned the opinions expressed by these young football players wanting to become professionals in this sport. Sport specialization seems also to eliminate fun from practice at adolescence years. References Baker, J., & Horton, S. (2004). ## RELATIONSHIPS BETWEEN PHYSICAL ACTIVITY IN DIFFERENT CONTEXTS AND COGNITIVE IMPAIRMENT AMONG OLDER ADULTS

KU, P.W., CHEN, L.J.

GRADUATE INSTITUTE OF SPORTS AND HEALTH, NATIONAL CHANGHUA UNIVERSITY OF EDUCATION, TAIWAN

Objective: The study aims to explore a) whether leisure-time physical activity (LTPA) and Non-LTPA (NLTPA) are independently associated with cognitive impairment; and b) the relation of specific components of physical activity (frequency, duration and intensity) and cognitive impairment in later life. Methods: A total of 2,727 persons (65+) participating in 2005 Taiwan National Health Survey was studied. It's a multi-stage stratified systematic sampling design with a nationally representative sample. Cognitive impairment was assessed by the Chinese version of Mini-Mental State Examination ranged 0-30. Cut-off points for illiterate and literate were 13/14 and 23/24 respectively. Information on names, frequency and durations for each type of LTPA and NLTPA during the past 2-week period was self-reported. Energy expenditure of each activity per week was calculated by: activity intensity code (kcal/min)  $\times$  frequency  $\times$  duration for each time (min)/2. The energy expenditure values were then added up into total weekly amount of energy expenditure for both LTPA and NLTPA. After adjusting for socio-demographic variables (gender, age, educational attainment, marital status, employment, income, living status), lifestyle behaviors (smoking and drinking) and health status (BMI, stroke, fall, activities of daily living and depression). Multivariate logistic regression models for predicting cognitive impairment were undertaken to compute adjusted odds ratios (AOR) for LTPA and NLTPA. Given that LTPA rather than NLTPA was associated with cognitive impairment, AORs for the three components of LTPA were calculated. Results: NLTPA was not associated with cognitive impairment ( $p = 0.26$ ). Participants expending less energy in LTPA had higher risk of cognitive impairment (0 kcal/week: AOR = 1.75, 95%CI: 1.16-2.62; 1-999 kcal/week: AOR = 1.35, 95%CI: 0.89-2.06; 1,000-1,999 kcal/week: AOR = 1.15, 95%CI: 0.71-1.87, reference 2,000+ kcal/week) ( $p = 0.02$ ). Risk reduction among the three components of LTPA energy amount was only associated with duration, which was marginally significant ( $p = 0.06$ ) (0-14 minutes: AOR = 1.76, 95%CI: 1.00-3.10; 15-29 minutes: AOR = 1.65, 95%CI: 1.03-2.65; 30-59 minutes: AOR = 1.05, 95%CI: 0.73-1.51, reference 60+ minutes). Conclusions: LTPA rather than NLTPA is associated with reduced risk of cognitive impairment in older adults. Among the three components of LTPA, only duration, especially engagement for at least 30 minutes, is significantly associated with reduced risk of cognitive impairment.

## FROM VISUAL PERCEPTION TO VISUAL-MANUAL COORDINATION.

SGAMBELLURI, R., GOMEZ PALOMA, F.

UNIVERSITY OF SALERNO

**Introduction** The Developmental Test of Visual Motor Integration (VMI) is a "paper and pencil" test, in which the child is required to copy a developmental sequence of geometric figures. The test, starting from the assumption of a significant correlation between the ability of children to reproduce geometric shapes and their scholastic performance (Hammill, et al., 1993), is based on the theory that the development of intelligence and learning have a sensory-motor basis. It consists of two main tests and two additional tests, one on visual perception a visual perception, and the other on motor coordination. **Aim** The research, based on a sample of 117 children in primary schools of Salerno area, is to implement a cognitive survey in order to identify any children at risk as well as analyze if two main tests are organic and consistent with the other additional tests. **Method** The research, after a first theoretical-argumentative phase, has provided a second experimental phase for the administration of the tests of 10-15 minutes; the test was carried out individually. **Results** The research results showing in graphical form, clearly affirm that: • the average percentile test of visual perception is much more than 50%; • the average percentile test of motor coordination is just under 50%; • the average percentile of the VMI test is very low, less than 20%. **Discussion** The results showed that the VMI test, which measures the accuracy of transcription (Motor Coordination) of geometric figures seen in developmental sequence (Visual Perception), shows great difficulties, although the two skills, motor coordination and visual perception measured individually with specific tests, clearly show a great capacity in the children of the sample. **References** HAMMILL, D.D., BARTELL, B.D.(1995). ## EYE-HAND COORDINATION ASSESSMENT IN SECOND-GRADE CHILDREN : PILOT STUDY OF CITY OF SALERNO'S PRIMARY SCHOOLS.

AMBRETTI, A., D'ELIA, F., SIBILIO, M.

UNIVERSITY OF SALERNO

**Introduction** The Italian National Guidelines for the curriculum of primary school of 2007 require the achievement of motor skills related to visual motor coordination as one of the goals for skill development at the end of primary school, measurable through a different use of evaluation tools. Among the several motor assessment tests recognised by the international scientific community, the VMI Developmental Test of Visual-Motor Integration (Beery & Buktenica, 2000) represents a valid instrument of assessing the visual-motor coordination skills and their constitutive elements. **Aim** of the present research has been to provide, through the use of the VMI battery of tests, to analyze an integrated model of eye-hand coordination assessment, in a sample of primary school. **Methodology** The methodology combined experimental research and action-research, involving University of Salerno (Italy), and 5 primary schools in Salerno. The research protocol has therefore involved definite procedures, jointly followed by schools and University which shared goals and methods. The team of school-university researchers has complied with the following criteria: • sample's auxological and psychomotor characteristics • involvement of handicapped subjects and handicap typology • integrated and rigorous use of the VMI battery of tests in scholastic according to the research project in order to be harmonically suitable for educational activities. • VMI administration training for the teachers involved. **administration of the VMI test:** The team of researchers, in cooperation with each class' regular teachers, has provided for the group administration of the VMI test. **Results** The results of the research among the 5 schools of the city of Salerno has shown a slight significant difference only between two of the schools using the same use of motor evaluation assessment. **Discussion** The study opens up to further researches on the use of motor evaluation assessment in the primary school to improve teaching strategies thanks to the introduction in the classroom context of motor assessment tests that would be consistent with the aims and the didactic organization of Italian primary school. **Reference** Meinel K. ## ELEMENTS OF COMPLEXITY IN ORIENTEERING FOR BEGINNERS

OTTOSSON, T., ERFORS, A.

KRISTIANSTAD UNIVERSITY

With few exceptions (e.g., Ottosson, 1987; Sigurjónsson, 2007), how beginners in orienteering manage the tasks they are presented is far from well researched. In Swedish orienteering clubs, beginner instruction is normally administered according to a well established pedagogy, most often talked about as a ladder of difficulty. This system builds on many years of collected experiences of instruction, and appears to be generally effective. However, if this pedagogy could be validated by empirical data, its application would be even further motivated. On the other hand, data could, alternatively, point to a more or less different ranking of orienteering difficulties, and thus provide indications of need of revisions of the pedagogy. In this research project, split times between control points on courses for children (aged 11 and younger) on regular orienteering events provide data for analysis. It is assumed that more difficult legs would result in greater spread in running times. In other words, a correlation between complexity of orienteering tasks and spread in running times is hypothesised. In a first analysis (Ottosson & Erfors, 2009), split times for 851 young competitors on the third stage of the International O-Ringen five days orienteering event in 2008 were analysed. A clear tendency that more complex legs of the course resulted in greater spread was found; both when a measure of Length Standardized Spread and when the simple measure Average Speed was used. It was further found that shorter legs resulted in greater spread than expected. A possible explanation might be that there is a certain amount of "tuning time" before a runner sets off towards the next control point. An observation study of young orienteers' behaviour at the outset of a new leg, performed at the O-Ringen event 2009 (Ottosson & Erfors, 2010), revealed that there seems to be such an effect, but relatively marginal. In this presentation, further data analyses are reported, together with a tentative classification of elements contributing to the complexity of orienteering tasks. Cases where information overload could be assumed are specifically discussed. Ottosson, T. (1987). Map-reading and wayfinding (Göteborg Studies in Educational Sciences, 65). **VISUAL SEARCH STRATEGIES IN VOLLEYBALL: A COMPARISON BETWEEN LABORATORY AND LIVE-ACTION SETTINGS**

AFONSO, J.1, MESQUITA, I.1, GARGANTA, J.1, MCROBERT, A.2, WILLIAMS, A.M.2,3

*1-UNIVERSITY OF PORTO – FACULTY OF SPORT 2-LIVERPOOL JOHN MOORES UNIVERSITY – SCHOOL OF SPORT AND EXERCISE SCIENCES 3- THE UNIVERSITY OF SYDNEY – DISCIPLINE OF EXERCISE AND SPORTS SCIENCE*

The majority of researchers examining visual search behaviours in sport have employed film-based tasks. A potentially difficulty with using film-based tests is the absence of depth information and lack of opportunity to interact in a dynamic environment, which may alter some of the underlying search behaviours employed. We compare data gathered in laboratory and live-action settings in an attempt to examine whether any significant differences exist across the two situations. Volleyball players were confronted with six offensive scenarios in random order, while positioning themselves as backcourt defenders. Twenty-seven participants were assigned to the live-action setting and sixteen were assigned to the film-based condition. In both conditions, scenarios lasted around 5 seconds. One-way ANOVA showed differences between film and live-action settings in number of fixations, total fixation duration, and number of fixation locations ( $p \leq 0.05$ ). In the live-action setting, participants employed more fixations and fixated more locations when compared with the film-based setting. Chi-square showed differences in the areas fixated across the two settings ( $p \leq 0.001$ ). While watching the test film, participants tended to frequently fixate the middle-attacker and the visual pivot between setter, ball, and middle-attacker. In the live-action setting, they more often observed reception and setting trajectories. Our findings suggest that care should be taken when attempting to generalise the findings from film-based test protocols to live-action settings in sport and highlight the benefits of collecting visual search data in-situ whenever possible. **16:15 - 17:45****Invited symposia****IS-PM10 Cellular and Molecular Responses to High Intensity Training****CELLULAR AND MOLECULAR RESPONSES TO HIGH INTENSITY TRAINING**

GIBALA, M.1, WISLOFF, U.2, HAWLEY, J.3

*1MCMMASTER UNIVERSITY, CANADA; 2NORWEGIAN UNIVERSITY OF SCIENCE & TECHNOLOGY, NORWAY; 3RMIT UNIVERSITY, AUSTRALIA*

High-intensity interval training (HIT) induces numerous physiological adaptations that resemble traditional endurance training despite a low total exercise volume. As little as six sessions of HIT over two weeks, totaling ~15 min of "all out" cycle exercise within a total training time commitment of ~2 h, increases the maximal activity of mitochondrial enzymes and improves performance during tasks that rely heavily on aerobic energy provision. These data suggest that HIT may be a potent and time-efficient strategy to induce skeletal muscle metabolic adaptations that improve functional exercise capacity and are linked to improved health. Accumulating evidence suggests that HIT activates many of the same signaling cascades that are believed to regulate mitochondrial biogenesis in response to endurance exercise. Recent work has shown that short-term training using a more "practical" model of HIT (e.g., 10 x 1 min repeats at ~90% maximal aerobic work capacity, interspersed by 1 min of recovery) increased muscle oxidative capacity and improved endurance performance. Other work has revealed this protocol also increased mitochondrial content and improved blood glucose control in previously sedentary individuals who might be at higher risk for inactivity-related disorders as well as type 2 diabetics. Regular exercise training also confers beneficial effects to the heart and vasculature, and accumulating evidence suggests that the magnitude of these benefits increases proportionally with the intensity of exercise training. It has emerged that regular exercise training also confers beneficial effects to patients at risk for, or who have, established heart dysfunction and disease. Moreover, exercise training may reduce the dysfunction of the heart itself and, at least, partly restore its ability to effectively function as a pump. Recent studies in patients with established heart disease suggest that a high relative, yet aerobic, intensity of the exercise training improves the intrinsic pump capacity of the myocardium, an effect not previously believed to occur with endurance training. However, more and larger studies are needed to establish the safety and efficacy of such exercise training in patients with heart disease. Finally, an emerging body of research has considered whether manipulating carbohydrate availability augments the adaptation to endurance training and HIT. Current evidence supports the hypothesis that commencing a portion of short-term training programs in the face of low muscle glycogen content and/or low exogenous carbohydrate availability promotes training adaptation (i.e., mitochondrial biogenesis) to a greater extent than when subjects undertake a similar training regimen with normal or elevated glycogen levels. Although several putative cell signaling pathways have been implicated in this nutrient-exercise adaptation process, further work is required to determine the precise mechanisms promoting the amplified endurance training adaptation when individuals commence selected training sessions with low carbohydrate availability.

**CARDIOVASCULAR EFFECTS OF HIT: FROM MICE TO MAN**

WISLØFF, U.

*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

Prospective, observational studies suggest that low aerobic fitness, measured as maximal oxygen uptake ( $\text{VO}_{2\text{max}}$ ), is a strong and independent predictor for total and cardiovascular mortality in healthy individuals and in patients with cardiovascular disease. The relationship between  $\text{VO}_{2\text{max}}$  and health has been studied using either a top-down or bottom-up strategy. The top-down approach starts by epidemiological studies, and then works its way towards identifying possible general physiological mechanisms. The bottom-up strategy begins by studying the basic molecular mechanisms induced by exercise training, and thence upwards to a coherent view of improved public health. Neither approach has alone been successful in establishing firm links between molecules and public health. The main focus of our research activity is to combine the two strategies into a more integrative approach bringing epidemiological, experimental and clinical expertise together. The presentation will review research from own laboratory using epidemiological, clinical and experimental studies to explore adaptation to high intensity interval training. To exemplify, in a rat model we demonstrated that aerobic interval training may be a potent modifier of post-infarction heart failure (HF). Based upon this animal model, we demonstrated the efficacy of aerobic interval training in enhancing cardiovascular fitness and reversing myocardial remodelling in patients with HF after a

myocardial infarction. At present, the group runs a clinical multicenter phase-II trial across Europe. Also novel data on contractile function, calcium (Ca<sup>2+</sup>) cycling and mechanisms of impaired contractile function in isolated cardiomyocytes from patients with coronary heart disease will be presented. Another example of translational research from the presenters group is the use of animal models with inborn low or high aerobic capacity. To determine whether there are more than a statistical link between VO<sub>2</sub>max and CVD, we hypothesized that artificial selection of rats based on Low and High intrinsic Running Capacity (LCR/HCR rats, respectively) would yield models that contrast for risk factors related to CVD. In summary, LCR rats had all symptoms of the metabolic syndrome as observed in man along with a 28-45% shorter lifespan than HCR rats which developed a healthy profile. These contrasting models provide the first demonstration that an intrinsic component of oxidative energy metabolism is inherently connected with longevity. Based upon these data we conducted two clinical studies in patients with metabolic syndrome, in obese adolescents and adults, followed by prospective epidemiological studies of more than 23 800 men and 25 991 women related to physical activity and prognoses for developing metabolic syndrome.

## NUTRITIONAL MANIPULATION OF HIT-INDUCED ADAPTATION IN TRAINED INDIVIDUALS

HAWLEY, J.

*RMIT UNIVERSITY*

Acute alterations in substrate availability modify many of the immediate exercise response and, when repeated over days and weeks, modulate several adaptive processes in skeletal muscle that ultimately underpin the phenotype-specific characteristics observed in trained individuals. Skeletal muscle glycogen concentration exerts a regulatory effect on many cellular processes. For example, commencing endurance exercise with low muscle glycogen stores results in a greater transcriptional activation of enzymes involved in carbohydrate metabolism including the adenosine monophosphate-activated protein kinase (AMPK), glucose transporter-4 (GLUT-4), hexokinase and the pyruvate dehydrogenase (PDH) complex, compared to when glycogen content is normal or high. Recent investigations have systematically manipulated carbohydrate availability before endurance-based high-intensity interval training (HIT). The results from these studies demonstrate that independent of prior training status, short-term HIT programs in which some workouts are commenced with either low muscle glycogen levels, and/or low exogenous carbohydrate availability augment training adaptation to the same or to a greater extent than when similar workouts are undertaken with normal glycogen stores. This talk will explore some of the potential mechanism(s) underlying the benefit to training adaptation with reduced carbohydrate availability and offer practical recommendations for the periodised training of endurance-based athletes.

### IS-SH08 Identity, Culture, Performance and Professional Sport

#### IDENTITY, PERFORMANCE, CULTURE AND PROFESSIONAL SPORT

RAVIZZA, K.

*CALIFORNIA STATE UNIVERSITY*

Ravizza (1990) has argued that there are a unique set of challenges around ethics and the identity of the sport psychologist in such intensely performance focused cultures. Discussions will consider how the sport psychologist can operate in an ethically sound and effective way within a culture where gaining trust and respect are key to any success. We will also examine how sport psychologists can maintain their independence to enable them to adopt a longer term view of performance enhancement and player focus despite being inside a culture where results must be immediate and contract termination is inevitable. Lindsay, P., Breckon, J.D., Thomas, D. and Maynard, I. (2007) In pursuit of congruence: a personal reflection on methods and philosophy in applied practice, *The Sport Psychologist*, 21: 335-52. Nesti, M. (2010) *Psychology in football*, London: Routledge. Ravizza, K. (1990) Sportpsych consultation issues in professional baseball, *The Sport Psychologist*, 4, 330-340. Ravizza, K. (2002) A philosophical construct: a framework for performance enhancement, *International Journal of Sport Psychology*, 33:4-18.

#### FAIRNESS, CHEATING, AND PROFESSIONALISM IN SPORT

LOLAND, S.

*THE NORWEGIAN SCHOOL OF SPORT SCIENCES*

FAIRNESS, CHEATING, AND PROFESSIONALISM IN SPORT Sigmund Loland, The Norwegian University of Sport Sciences (Oslo, Norway) Introduction When voluntarily engaged in a rule-governed practice, a moral obligation arises to keep the rules. This is an obligation of fairness (Rawls 1971). Its rationale is that it is unfair to benefit from the cooperation of others without doing one's share. Cheating is the intentional violation of rules to gain an (unfair) advantage. The paper presents an overview and a discussion of the variety of cheating in the context of professional sports (Loland 2002). Method The approach is one of practical ethics in which general principles are weighed against considered judgments in actual practice. The aim is to reach a 'reflective equilibrium' in which principles and concrete judgments are consistent and mutually supportive (Rawls 1971). Results and discussion One common version of cheating is hidden violations of rules to escape penalty and thus gain an exclusive advantage. This is a classic form of deceit. A second version is the so-called 'professional foul'. Rules are violated openly and the penalty is accepted. The consideration is that the advantage gained outweighs the penalty given. A third version is what in ball games is called 'play acting' or 'diving'. A rule violation is simulated to gain an advantage and usually with the additional intention of imposing penalty on a competitor. The moral status of the various ways of cheating is critically discussed in the context of ideals of professionalism, and it is speculated about the future of fair play in professional sports. References Loland, S. (2002). Fair play in sport: a moral norm system. London: Routledge Rawls, J. (1971). A theory of justice. Cambridge, Mass.: Harvard UP

**IDENTITY, CULTURE, PERFORMANCE AND PROFESSIONAL SPORT**

NESTI, M.

LIVERPOOL JOHN MOORES UNIVERSITY

Presenters will discuss the demands placed on the sport psychologist working in professional team sport environments. Drawing on over 9 seasons work inside the English Premier League as a sport psychologist, Nesti (2010) has argued that issues around confidentiality, values and authenticity impact on what can be achieved and overall effectiveness. Lindsay et al. (2007) have discussed this in terms of the importance of philosophy of practice, and Ravizza (2002) has suggested that developing self awareness and self knowledge is essential for those hoping to work in the brutal and exciting culture of professional sport.

**Oral presentations****OP-BN08 Biomechanics in Children and Women****THE INFLUENCE OF ANTHROPOMETRIC MEASURES ON THREE-DIMENSIONAL BREAST KINEMATICS**

BROWN, N.1, WHITE, J.2, MILLIGAN, A.2, RISIUS, D.2, SCURR, J.2

1: ST MARY'S UNIVERSITY COLLEGE, UNITED KINGDOM, 2: UNIVERSITY OF PORTSMOUTH, UNITED KINGDOM

**INTRODUCTION** Investigation of breast kinematics in three-dimensions (3D) during physical activity has informed breast support requirements. However, despite substantial individual differences observed in the dimension and weight of the female breast (Gefen & Dilmoney, 2007), empirical research has not firmly established if breast size is related to body size and composition and the influence of anthropometric measures on 3D breast kinematics is under-reported. The purpose of this study was to investigate the ability of anthropometric measures to explain variation in 3D breast displacement, velocity and acceleration. **METHODS** Following institutional ethical approval, 3D displacement of the trunk and right nipple were recorded using eight calibrated infrared motion capture cameras (200 Hz; Oqus, Qualisys) for 48 A to DD cup size women (mean  $\pm$  SD; age  $25 \pm 7$  yrs, height  $167.0 \pm 6.4$  cms, weight  $63.0 \pm 8.2$  kg) during bare-breasted treadmill running ( $2.8$  m.s<sup>-1</sup>). Movement of the trunk in six-degrees of freedom was eliminated from movement of the breast and resultant kinematics calculated during 5 gait cycles. Chest and cup size were determined by a trained bra fitter and estimations of breast mass (g) made (Turner & Dujon, 2005). Following ISAK procedures restricted anthropometric profiles were recorded for each participant. Body mass, stature, body mass index, WHR, individual skinfolds (SF), somatotype, percent body fat, breast mass and suprasternal notch to nipple distance were included in analyses. **RESULTS** Breast mass and suprasternal notch to nipple distance were related to mediolateral (M-L) breast displacement, velocity and acceleration ( $R^2_{adj} = 0.569$ ,  $R^2_{adj} = 0.415$  and  $R^2_{adj} = 0.331$ ,  $P < 0.05$ ). Breast mass, suprasternal notch to nipple distance and iliac crest SF accounted for 37% and 45% of the variance observed in anteroposterior (A-P) breast acceleration and velocity, respectively ( $P < 0.05$ ). Vertical breast displacement and velocity were related to breast mass and iliac crest, triceps and subscapular SFs ( $R^2_{adj} = 0.561$ , and  $R^2_{adj} = 0.640$ ,  $P < 0.05$ ). **DISCUSSION** Findings suggest that breast mass and suprasternal notch to nipple distance significantly contribute to the explanation of M-L breast kinematics. Therefore bra design for larger-breasted women may need increased focus on reducing M-L breast motion. Furthermore, breast mass and upper body fat distribution influences vertical breast displacement and velocity. This may have implications for females in terms of performance and comfort during exercise and lead to altered breast support requirements following changes in breast mass and body composition. **REFERENCES** Gefen A, Dilmoney B. (2007). Rehab Asst Tech, 15, 259-271. Turner AJ, Dujon DG. (2005). Br J Plast Surg, 58, 290-298.

**DIFFERENCES IN TRUNK KINEMATICS BETWEEN MALES AND FEMALES DURING CUTTING MOVEMENT**

MORNIEUX, G., GEHRING, D., GLUNZ, B., GOLLHOFFER, A.

UNIVERSITY OF FREIBURG

**Introduction** Knee valgus moment during side-step cutting has frequently been investigated to understand knee injury rate differences between males and females (McLean et al., 2005; Pollard et al., 2004; Sigward et al., 2006). It has for instance been demonstrated that hip and knee kinematics at initial contact were related to higher knee valgus moments observed in females (McLean et al., 2005). However, the role of the trunk remains unclear, even if trunk and knee valgus motions were reported to be combined during knee injury situations for female athletes (Hewett et al., 2009). Therefore the aim of the study was to investigate the influence of gender on trunk kinematics and its possible link to knee valgus moment during a side-step cutting task. **Methods** 12 males ( $180 \pm 6$  cm;  $74 \pm 8$  kg) and 12 females ( $167 \pm 5$  cm;  $59 \pm 7$  kg) performed side-step cutting maneuvers with different cutting angles at a 4m/s approach velocity. All trials were randomized and subjects get the information in which direction they had to cut by means of a light system, about 450ms before the foot came into contact with a forceplate. 3D kinematics (Vicon) of the trunk and knee joint as well as knee valgus moment were measured at initial contact (IC) and at the time when peak knee valgus moment occurred (peak knee moment). A paired t-test was used to determine the influence of gender on the different dependent variables during the 60° cutting maneuver. **Results** Knee valgus was significantly higher for females ( $1.5 \pm 3.9^\circ$ ) than males ( $-2.0 \pm 3.6^\circ$ ) at IC ( $p=0.031$ ) and at peak knee moment ( $p=0.02$ ). Moreover, females exhibited larger trunk external rotation ( $30.1 \pm 7.7^\circ$ ) than males ( $24.1 \pm 6.2^\circ$ ) at IC ( $p=0.045$ ) but not at peak knee moment ( $p=0.08$ ) anymore. Knee valgus moment was not significantly influenced by gender. **Discussion** The higher knee valgus at IC and at peak knee moment for females than males was consistent with previous studies (McLean et al., 2005; Sigward et al., 2006). This could be related to differences in anatomy or in neuromuscular control and would possibly increase the risk of knee injuries in females. The 3D kinematical analysis of the trunk revealed that the trunk rotation was influenced by gender. The increased trunk external rotation at IC for females could reflect less effective coupling between the trunk and the lower limb. However, there was no difference between males and females in the knee valgus moment. Therefore the possible influence of the trunk on the knee valgus moment needs further research. **References** Hewett T., Torg J., Boden B. (2009). Br J Sports Med, 43(6), 417-422. **WHAT ARE THE EFFECTS OF EXCESSIVE BODY MASS ON FOOT LOADING IN CHILDREN?**

COUSINS, S.1, MORRISON, S.2, DRECHSLER, W.2

1: CDU (DARWIN, AUSTRALIA), 2: UEL (LONDON, ENGLAND)

**Introduction** The feet, as the bodies' base of support, are continually subjected to changing patterns of foot stress; continually resisting ground reaction forces during common activities of daily living. The presence of obesity may lead to foot alterations, especially in children due to their immature foot structure and late ossification. These factors can contribute to undermining the foot as a weight bearing structure resulting in pain and structural alterations; however few studies have examined the association between foot loading and body mass in children. The aim of this study was to determine the impact of excessive body mass on the foot loading characteristics in children during level walking. **Methods** 100 participants (22 obese, 22 overweight, 56 normal weight) were recruited from local schools in East London. Participants were asked to walk at a self-selected speed on a pre-defined walkway with the MatScan® (TekScan, USA) placed in the centre. The following variables were extracted for further analysis: peak pressure, peak force, pressure-time and force-time integrals. Data for 3 trials were used to determine the foot loading characteristics at the lateral and medial heel, midfoot, 1st metatarsal, 2nd-5th metatarsals and Hallux. **Results** During walking obese and overweight children experienced increased loading at all 6 regions of the foot in comparison to normal weight children. A one-way ANOVA and Tukey post-hoc test revealed obese and overweight children experienced significantly greater loading at the midfoot and 2nd-5th metatarsals in comparison to the normal weight group ( $p < 0.05$ ). **Discussion** These results revealed that obese and overweight children demonstrated increased loading at all regions of the foot in comparison to normal weight children. The increased loading was particularly prevalent at the midfoot and 2nd-5th metatarsals. These results are similar to previous findings where obese children experienced significant greater loading at the midfoot and metatarsals compared to non-obese children (Dowling et al. 2001). The increase in foot loading at the midfoot may be related to structural deformities at the feet indicative of a collapsed medial-longitudinal arch, with several studies reporting flatter feet in obese children as a result of structural maladaptations at the midfoot (Dowling et al. 2004; Mickle et al. 2006). The foot loading characteristics displayed by these participants were useful to distinguish between normal and abnormal loading patterns on the plantar aspect of the foot however the effects of excessive body mass on the structural and functional characteristics of the feet in children requires further investigation. **References** Dowling A, Steele J. (2001). *Int J Obes*, 25, 845-852. Dowling A, Baur L. (2004). *Int J Obes*, 28, 1514-1519. Mickle K, Steele J, Munro B. (2006). *Int J Pediatr Obes*, 1, 183-188.

**DETERMINANTS OF MUSCULAR FORCE PRODUCTION IN PRE-PUBERTAL CHILDREN: THE ROLES OF TENDON STIFFNESS AND MUSCLE ACTIVATION**

KORFF, T., WAUGH, C., FATH, F., BLAZEVOICH, A.

BRUNEL UNIVERSITY

**Introduction** The overall purpose of this study was to gain a better understanding of the mechanisms underlying age-related differences in muscular force production during childhood. Differences in the capacity for muscular force production between children and adults have been shown to be influenced by increases in muscle size and improvements in motor unit recruitment. Here, we asked if age-related changes in tendon stiffness would influence the capacity of muscular force production in pre-pubertal children. In adults, tendon stiffness has been shown to influence both electro-mechanical delay (EMD) and the contractile rate of force development (RFD). The first specific aim of this study was therefore to determine the relationships between tendon stiffness and EMD as well as tendon stiffness and RFD in pre-pubertal children. The second purpose of this study was to determine the relative neural and mechanical contributions to age-related changes in muscular force production by examining the effects of both tendon stiffness and rate of muscle activation on EMD and RFD. **Methods** Achilles tendon stiffness, EMD (time between the onsets of muscle activity and force), RFD (slope of the force-time curve) and rate of EMG rise (RER; slope of the EMG-time curve) were determined during plantarflexion contractions performed with a maximum RFD in forty-seven prepubertal children (age =  $8.3 \pm 1.6$  yrs). **Results** Tendon stiffness was negatively correlated with EMD ( $r = -0.66$ ) and positively correlated with RFD ( $r = 0.58$ ). A regression analysis indicated that both the RER and tendon stiffness were significant predictors of RFD and cumulatively accounted for 61% of the variance in RFD in children. **Discussion** These results demonstrate the importance of both neural and mechanical factors for muscular force production during childhood. They thereby significantly add to our understanding of the mechanisms underlying age-related improvements in muscular force production and may have further implications with respect to the interpretation of age-related differences in the performance of more complex motor tasks. Supported by the Engineering and Physical Sciences Research Council

**BREAST EXTENSION DURING TREADMILL RUNNING: A CASE STUDY**

SCURR, J., WHITE, J., MILLIGAN, A., RISIUS, D., HEDGER, W.

UNIVERSITY OF PORTSMOUTH

**Introduction** Movement-related breast pain is reported in up to 72% of exercising females (Gehlsen & Albohm, 1980) and may arise from tension on breast skin and fascia (Mason et al., 1999). Additionally, the supporting structures of the breast may be stretched with repeated loading during exercise (Page & Steele, 1999). Previous breast biomechanics research has predominantly considered vertical breast displacement during exercise, but whether this causes tension or stretching on breast structures beyond their static position is unknown. Therefore, the aim was to present a protocol to measure multi-planar breast movement beyond the static positions during running. **Methods** One female (32D breast size) had markers attached to the thorax and right nipple. To determine static breast positions (gravity loaded), markers were tracked with the participant standing (inferior), upside-down (superior), lying on the right and left (lateral and medial), on all fours and prone (anterior and posterior). Markers were then tracked during treadmill running ( $10 \text{ km} \cdot \text{h}^{-1}$ ) in three conditions; no bra, everyday bra and sports bra. Peak breast movement beyond the static positions in each direction determined breast extension. Additionally, vertical, anteroposterior and mediolateral breast displacement relative to the thorax was calculated. **Results** With no breast support, running caused movement beyond all static positions (inferior 19 mm, medial 8 mm, lateral 4 mm, anterior 3 mm, posterior 22 mm) except the superior position. Both bras reduced movement to within all static boundaries except the posterior. The greatest breast extension occurred posteriorly and neither bra eliminated this. During running breast displacement was greatest vertically (no bra 69 mm, everyday bra 34 mm, sports bra 25 mm). Despite the sports bra being most effective at reducing vertical displacement, it allowed movement beyond the inferior static position during running. **Discussion** Running in no bra resulted in multi-planar breast extension; bras effectively eliminated this, except posteriorly. Considerable posterior extension occurred which may relate to breast tissue compression. Previous research reports breasts slapping against the chest during running (McGhee et al., 2007), which may characterise this com-

pression. Minimum breast lift in the sports bra meant that despite displacement reductions, the breast still extended beyond the inferior static position during running. Future research should utilise this protocol to compare multi-planar breast extension and breast pain during running. References Gehlsen G, Albohm M. (1980). *Physician Sports Med*, 8, 89-96. ### POSTURAL SWAY FEATURES IN EARLY ADOLESCENT FEMALE ATHLETES

PAU, M., LOI, A., LIGGI, M., PEZZOTTA, M.C.

UNIVERSITY OF CAGLIARI

POSTURAL SWAY FEATURES IN EARLY ADOLESCENT FEMALE ATHLETES Pau, M1., Loi, A2., Liggi, M.1 and Pezzotta, M.C2. 1: Department of Mechanical Engineering, University of Cagliari (Italy) 2: Scuola Regionale dello Sport della Sardegna, Italian Regional Olympic Committee (Italy) Introduction Elite athletes of disciplines where balance is an essential component in achieving a high level performance exhibit different capabilities in terms of postural sway assessed during upright stance, depending on the specific sport practiced (Perrin et al., 2002, Herpin et al., 2010). Is this true even in the case of young subjects? We tested this hypothesis by analyzing postural sway features of early adolescent rhythmic gymnasts, basketball and volleyball players with at least three years of experience. Methods Forty-five female athletes in the early adolescence stage were recruited for the study. All subjects belonged to teams involved in competitive activities, and attended at least three 90-minute training sessions per week. Using a pressure platform, time series of center of pressure (COP) position were acquired under bipedal (eyes open, EO and closed, EC) and unipedal conditions. Data processing made it possible to calculate Sway Area (SA), COP Path Length, COP displacements in Antero-Posterior (AP) and Medio-Lateral (ML) directions, as well as COP velocity. Results In bipedal stance, EC values of SA and COP displacements in ML and AP directions were found to be significantly higher with respect to the EO condition for all the sports, while the discipline appeared to be responsible for differences in COP path length and velocity in the AP and ML directions. In the unipedal stance, gymnasts exhibited better performances as regards SA and COP displacements for the dominant limb, while the volleyball group of subjects was characterized by lower values of COP velocity and, correspondingly, by lower COP path length for the non-dominant limb. Discussion The specific content of rhythmic gymnastic training would lead one to expect a better balance performance even for basic balance tasks (Calavalle, 2008), but in our study this was not clearly observed. On the contrary, bipedal balance was somewhat better in volleyball and basketball players. Gymnasts exhibit lesser sway amplitude in the unipedal stance probably due to the specific content of training sessions. In any case, it appears that the not fully developed postural system limits the possibility of transferring abilities acquired in the specific training in basic balance tasks, and that different disciplines appear to improve balance capabilities in a similar manner. ### OP-PM20 Cardiovascular: Blood Pressure and Flow

#### FORCE DISTRIBUTION AFFECTS BLOOD PRESSURE IN RECREATIONAL ALPINE SKIING.

SCHEIBER, P., SEIFERT, J., MUELLER, E.

UNIVERSITY OF SALZBURG, DEPARTMENT OF SPORT SCIENCE

INTRODUCTION: It has been demonstrated that the individual skiing style has an important influence on the physiological stress of older recreational skiers (Scheiber 2010). Blood pressure of older exercising people may be elevated during rest and exercise. Consequently, the knowledge on the relationship between blood pressure response and individual skiing styles is of interest. METHOD: Kinetic (ground reaction forces), kinematic (knee angle) variables, systolic and diastolic blood pressure of 9 advanced older skiers (61.1 $\pm$ 5.6 yrs.) were collected simultaneously during recreational skiing on a medium steep slope (17°). Pearson's correlations were obtained to analyze the relationships among biomechanical and mean arterial pressure (MAP) data. Intra-class correlation coefficients (Cronbach's Alpha) were calculated to test reliability of MAP measurements. Level of significance was set a priori at  $p < 0.05$ . RESULTS: MAP ranged from 90 to 136 mmHg and the test-retest reliability (three trials) of the blood pressure measurements resulted in ICC=0.953,  $p < 0.01$ . No significant correlations were found between the variables knee angle, mean and peak ground reaction force and the MAP data. However, the individual co-loading of the inner leg (ranging from 30 to 45%) correlated significantly positive with the MAP ( $R^2 = .602$ ). DISCUSSION: Heart rate and blood lactate responses in older recreational skiers were found to be mainly determined by the kinematic variables of the individual skiing style (Scheiber et al. 2010). However, in this study the co-loading of the inner leg significantly influenced the hemodynamic response of these skiers. In general, recreational skiing was characterized by an alternation of loading and unloading phases, due to a higher loaded outer and a lower loaded inner leg. However, this alternation will be reduced when skiers tend to load both legs equally and the recruitment patterns of the leg muscles may change substantially (Kröll et al. 2010). This, in turn, may hinder perfusion and blood pressure has to increase to keep total blood flow constant. CONCLUSION: Skiing with an increased co-loading of the inner leg seems to be critical, because the reduced perfusion may result in increased anaerobic metabolism during consecutive skiing. #### CARDIOVASCULAR RESPONSE DURING INCREMENTAL CYCLE ERGOMETER TESTS: GENDER AND AGE DIFFERENCES

BARALDO, A., TAPERI, C., CEVESE, A.

UNIVERSITY OF VERONA

Introduction The literature on cardiovascular responses to aerobic exercise does not clarify the role of stroke volume changes in the enhancement of cardiac output (Ogawa 1992). The aim of this project was to characterize the cardiovascular response, in terms of Heart Rate (HR), Stroke Volume (SV) and Cardiac Output (CO), during cycle-ergometer incremental tests, in young and aged subjects of both sexes. Methods We recruited 34 healthy volunteers (years, BMI): 8 Young Males (YM) (25  $\pm$  2, 22.3  $\pm$  3); 8 Elderly Males (EM) (66.5  $\pm$  3.5, 29.09 $\pm$ 2.9); 9 Young Females (YF) (23  $\pm$  2.4, 20.4  $\pm$  2.3); 9 Elderly Females (EF) (67 $\pm$  6.9, 23.1 $\pm$  2.7). We recorded cardiovascular data with

Portapres TNO, during cycle ergometer incremental tests, starting with a load of 40 W for 3 min followed by 10 W (YF, EF) or 20 W (YM, EM) increments each minute, up to voluntary exhaustion. Since the time course of exercises was not identical among the subjects, data are presented as mean $\pm$ SD at 3 points: rest, 40% and 80% maximum workload ( $V'O_2$  max). Three way ANOVA was used to detect significant differences ( $P < 0.05$ ). Results In all groups HR (bpm) increased linearly and progressively with the effort, although the increase was limited in the elderly group, both males and females, but the difference was significant at 80% $VO_{2max}$  only: YM  $74 \pm 13.2$ ,  $110 \pm 23.8$ ,  $165 \pm 14.3$ ; EM  $83 \pm 9.6$ ,  $108 \pm 7.3$ ,  $144 \pm 13.1$ ; YF  $88 \pm 12.9$ ,  $112 \pm 1.7$ ,  $167 \pm 1.4$ ; EF  $87 \pm 14$ ,  $101 \pm 2.1$ ,  $144 \pm 1.3$ . At rest, SV (ml) was higher in males than in females, and in young than in older subjects. Irrespective of the age, in the males it increased at 40% but declined slightly at 80%, while in the females it increased at 40% and increased further at 80%; differences between males and females were significant: YM  $95 \pm 23$ ,  $135 \pm 23$ ,  $128.7 \pm 17$ ; EM  $65 \pm 18.3$ ,  $84 \pm 20.2$ ,  $82 \pm 21.1$ ; YF  $62 \pm 7.8$ ,  $66 \pm 0.7$ ,  $77 \pm 0.6$ ; EF  $52 \pm 12.7$ ,  $60 \pm 0.8$ ,  $70 \pm 0.08$ . In all subjects, CO (l/min) significantly increased in proportion to the effort, and differences in changes were significant among the groups: YM  $7 \pm 0.8$ ,  $14 \pm 1.7$ ,  $21 \pm 2.4$ ; EM  $5 \pm 1.5$ ,  $9 \pm 2.1$ ,  $12 \pm 2.4$ ; YF  $6 \pm 1.2$ ,  $7 \pm 0.05$ ,  $12 \pm 0.2$ ; EF  $5 \pm 1.6$ ,  $6 \pm 0.1$ ,  $9 \pm 0.07$ . Discussion While the overall cardiovascular response to exercise was similar in the 4 groups, if expected age and gender related differences are accounted for, all females appeared to apply a different strategy for CO enhancement during exercise, relying on continuous deployment of the pumping reserve function of their heart, while males used only tachycardia after the initial rise in SV (Vella 2005; Proctor 1998). The mechanism underlying this remarkable gender related difference deserves further examination. ## EFFECTS OF HYDRATION ON POST-EXERCISE HYPOTENSION AND HEMODYNAMIC MECHANISMS

FORJAZ, C.L.M., LOBO, F.S., MEDINA, F.L., COSTA, L.A.R., QUEIROZ, A.C., TINUCCI, T.

SCHOOL OF PHYSICAL EDUCATION AND SPORT, UNIVERSITY OF SÃO PAULO

Introduction: Post-exercise hypotension (PEH) has been extensively reported in healthy subjects, but its hemodynamic mechanisms remains controversial when recovery is conducted in the seated position. Exercise causes a state of hypo hydration that might influence hemodynamic responses during the recovery period. Previous studies observed that intravenous hydration may prevent PEH (Charkoudian et al., 2003). However, the effect of oral hydration that is recommended before and after exercise is not clear. Thus, this study was designed to investigate the effects of oral hydration on post-exercise blood pressure (BP) and its hemodynamic mechanisms. Methods: Sixteen young men underwent four sessions executed in a random order: control without hydration (CW), exercise without hydration (EW), control with hydration (CH) and exercise with hydration (EH). In the hydration sessions, subjects drank 1l of water in the night before, 500 ml of water 60 min before the intervention (rest or exercise) and 1ml of water for 1g of body mass lost immediately after the intervention. In exercise sessions, they exercised for 45 min on a cycle ergometer at 60% of  $VO_{2peak}$ . Systolic (S), diastolic (D) and mean (M) BP, as well as cardiac output (CO) and heart rate (HR) were measured before and 60 minutes after the interventions. Data was analyzed by a 3-way ANOVA for repeated measures. Results: Contrary to the hypothesis, hydration did not change hemodynamic responses after the exercise. Exercise produced a significant reduction in SBP (EW= $105 \pm 1$  vs.  $99 \pm 1$  mmHg and EH= $105 \pm 1$  vs.  $102 \pm 1$  mmHg,  $p < 0.05$ ), and abolished the increase in DBP observed in the control sessions. CO decreased while SVR increased significantly and similarly after the control and exercise sessions. However, the decreases in CO after the control sessions were accompanied by decrease in HR (CW =  $68 \pm 2$  vs.  $63 \pm 2$  bpm and CH= $67 \pm 2$  vs.  $61 \pm 2$  bpm,  $P < 0.05$ ), while they were due to a reduction in stroke volume after the E sessions (EW= $63 \pm 3$  vs.  $58 \pm 4$  ml and EH= $64 \pm 3$  vs.  $60 \pm 5$  ml,  $p < 0.05$ ). Discussion: Results from this study indicated that in healthy young subjects hydration did not modify the hypotensive effect promoted by the aerobic exercise during the recovery period, and it also did not affect the hemodynamic determinants of PEH. ## RAPID LOSS OF ISOMETRIC TRAINING-INDUCED REDUCTIONS IN RESTING BLOOD PRESSURE

WILES, J., DEVEREUX, G., COLEMAN, D., SWAINE, I.

CANTERBURY CHRIST CHURCH UNIVERSITY

Introduction Few studies have investigated the loss of isometric exercise training (IET) induced reductions in resting blood pressure (RBP). It seems only Howden et al (2002) have followed-up RBP assessment after a period of de-training. They showed that training-induced reductions in RBP were lost within 10 days of completion of a 5-week programme. The purpose of this study was to follow-up participants, 1 week after a 4-week bilateral-leg IET programme. Methods 13 healthy males, mean age  $21.0 \pm 2.4$  yrs, body mass  $78.1 \pm 18.2$  kg and stature  $177.1 \pm 4.6$  cm (mean  $\pm$  s), gave informed consent and completed a 4 week IET crossover study. Crossover between exercise and control conditions was separated by 6 weeks. IET intensity was set at the proportion of peak EMG (%EMG<sub>peak</sub>), which corresponded to 95% of the peak heart rate (HR<sub>peak</sub>) achieved during an incremental isometric exercise test to exhaustion. IET consisted of 4x2 min bouts, separated by 3 minutes of rest, on 3 days.wk<sup>-1</sup>. Training intensity (EMG mV) was updated if the mean training session HR deviated from the pre-set HR by  $> 5\%$ . RBP was measured at the brachial artery, seated, using an automated oscillometric device. This was done at baseline, post-training and following 7 days of detraining. Results 4 weeks of bilateral-leg IET resulted in significant reductions in resting SBP, DBP and MAP ( $-4.9 \pm 5.8$ ,  $-2.8 \pm 3.2$  and  $-2.8 \pm 2.2$  mmHg respectively;  $p < 0.05$  in all cases) compared to control. These training-induced reductions in RBP were lost following 1 week of de-training. Discussion These findings demonstrate that the training-induced reductions in resting blood pressure are rapidly lost upon cessation of 4 weeks of IET (bilateral-leg exercise performed at 95% HR<sub>peak</sub>, which equates to approx 24% MVC). These findings suggest that: (i) the adaptive mechanism responsible for the reduced RBP from this duration of IET, is unlikely to involve structural changes in the cardiovascular system, and (ii) IET must be continued weekly in order to benefit from the potential prophylactic hypotensive effect. ## BLOOD PRESSURE AND PLASMA VOLUME RESPONSES DURING RECOVERY: EFFECT OF EXERCISE INTENSITY AND EXERCISE LIMB

GRAHAM, M.J.1, FRANCOIS, M.E.1, PARR, E.B.1, STAVRIANEAS, S.2, LUCAS, S.J.E.1, COTTER, J.D.1

1. OU (DUNEDIN, NEW ZEALAND) AND 2. WU (OREGON, USA)

**Introduction** Arterial and central venous blood pressures (BP) are reduced following exercise, which contributes to exercise being a key anti-hypertensive therapy and facilitates expansion of plasma volume (PV). However, the effects of exercise intensity, duration and exercising limb on post-exercise hypotension and hypervolaemic responses are not resolved. Therefore, the purposes of this study were to identify the acute (<24 h) profiles of arterial BP and PV for (i) endurance (END) versus repeated high-intensity exercise (RHIE), and (ii) lower-body versus upper-body exercise (RHIE-L vs. RHIE-U). **Methods** Twelve untrained males (age:  $23 \pm 3$  y, body mass:  $72.4 \pm 12.8$  kg,  $\text{VO}_2$  max:  $44 \pm 8$  mL/min/kg) completed one END (50 min at 65%  $\text{VO}_2$  max), one RHIE-L and one RHIE-U exercise trial (both RHIE, five 30-s maximal sprints with 4.5-min recovery), ~2 wk apart. Measurements were taken at baseline, during exercise (cycle ergometry), continuously (beat-to-beat BP) or at 15-min intervals (blood samples) throughout the first 3-h seated recovery, then at 8 and 22 h. Change in PV was calculated from haemoglobin and haematocrit. Responses were modelled for key parameters (e.g., nadir) before inferential analysis. Results RHIE-L led to a one fold larger post-exercise hypotension compared with END (Area 'Under' Curve:  $7540 \pm 3853$  vs.  $3897 \pm 2757$  mm Hg/min,  $p=0.05$ , 95%CI:  $3392 \pm 3372$ ), whereas similar responses were evident for exercising different limbs (RHIE-U  $6420 \pm 3947$ ,  $p=0.48$ , CI:  $-1261 \pm 3896$  mm Hg/min). RHIE-L led to a two fold larger post-exercise decrease in PV compared with END ( $789 \pm 268$  vs.  $251 \pm 175$  %/min, CI:  $537 \pm 236$ ), whereas it was similar to RHIE-U ( $692 \pm 284$  %/min, CI:  $-97 \pm 237$ ). In contrast, arterial BP at 22 h was reduced after END ( $-8 \pm 8$  mm Hg) but not after RHIE-L ( $0 \pm 7$  mm Hg,  $p=0.04$ , CI:  $7.8 \pm 7.2$  mm Hg) or RHIE-U. PV expansion at 22 h was similar (CI:  $0 \pm 5\%$ ) for END ( $+5 \pm 5\%$ ) and RHIE-L ( $+5 \pm 5\%$ ), as well as for RHIE-U ( $5 \pm 7\%$ , CI:  $-1 \pm 7\%$ ). **Discussion** The different post-exercise hypotension responses between END and RHIE may implicate peripheral dilatory factors associated with exercise intensity. Whereas, the similar hypotension following exercise with the arms may implicate central factors. Only END reduced BP the next day, possibly due to extended neuroendocrine or endothelial disturbance following intense interval exercise. Similar plasma volume expansion by 22 h, irrespective of intensity and exercising limb, indicates that a variety of exercise regimes may induce hypervolaemia, not obviously related to acute arterial hypotensive responses. Thus, exercise intensity may be a more important parameter for post-exercise hypotension but not the subsequent hypervolaemia.

## THE EFFECTS OF ISOMETRIC EXERCISE TRAINING ON ARTERY DIMENSIONS AND BLOOD FLOW IN MIDDLE-AGED MEN

BAROSS, A.W.1, WILES, J.D.2, SWAINE, I.L.2

1: SPORT AND EXERCISE SCIENCE, UON (UK) 2: SPORT AND EXERCISE SCIENCE, CCCU (UK)

**Introduction** Previous isometric training studies reporting reductions in resting blood pressure have not explored whether there are concomitant changes in resting artery dimensions and blood flow. Furthermore, the influence of isometric training intensity on these adaptations has not been investigated. Therefore, the purpose of this study was to explore whether training-induced reductions in resting blood pressure are associated with concomitant changes in the vasculature of the trained and untrained limbs and to establish if these adaptations were intensity dependent. **Methods** Subjects undertook an 8 week training programme consisting of 4x2 min bilateral-leg isometric contractions 3 x per week (Wiles et al., 2010). Two groups exercised at intensities equivalent to 70% ( $n=10$ ) or 85% ( $n=10$ ) of their peak heart rate (%HRpeak; as established in a prior incremental test), and a third group acted as controls ( $n=10$ ). Resting systolic (SBP), mean arterial (MAP) and diastolic (DBP) blood pressure was measured at baseline and post-training. Artery diameter and mean blood flow (brachial and femoral) were also measured at rest using Doppler ultrasound. Analysis of variance was used to determine whether post-training measures were significantly different to baseline. Also, baseline values were used as a covariate to account for initial resting blood pressure values. **Results** There were significant reductions in resting SBP ( $-10.8 \pm 7.9$  mmHg) and MAP ( $-4.7 \pm 6.8$  mmHg) in the 85%T group post-training and concomitant significant increases in resting femoral mean artery diameter (FMAD;  $1.0 \pm 0.4$  mm) and femoral mean blood velocity (FMBV;  $0.68 \pm 0.83$  cm/s), which resulted in increased femoral artery blood flow (FABF;  $82.06 \pm 31.92$  ml/min). There were no significant changes in brachial artery measures after training. Furthermore, there were no significant changes in any resting measure in the 70%T or control group. **Discussion** This study shows that the reductions in resting SBP and MAP observed after isometric training are associated with concomitant increases in resting artery dimensions and blood flow, but these changes were restricted to the trained limbs. This suggests that the vascular adaptations were localised. Furthermore, these adaptations seem to be training-intensity dependent, as they were not observed in the 70%T training group. These findings could be explained by reduced resting vascular tone, enhanced endothelium-dependent function or by vascular remodelling. The stimulus for such adaptations may arise from changes in availability/activity of nitric oxide as a result of sheer stresses during isometric exercise (McGowan et al. 2007). Exactly how these sheer stresses occur during isometric exercise and how they might be related to isometric training intensity would be deserving of future study. ### IS-BN01 Motor Control - From Basics to Applications

#### SHORT-TERM AND LONG-TERM EFFECTS OF VARIABILITY-INCREASING CON-STRAINTS

BIRKLBAUER, J., HAUDUM, A., MÜLLER, E.

DEPARTMENT OF SPORT SCIENCE AND KINESIOLOGY, UNIVERSITY OF SALZBURG

The development and successful integration of approaches such as synergetics or dynamic system approaches, stochastic resonance and neurobiological insights, as well as artificial neural network simulations contributed to a reconsideration and acceptance of variability. Motor studies on practical developments (e.g. contextual interference or differential learning) have underpinned that induced variability facilitates learning (e.g. Brady, 2004; Frank et al., 2008) and that it enables flexible and, thus, stable patterns of coordination (Bernstein, 1967). However, the amount and structure of optimal movement variability in the course of successful learning is still under debate. A generally valid training concept is complicated by the fact that various moderator variable, such as age, skill level, type of skill, or individual pre-experiences, are suggested to strongly affect variable training regimes. By starting with a broad range of different movement

experiences which is steadily reduced in the process of learning, the solution space (i.e., the space that covers the different executions) may be adequately covered to encourage the task specific interpolation ability (Birklbauer, 2006; Schöllhorn et al. 2009). That is, especially on a higher skill level, movement variability should remain within the functional boundaries of the skill to be learned. Such a convergent variability structure should enable an adequate fine-tuning. This talk will highlight experiments in various sports that demonstrate benefits and limits of variable training and practical applications. Besides different forms of variable practice, the main focus lies on alternative ways to increase variability within the movement skill and in a sport specific manner, respectively. Research on the application of special variability-increasing constraints will be presented. One example demonstrates the acute effect of running with elastic cords when first exposed to the cords and their effect after an acquisition period as well as long-term effects on different observational levels. Other examples show the practical application in different ball games and on different skill levels. These results especially highlight the positive transfer performances after variable training. A third example shows the effects of different cord applications during the golf swing in comparison to a golf-specific training tool. Bernstein, N. A. ## NEUROPHYSIOLOGICAL FUNDAMENTALS OF MOTOR CONTROL

TAUBE, W.

UNIVERSITY OF FRIBOURG

Human motor control enables all kinds of motor actions from simple reflexes to highly complex manipulative skills. The central nervous system (CNS) is challenged to move the body in a three dimensional environment by coordinating activity of up to 600 muscles. Most actions therefore require profound MOTOR PLANNING. Thus, before motor cortical neurons are activated, input from other centres is necessary. In voluntary actions, one key input reaches the motor cortex from the presupplementary motor area, which in turn receives inputs from the basal ganglia and the prefrontal cortex (Haggard, 2008). Interestingly, the onset of activity in these areas was shown to precede the time when subjects became aware of their motor decision. After motor planning, the MOTOR COMMAND is released. Recent studies indicated that motor commands for dynamic muscle activation differ from motor commands responsible for tonic contractions. Beck et al. (2008) demonstrated that at the onset of dynamic movements, excitation of the motor cortex (M1) is spatially restricted to areas representing the involved muscles whereas adjacent areas are inhibited. Apart from the 'spatial restriction' there seems also to be a 'temporal restriction' indicated by preferential activation of cortical neurons responsible for fast corticospinal projections (Taubé et al. unpublished). The functional significance of such a cortical activation pattern may be a temporally focused motor command. Although the release of the cortical motor command will cause a movement, this movement would most often not result in the desired consequences without the help of SENSORY FEEDBACK. This can easily be seen in patients with loss of proprioceptive feedback who are not able to adequately control posture, locomotion and other motor tasks. Thus, sensory feedback is required to ensure that the motor command in fact causes the predicted consequences. However, sensory feedback is not only used to detect movement errors but also to maximise power output. For instance, in plyometric movements the integration of sensory feedback is used to provide adequate muscle stiffness and allow elastic properties. An appropriate integration of sensory feedback as well as a proper conceptualization of the motor command can only be achieved by FEEDFORWARD MOVEMENT CONTROL. Especially fast and ballistic movements rely on feedforward control. On a behavioural level, inaccuracy of feedforward control can be demonstrated by 'aftereffects', where a specific movement pattern is preserved although the environmental context has changed. On the level of the CNS, the cerebellum plays a crucial role in adapting feedforward control (Bastian, 2006). The talk will give a short overview about the stages and corresponding neural substrates, which are necessary for a successful motor control, i.e. motor planning, conceptualization of context specific motor commands, processing of sensory feedback and operation of feedforward control. ## FUNCTION OF VARIABILITY IN MOTOR CONTROL

HAMILL, J.

UNIVERSITY OF MASSACHUSETTS

Introduction Recently, researchers have explored the use of non-linear techniques to analyze human movement. Variability in human movement is often considered as noise or error in the data. However, in the dynamical systems approach, variability is considered a natural variation in the biological system and is inherent in the biological signal while noise is not part of the signal. The purpose of this lecture is to present methods of evaluating variability and the meaning of variability in terms of human motion. Methodological Approaches Coordination in this approach is defined as the interaction of contiguous joints or segments. Two methods that are often used to evaluate coordination are modified vector coding (VC) and continuous relative phase (CRP). The modified vector coding approach was developed using an angle-angle approach. Multiple profiles (i.e. trials) are computed the same way and then averaged to develop mean and standard deviation profiles of these trials. It must be noted that the vector coding angles are directional and thus circular statistics must be used to calculate the mean and standard deviation (Bachelet, 19xx). CRP is considered a higher order analysis. In a CRP analysis, the angle and angular velocity of a segment are plotted on the ordinate and abscissa from which a phase angle is calculated from the origin to the data point at each instant in time throughout the cycle. The same procedure is done with the other segment. The two phase angles are then subtracted to develop the CRP angle. A mean and standard deviation can be calculated over multiple trials (Hamill et al., 1999). In both cases, the standard deviation profile indicates the variability in the coordination between the segments. Discussion Bernstein (1967) suggested that coordination variability is essential to ensure flexibility in task execution. In evaluating the biological variability inherent in a movement over a number of trials it has been reported that a higher level of coordination variability is a normal or healthy or less skilled scenario while a lower level of coordination variability is the opposite (Hamill et al., 1999; Pollard et al., 2005). This interpretation has been well-established in cardiovascular heart disease. The major problem with this approach is that the windows of high and low variability have not been established. It is clear that References Batschelet, E. (1981). New York: Academic Press. Bernstein, N. (1967). Oxford: Pergamon Press. Hamill, J, Van Emmerik, R., Heiderscheit, B, Li, L. (1999). ## COMPUTATIONAL MOTOR CONTROL OF HUMAN MOVEMENTS

STEIN, T.1, SIMONIDIS, C.2, SEEMANN, W.2, SCHWAMEDER, H.1

KARLSRUHE INSTITUTE OF TECHNOLOGY

Due to the numerous degrees of freedom in the human motor system, there exist an infinite number of possible movements for any given task. A central issue in motor control research is how the brain selects particular movements given the large set of possibilities (Diedrichsen et al., 2010). The purpose of this study was the construction of a computational model to unravel the principles the brain might use to select one movement out of the plethora of possible movements in a given situation. Thereby, based on different optimization criteria human movements were generated via computer simulations and compared to measured human movements for validation purposes. Eight subjects performed five pointing movements to each of two targets. All movements were tracked using an IR-tracking system (Vicon). A computational framework was developed consisting of three optimization criteria (MHJ: minimum hand jerk, MAJ: minimum angle jerk, MTC: minimum torque change), a biomechanical full-body model and an optimization algorithm for the calculation of optimal movements based on the three criteria (Simonidis et al., 2009). Motion capture data was mapped on the biomechanical model in order to yield reference movements. Pointing movements were synthesized for each trial based on the three criteria. Orthogonal reference functions were used to quantify the similarities between human and synthesized pointing movements. The resulting coefficients can be interpreted as correlation coefficients (Schöllhorn, 1995). Averaged over 40 trials the results for the hand movements reveal only small differences in similarity coefficients in extrinsic kinematic coordinates (e.g. target 2, hand trajectories: MHJ=.996, MAJ=.998, MTC=.992; tangential hand velocities: MHJ=.959, MAJ=.973; MTC=.883). On joint level the MAJ-criterion showed a closer fit to the human data than the MTC-criterion (e.g. target 2, joint angles: MAJ=.906, MTC=.578; joint angular velocities: MAJ=.677; MTC=.324). Based on these results, the brain most likely uses a MAJ-criterion in movement production. Since the MAJ-criterion did not fully reproduce the human movements an exclusive application of this principle by the brain seems unlikely. Therefore, future research will include combinations of optimality criteria as well as different types of movement tasks. Diedrichsen, J., Shadmehr, R., Ivry, R.B. (2010). #### EFFECT OF DHA-RICH FISH OIL CHRONIC SUPPLEMENTATION ON NEUTROPHIL FUNCTION, INFLAMMATORY MEDIATORS AND MUSCLE DAMAGE MARKERS BEFORE AND AFTER A MARATHON RACE

CURY-BOAVENTURA, M.F.1, SANTOS, V.C.1, LEVADA-PIRES, A.C.2, ALVES, S.R.1, PITHON-CURI, T.C.1, CURI, R.2

Introduction: Marathon race is associated with transient suppression of neutrophil function and changes in inflammatory mediators. Docosa-hexaenoic acid (DHA) has anti-inflammatory and beneficial effects on neutrophil function. Objective: The aim of this study was to investigate the effect of DHA-rich fish oil (FO) supplementation on neutrophils function and plasma concentration of inflammatory mediators and muscle damage markers in marathon runners before and after a marathon race. Methods: Twenty one athletes (age: 36± 0.2 years; body mass: 60 ± 1.1 kg, height: 164 ± 0.01 cm, body fat: 9.4 ± 0.6, BMI: 22.4 ± 0.4 kg/m<sup>2</sup>; race duration: 2h52min + 5 min; training program: 136 ± 15 km/wk) were recruited. Eight marathon runners were supplemented with 3 g of FO per day (FO group) and thirteen were not supplemented (C group). The following determinations were carried out: plasma concentration of creatine kinase (CK), lactate dehydrogenase (LDH), C reactive protein (CRP), PGE<sub>2</sub>, IL-1 beta, TNF-alpha, IL-6, IL-8, IL-1ra IL-2 and IL-10 and neutrophil function (phagocytosis capacity, viability, phosphatidylserine externalization and DNA fragmentation). Results: Plasma concentration of CK, LDH and CRP were already above the maximum reference value before race indicating muscle damage and systemic inflammation in C and FO group. We observed a significant increase in the plasma concentration of PGE<sub>2</sub>, IL-6, IL-10 and IL-1ra in C group after race. Plasma PGE<sub>2</sub>, IL-6, IL-10 and IL-1ra were maintained before and after race in FO group. The marathon race led to a decrease in phagocytosis capacity in C and FO group. We also observed an increase in loss of membrane integrity, phosphatidylserine externalization and DNA fragmentation in C group neutrophils at recovery period of training (before race). FO supplementation prevents the loss of membrane integrity but induced phosphatidylserine externalization and DNA fragmentation in neutrophils. Conclusion: FO supplementation partially reversed inflammatory response and death induced by training and /or marathon but didn't prevent the muscle damage and neutrophils function.

#### KINETICS OF DIABETES INFLAMMATORY RESPONSE TO INTENSE EXERCISE

HATANAKA, E.

CRUZEIRO DO SUL UNIVERSITY

Hatanaka E1, Bortolon JR1, Silva Junior AJA1, Murata GM1, Newsholme P2, Curi R3, Pithon-Curi TC1, 1Post-Graduate Program in Human Movement Sciences, Institute of Physical Activity Sciences and Sports, Cruzeiro do Sul University (São Paulo, Brazil), 2School of Biomolecular and Biomedical Science, Conway Institute, University College Dublin (Dublin, Ireland) 3Department of Physiology and Biophysics, Institute of Biomedical Sciences (São Paulo, Brazil). Introduction: High intensity exercise imposes major acute endocrine, metabolic and immune alterations which persist for a period of several hours after the exercise and may be detrimental to the health of diabetics [1]. In this study we evaluated installation and resolution of inflammation in control and diabetic rats subjected to a session of intense exercise. Methods. Blood samples were taken from rats before, immediately after, 2 hours and 24 hours after exercise. Pro-inflammatory cytokines (TNF-α, IL-1β, CINC-2α/β, MIP-3α, L-selectin and IL-6), anti-inflammatory cytokines (IL-1ra and IL-10), growth factor (VEGF-α), Immunoglobulins (IgA and IgM), acute phase proteins (PCR and C3), muscle lesion marker (CK), and glycemia were measured. We also analyzed the occurrence of macrophage death by necrosis and/or apoptosis. Results. In the control group, intense exercise diminished serum glucose levels time-dependently (r=0.97). The diabetic group remained hyperglycemic in all the conditions studied, showing a slight decrease in glucose levels (24%) after 2 hours of exercise. Twenty-four hours after reaching exhaustion, diabetic rats still showed a continuing increase in the concentration of IL-1β (1.6-fold) and TNF-α (2.0-fold) and proportion of necrotizing macrophages (4.5-fold), while the control group returned to basal conditions. The control group presented a peak of IL-6 after two hours of exercise. No changes were observed in

IL-6 concentrations in the diabetic group. Moreover, no differences were found in the levels of IgA, IgM, C3, CINC-2 $\alpha/\beta$ , MIP-3 $\alpha$ , L-selectin, IL-1 $\alpha$ , IL-10 and VEGF- $\alpha$  under the conditions of this study. Conclusion. We concluded that injury was induced in the non-trained diabetic group after 24 hours of exhaustive exercising, while the control group returned to basal conditions. This is the first time it has been observed that the resting time for diabetics undergoing intense training must differ from that of non-diabetic controls. Additionally, the inflammatory markers, IL-1 $\beta$ , TNF- $\alpha$  and proportion of macrophages in necrosis may be used as markers of recovery in sports practice after intense exercise. ## PHYSICAL EXERCISE AND REDOX BALANCE IN TYPE 2 DIABETICS: EFFECTS OF TRAINING ON CELLULAR DAMAGE AND BIOCHEMICAL MARKERS OF OXIDATIVE STRESS

PITTALUGA, M.

UNIVERSITY OF ROME "FORO ITALICO" – IUSM

Physical exercise and redox balance in type 2 diabetics: effects of training on cellular damage and biochemical markers of oxidative stress M. Pittaluga<sup>1</sup>, F. Magli<sup>1</sup>, I. Dimauro<sup>1</sup>, A. Sgadari<sup>2</sup>, B. Tavazzi<sup>2</sup>, S. Fulle<sup>3</sup>, R. Mancinelli<sup>3</sup>, P. Parisi<sup>1</sup>, D. Caporossi<sup>1</sup> <sup>1</sup>Dept. of Health Sciences – University of Rome "Foro Italico", Italy; <sup>2</sup>Dept. of Gerontological, Geriatric and Physiatric Sciences, Catholic University of Sacred Heart – Rome, Italy; <sup>3</sup>Dept. Basic and Applied Medical Sciences (BAMS), Interuniversity Institute of Miology (IIM), University 'G d'Annunzio' – Chieti, Italy Altered redox balance has been suggested as a contributory factor for initiation and progression of diabetes and its complications. It is supposed that a moderate physical training can improve the oxidative-stress dependent cellular response in diabetic patients both stimulating the molecular pathway of short-term answers, and, following a long term exposition, modulating the expression of genes involved in antioxidant response and DNA damage check and repair. To evaluate both the short- and long-term effects of physical training (PT) on oxidative stress markers in type 2 diabetics we planned a two steps protocol. In the first phase we evaluate the effect of a 4-months moderate PT both on 12 diabetic sedentary males (62.1 $\pm$ 4.3 yrs), and 12 healthy sedentary males (61.7 $\pm$ 3.9 yrs). DNA damage (Comet assay) in lymphocytes in untreated as well as H<sub>2</sub>O<sub>2</sub> treated samples, and multiple biochemical markers of antioxidant status were assessed. In the long-term protocol 10 diabetic males were selected: 5 sedentary (62.0 $\pm$ 4.5 yrs); 5 (62.2 $\pm$ 9.5 yrs), practicing a moderate PT from at least 1 year. Gene expression changes was evaluated, performing a RT PCR Array on 46 genes selected among the the gene sets of antioxidant response and DNA damage check and repair. After training, in diabetic patients % DNA in Comet tails resulted significantly lower both in untreated and in treated cells. In both groups, training led to a significant increase of reduced glutathione, glutathione balance, as well as ascorbic acid levels. In diabetic patients, PT induced a significant diminution in malonylaldehyde. No differences were seen in apoptosis frequency between trained and untrained diabetics. Regarding the gene expression changes, the most interesting result is the overexpression of GADD45 (3.5 folds). Our data suggest that moderate physical training reduces the susceptibility to both spontaneous and H<sub>2</sub>O<sub>2</sub> induced DNA damage in diabetic patients. Biochemical data confirm the hypothesis that training can cause adaptive responses in terms of endogenous antioxidant, as well as an improvement in ascorbic acid recycling mechanisms. Preliminary RT PCR Array analysis show that long term moderate physical training can lead to a modulation of the expression of some DNA repair systems and cell cycle control genes. Further studies are planned to validate this findings on a larger sample.

## LEVELS OF INFLAMMATORY PROTEINS IN SUBCUTANEOUS ADIPOSE TISSUE AND THE CIRCULATION, IN RESPONSE TO 2 WEEKS OF HIGH INTENSITY INTERMITTENT TRAINING.

LEGGATE, M., CARTER, W.G., NIMMO, M.A.

LOUGHBOROUGH UNIVERSITY

Insulin resistance has been shown to be causatively linked to the modulation of the levels of cytokines and chemokines. Adipose tissue is a major source for production of many cytokines and an increase in the volume of adipocytes and infiltration of macrophages can lead to an elevation of inflammatory cytokines, which if prolonged, results in chronic low grade inflammation. Chronic low grade inflammation underpins many long term illnesses including type 2 diabetes and cardiovascular disease (Libby et al. 2002). Exercise training can reduce resting levels of certain inflammatory biomarkers (e.g. Thompson et al. 2010), but despite this, other studies have reported no change in inflammatory status after a 3 month exercise programme (Christiansen et al. 2010). This latter group suggested that modification of the cytokine profile may require higher intensity exercise. Two weeks of high intensity intermittent training (HIIT) has been shown to increase fat oxidation within skeletal muscle and aerobic capacity (Talanian et al. 2007), but the inflammatory response to HIIT is unknown. Twelve overweight/obese, but otherwise apparently healthy young males (Mean  $\pm$  SD) 23.7  $\pm$  5.2 y, body mass 91.0  $\pm$  8.0 kg, body mass index 29.1  $\pm$  3.1 kg-m<sup>-2</sup> completed 2 weeks of HIIT. Each session of HIIT consisted of 10X4 min cycling at 85.0  $\pm$  4.6 % VO<sub>2</sub>peak separated by 2 min rest. Resting blood and subcutaneous adipose tissue samples were taken before and after the 2 week training period. IL-6, IL-6 receptor (IL-6R), TNF- $\alpha$ , adiponectin and MCP-1 protein content were quantified in plasma and adipose tissue by ELISA. An oral glucose tolerance test was completed before and after training to assess changes in insulin sensitivity. Preliminary analysis of protein content has shown a reduction in IL-6 production within the adipose tissue ( $P < 0.05$ ), as well as an increase in IL-6R concentration ( $P < 0.05$ ). Analysis has also shown a significant reduction in IL-6R and MCP-1 in the circulation ( $P < 0.05$ ). No alterations in insulin sensitivity were observed after the training period. Therefore, this suggests that just 2 weeks HIIT is sufficient to induce beneficial alterations in the resting inflammatory profile of an overweight/obese population. ## PHYSICAL ACTIVITY, FITNESS, CHRONIC SYSTEMIC LOW-GRADE INFLAMMATION, CARDIOVASCULAR RISK FACTORS AND BODY MASS INDEX IN CHILDREN AND ADOLESCENTS AGED 10 – 19 YEARS

WESSNER, B., HACKL, M., VIDOTTO, C., TSCHAN, H., BACHL, N.

UNIVERSITY OF VIENNA

Introduction Regular physical activity exerts well documented beneficial effects on markers of the metabolic syndrome and chronic low-grade inflammation as well as on cardiovascular risk factors in children (Platat et al., 2006; Tanha et al, 2011). The aim of this cross-sectional study was to investigate whether additional physical activity through sports activities on a competition level is able to influence the above mentioned parameters. Methods Pupils (10-19y) from a particular high school in Vienna with two distinct school-types (elite

sports vs. regular) agreed to participate in the study. Anthropometric data, physical activity and fitness were assessed in 344 pupils (regular school: n=202; elite sports school: n=142). Fasting blood samples were withdrawn from 201 pupils (regular school: n=101; elite sports school: n=100). Metabolic parameters (blood glucose, insulin, cholesterol, and triglycerides), inflammatory parameters (hs-CRP, hs-IL-6, hs-TNF- $\alpha$ ), adipokines (leptin, leptin sR, adiponectin) and cardiovascular risk factors (homocysteine, NT-proBNP) were measured. Statistical comparisons were performed separately for girls and boys using a univariate factor analysis (school type & age groups). Results As expected, pupils from elite sports classes were involved in physical activity on more days per week (median: 6d; 4-7) than pupils from regular school classes (median: 4d; 1-7) ( $p<0.001$ ). Both, girls' and boys' shuttle run performance was significantly higher in elite sports scholars (up to +55%,  $p<0.001$ ) as was the width of medicine ball throw (up to +44%,  $p<0.001$ ). Anthropometric data did not differ between school types. Cardiovascular risk factors (NT-proBNP and homocysteine), leptin sR and inflammatory parameters were associated with BMI and age. However, the school type did not influence these parameters. Discussion It has been shown that illnesses such as diabetes, cardiovascular diseases, cancer and others are associated with physical inactivity – a risk factor for the accumulation of visceral fat and consequently of chronic systemic inflammation (Pederson, 2009). The results of this study contribute to the growing evidence that higher body mass index correlates with metabolic and cardiovascular risk factors even in childhood and adolescence. Our study might be biased by the unusual low participation of overweight children even in the regular school classes which could explain the lack of association of risk parameters and school type. #### THE IMPACT OF OVERWEIGHT AND OBESITY IN HEALTH AND CARDIORESPIRATORY FITNESS IN ADOLESCENTS OF A TOWN OF SAO PAULO STATE -BRASIL.

ROSSATO, A.A.1, PIMENTA, L.D.1,2, GIMARÃES, B.R.1,2, NEIVA, C.M.1,3

1: UNIFRAN (FRANCA-SP), 2: CORPUS STUDIO CLINIC (DIVINÓPOLIS-MG), 3: UNESP (BAURU-SP)

**Introduction** Obesity is a multifactorial problem characterized by excessive accumulation of fat, which causes a lot of disturbances to health, reducing life expectancy, threatening its quality. Obesity and overweight, are significant risk factors for development of chronic cardiovascular diseases, insulin resistance, diabetes mellitus and some types of cancer, and orthopedic diseases. One way to identify how obesity is affecting an individual health is by checking the level of cardiorespiratory fitness, which is associated with low and very low levels of fitness and a sedentary lifestyle that surrounds the disease. **Methods** The study sample consisted of 91 students in 9th grade of elementary school (in Cristais Paulista City, in Sao Paulo State - Brasil), aged 14 to 17 years, which, had been invited to volunteer to participate and the study aimed to classify the level of overweight and obesity by body mass index (BMI) also classify the level of physical activity by international questionnaire of physical activity (IPAQ), evaluating the level of cardiorespiratory fitness by means of a submaximal VO<sub>2</sub> (Bench McArdle Test), and make possible associations and correlations of the variables mentioned, for the adolescents. The comparisons, associations and correlations between the results obtained for physical fitness by scoring the IPAQ and also by ratings by VO<sub>2</sub> test, and the state of obesity were performed with the Mann-Whitney, Fisher, and Person (Simple Correlation), respectively. The analysis was conducted using the statistical software GraphPad InStat® for Windows® and the significance value of 0.05 was adopted for all statistical procedures. **Results** The prevalence of overweight and obesity is well below the national average (15.38% overweight/obese against 84.62% eutrophic). However, when stratified between gender, this study found a high prevalence of overweight/obesity for males (23.7% boys against 15.38% girls). When dealing with the physical activity level, there is a much higher rate of population studied compared with the national average (22% was weak against 78% regular/good). In relation to cardiorespiratory fitness, we found a negative correlation with the fitness of overweight and obesity. **Discussion** The results tell us that, in the case of obesity and overweight, instruments that assess the status of isolated physical activity without pointing out the degree of fitness may not be able to associate or relate this indicator to the health of people, since these instruments consider low-intensity activities, which are known not to contribute to the cardiorespiratory gain and thus little or no influence on metabolic aspects such as weight control.

#### EXERCISE TRAINING REDUCES VISFATIN LEVELS IN OBESE CHILDREN

JAMURTAS, A.Z.1, AGGELOUSI, S.1, THEODOROU, A.A.1, PASCHALIS, V.1, NIKOLAIDIS, M.G.2, FATOUROS, I.G.3, KOURETAS, D.1, KOUTEDAKIS, Y.1

1: UTH (GREECE) 2: CERETETH (GREECE) 3: DUTH (GREECE)

**Introduction** Obesity is a major global epidemic problem involving both children and adults (Koutedakis et al., 2005). The traditional view of adipose tissue, as a passive reservoir for energy storage, is no longer valid and it is clear that the adipose tissue is a complex and highly active metabolic endocrine organ that secretes a large number of proteins that are collectively referred to as adipocytokines (Kershaw & Flier 2004). Adipocytokines, i.e. leptin, adiponectin, resistin, visfatin, have numerous functions, including regulation of satiety, carbohydrate and lipid metabolism and insulin sensitivity. The purpose of the present study was to investigate the effects of obesity and exercise on plasma visfatin, adiponectin and resistin levels in children. **Methods** A sample of 42 children (lean=24, obese=18), aged 10-14 years old, were divided into 4 age-matched groups: a lean inactive group (n=11), an obese inactive group (n=9), a lean active group (n=13) and an obese active group (n=9). Active participants were engaged in regular swimming ( $\geq 1$  y,  $\geq 3$  times/week,  $\geq 1$  h per session). Resting blood samples were drawn in the morning and the assessment of each adipocytokine was measured by ELISA. Results For visfatin the analysis revealed effects that approached significance for BMI group,  $F(1, 41) = 3.64$ ,  $p = .06$ ,  $\eta^2 = .09$  (Table 2), and exercise group,  $F(1, 41) = 3.66$ ,  $p = .06$ ,  $\eta^2 = .09$ . Obese individuals demonstrated greater visfatin levels ( $3.3 \pm 1.3$  ng/ml) than their lean counterparts ( $2.6 \pm 1.1$  ng/ml) whereas active children exhibited lower visfatin levels ( $2.6 \pm 1.1$  ng/ml) than their active counterparts ( $3.3 \pm 1.2$  ng/ml). Furthermore, within obese individuals, active individuals had lower visfatin concentration ( $2.8 \pm 1.2$  ng/ml) compared to their inactive counterparts ( $3.8 \pm 1.2$  ng/ml). Adiponectin demonstrated lower mean values in obese children ( $3.8 \pm 1.9$ ) than their lean counterparts ( $5.9 \pm 2.7$ ). Resistin levels were comparable between groups. **Discussion** These results indicate that childhood obesity elevates visfatin and lowers adiponectin levels whereas exercise training may be able to reduce visfatin levels in obese children. ## SUCCESSFULLY IMPLEMENTING PHYSICAL ACTIVITY PROJECTS FOR FAMILIES: LESSONS LEARNED

ROMEO-VELILLA, M., MURPHY, R., STRATTON, G.

LIVERPOOL JOHN MOORES UNIVERSITY

**SUCCESSFULLY IMPLEMENTING PHYSICAL ACTIVITY PROJECTS FOR FAMILIES: LESSONS LEARNED** Romeo-Velilla, M.I, Murphy, R.I, Stratton, G.I  
1: RISES, LJMU (Liverpool, UK) Introduction The necessity to influence health behaviour in family units is endorsed by recent national reports in the UK (e.g. Healthy Weight, Healthy Lives report (2008)). The National Institute for Health and Clinical Excellence (2009) outlined recommendations for families and their physical activity. The Active Families Programme 2009-2010 was delivered as part of the Liverpool Active City (LAC) strategy 2005-2010. Community based organisations were invited to tender for a grant to increase physical activity in family groups. The evaluation of the family projects aimed to explore families' needs; identify families' and practitioners' views on how a family project should be delivered; and find out key aspects of the implementation process to inform future interventions for families. Methods An in-depth qualitative evaluation was designed to explore family and practitioners experiences of engaging with and delivering the projects. Semi-structured interviews were conducted with families (n=3 families, 3 mothers + 3 teenagers) and practitioners (n= 4 instructors, n= 3 project leads, n=2 LAC coordinators). In addition, a focus group was conducted with mothers (n=4) and project leads (n=3) on separate occasions. Content analysis was applied. Results Relatively little is known about how to successfully intervene with families to promote physical activity. Marketing strategies were carried out with a different approach: comprehensive ongoing marketing strategies vs. one-off actions at the beginning of the project. Practitioners had difficulties engaging with families before and during the projects. Instructors had difficulties keeping motivated all participants due to vast age differences and showed concerns about providing the same fitness level to all ages. Some mothers expressed that their children's school was an accessible venue, as they did not feel comfortable going to leisure sport centres or gyms. They also found positive the time (6pm), price (£1 per adult, £0.50 per child) and remarked the importance of the fun component as the key aspect to keep attending. Conclusion An ongoing comprehensive marketing strategy seemed to better engage families. Project objectives need to be clearly set and well defined in terms of their priority: fun for all vs. fitness for all. It is recommended to only recruit experienced instructors and to provide training to instructors and leads on how to deliver family sessions. References Department of Health, 2008. ## DEVELOPMENT OF NORMAL WEIGHT OBESITY DURING ADOLESCENT GROWTH: A COHORT STUDY IN NORTHERN PORTUGAL

LEITÃO, R.I.2, RODRIGUES, L.2.3, NEVES, L.2, CARVALHO, G.1

UNIVERSITY OF MINHO

1: Institute of Education, University of Minho (Portugal), 2: College of Education at Polytechnic Institute of Viana do Castelo (Portugal), 3: Research Center for Sports Science, Health and Human Development (Portugal) Introduction Normal weight obesity (NWO) refers to a condition that combines a normal body mass index (BMI) with an excessive body fat (De Lorenzo et al., 2006). Given the current increasing prevalence of obesity and physical inactivity among children and adolescents, we hypothesized that NWO might develop early in life. Therefore, the aim of the present study was to determine the incidence and prevalence of NWO in schoolchildren followed from age 9 to age 15 years. Methods Anthropometric assessments (baseline, age 9 and follow-up, age 15) were performed in a cohort of 288 children enrolled in the EMCV (Estudo Morfofuncional da Criança Vianense) at school setting. Stature, weight and skinfold thickness (triceps and subscapular) were measured using standard procedures (Lohman et al. 1988). BMI and percentage body fat (%BF) derived from skinfolds (Slaughter's equations) were calculated. "Normal BMI" and "excessive body fat" were defined by the International Obesity Task Force (IOTF) standards (Cole et al., 2000) and the health-related cut-offs of 25%BF in boys and 30%BF in girls, respectively (Williams et al., 1992). Results In boys, the prevalence of NWO was less than 1% at both assessments and no new cases occurred in the 6-year study period. Unlike boys, the prevalence of NWO in girls increased from 0% (baseline) to 8.3% (follow-up) ( $p < 0.05$ ), revealing that all cases emerged during adolescence (cumulative incidence of 8.3%). Conclusion In girls, but not in boys, there was a concerning development of NWO during adolescent growth. Future research is needed for a better understanding of this difference and of the role of physical activity in the prevention and treatment of NWO. ## LONGITUDINAL EFFECTS OF PHYSICAL ACTIVITY PATTERNS AND BODY MASS INDEX IN CARDIORESPIRATORY FITNESS DURING ADOLESCENCE

AIRES, L., SILVA, G., MARTINS, C., SANTOS, M.P., RIBEIRO, J.C., MOTA, J.

FACULTY OF SPORTS - UNIVERSITY OF PORTO

**Introduction** In last decades, children's CRF and PA are declining globally, probably as a consequence of youth preferences for sedentary activities. Several longitudinal studies have reported the relationships of total physical activity and intensity with fitness and fatness or with other risk factors in children, but few have addressed the influence of different context of physical activity in health related cardiorespiratory fitness in youth. Therefore, the aim of this longitudinal study was to explore the effect of BMI, overall PA and different domains of PA in CRF over four years of observation throughout adolescence. **Methods** 170 students (96 girls, 56.5%) from one high school (Valongo-Porto) were followed with starting ages of 11 to 17 yr-old. Cardiorespiratory was evaluated with the 20m-Shuttle Run (20m-SR) from Fitnessgram battery test as number of laps. Physical activity and Parents' education were obtained through a standard questionnaire. Parents' education was categorized in Low, Middle and High education, and BMI in normal weight, overweight and obesity, according to established cut points (1). CRF was used as dependent variable in a multilevel analysis using LMwIN. Two levels' structures were used: first level for individuals and second level for time observations. **Discussion** CRF was negatively associated with BMI and positively with PAI. Each question from physical activity questionnaire, were almost positive and increasingly associated with CRF in the crude model. However, in the adjusted model (for age, gender, mother education and BMI) this association was observed only for the highest categories regarding frequency in organized sports outside school and participation in sports competitions. The results highlight the participation of children

and adolescents in organized activities and competitive sports to achieve health-related fitness benefits. Efforts should be made to ensure that high levels of moderate to vigorous exercise are sufficiently maintained over time to enhance health-related stage in CRF. References 1. ### YEAR-ON-YEAR IMPROVEMENT IN OUTCOMES FROM A COMMUNITY CHILDHOOD OBESITY INTERVENTION : RECOMMENDATIONS FOR A PHASED APPROACH

WATSON, P.M.1, DUGDILL, L.2, PICKERING, K.1, BOSTOCK, S.1, HEPPLES, J.3, STANIFORD, L.1, CABLE, N.T.1

1LIVERPOOL JOHN MOORES UNIVERSITY, UK 2UNIVERSITY OF SALFORD, UK 3LEEDS METROPOLITAN UNIVERSITY, UK

**Introduction** Evidence supports a multidisciplinary family-based approach to childhood obesity treatment (Oude Luttikhuis et al., 2009). Using this evidence to implement interventions in real world community settings can be a challenge. The Medical Research Council (2008) recommends a stepped approach with a feasibility phase to explore delivery processes, plus potential impact of the intervention. This study explored changes in child BMI SDS during the feasibility phase of a UK community-based childhood obesity intervention. **Methods** The Getting Our Active Lifestyles Started (GOALS) intervention supported families with overweight children (aged 4 to 16, >91st%ile BMI for age and sex) through an 18-session programme of diet (Fun Foods), physical activity (Move It) and behaviour change (Target Time). The feasibility phase covered three fiscal years, each with developments to the intervention and its components. Seventy-seven children completed GOALS (23 during year 1, 27 during year 2 and 27 during year 3). Change in child BMI SDS pre- to post-intervention (6 months) was measured using paired samples t-tests. Associations between year of participation and the proportion of children reducing BMI SDS were explored using the Chi-squared test of independence. **Results** One outlier who completed during year 1 was removed (BMI SDS change was -0.71 compared with a range of -0.40 to 0.33 for the other cases), leaving 76 cases for analysis. When pooling the whole cohort, child BMI SDS change pre- to post- intervention was -0.06 (n=76, SD 0.16, p=0.001). Change was highest for children attending in year 3 (-0.12 (n=27, SD 0.14, p=0.000)). There was a significant association between year of participation and proportion of children reducing BMI SDS ( $\chi^2(2) = 8.575$ , p=0.014). In the first year 9/22 (41%) decreased BMI SDS, the second year 16/27 (59%) and the third year 22/27 (81%). **Discussion** We found a year-on-year improvement in outcomes during the feasibility phase of GOALS. This data highlights the merits of taking a phased approach to develop complex evidence-based interventions prior to experimental trial. #### EFFICIENCY OF SKELETAL MUSCLE ACTIVITY AFTER REHABILITATION IN PATIENTS WITH CARDIAC DISEASE

ALBERTUS-KAJEE, Y., JOHNSTON, N., SCHWELLNUS, M., DERMAN, W.

UNIVERSITY OF CAPE TOWN

**Introduction** Patients with chronic cardiovascular disease are shown to have secondary changes in the skeletal muscle, which can contribute to decreased functional capacity and exercise intolerance. Previous studies show that supervised exercise rehabilitation programs are beneficial in the recovery phase of these patients but the exact effect of exercise on skeletal muscle activity is unknown. Therefore the aim of the study was to determine the effect of a medically supervised 12-wk exercise program on the EMG activity of the lower legs during the 6 min walk test. **METHODS:** 10 Patients with ischaemic heart disease and 14 healthy matched controls consented to partake in this study. Electrodes were placed on the vastus lateralis, vastus medialis, medial and lateral gastrocnemius muscles of the right leg. Resting heart rate (HR) and blood pressures (BP) were taken. They then walked around a 70 m track for 6 min, trying to cover as much distance as possible. HR and rating of perceived exertion were measured every minute during the test. Post 1 min recovery HR and BP was recorded. After 12 wks the same protocol was repeated. The EMG was normalized to the participants walking at a normal pace over 10 m. **RESULTS:** Patients showed a 19.7 % ( $\pm 104$  m) improvement in distance covered Post rehabilitation (p=0.00), whereas the Controls did not improve. Additionally, average HR increased significantly from  $97 \pm 5$  bpm to  $112 \pm 5$  bpm during the 6 min walk test Post rehabilitation (p=0.007). The EMG activity was not significantly different between the Controls and Patients nor did EMG change during the 6 min walk test Post rehabilitation for all muscles; VM= $115 \pm 6.2\%$  vs  $124.6 \pm 12.8\%$ ; VL= $117.3 \pm 5.2\%$  vs  $113.1 \pm 14.1\%$ ; MG= $116 \pm 7.8\%$  vs  $129.7 \pm 8.7\%$ ; LG= $128.6 \pm 6.4$  vs  $131.7 \pm 8.4\%$ . **CONCLUSIONS:** The findings of this study suggest that exercise tolerance improves following rehabilitation, yet EMG remains unchanged. Improvements in functional capacity could therefore be related to factors that relate to muscle efficiency or biomechanical advantage achieved through exercise training (1). #### CAN PATELLOFEMORAL JOINT ALIGNMENT BE ASSESSED CLINICALLY?

CAMPBELL-KARN, K.1,2, KORFF, T.2, MCDERMOTT, I.2

BRUNEL UNIVERSITY (2) AND LONDON METROPOLITAN UNIVERSITY (1)

**Introduction** Knee injuries account for 23-31% of lower limb injuries (Thomee et al., 1999). A common cause of knee pain is malalignment of the PFJ. Therapeutic and operative procedures are reliant upon correct diagnoses of PFJ malalignment origins. Current diagnostic methodologies include X-ray, MRI and physical examination with conflicting outcomes (Smith et al., 2009). Of specific concern is the lack of objectivity and reliability of the McConnell clinical method for measuring alignment of the PFJ carried out by Physiotherapists and Sports Therapists internationally. The aim of this study was to objectify the McConnell technique and compare it to established radiological methods. **Method** Twenty-six right knees were scanned using an MRI scanner and the radiological slides were analysed by three accepted methods for assessing patellofemoral alignment (lateral patella displacement [LPD], congruence angle and bisect offset [BO]). The participants also had their knees assessed using an objective assessment tool to replicate the McConnell technique (Patellofemoral tracking calliper [PFTC]). The radiological and clinical assessment methods were correlated using Pearson's correlation coefficient and Spearman's rho. **Results** None of the radiological methods correlated with the PFTC. Additionally, only the BO and LPD method showed a

nearly moderate correlation ( $r=0.392$ ). Discussion The lack of correlation between most of the radiological assessment methods highlights that there are still discrepancies surrounding what constitutes dysfunctional alignment of the PFJ. Further, the PFTC results do not correlate to any of the radiological methods therefore highlighting that when the McConnell method for assessing PFJ alignment is adopted, there is a severe lack of agreement with the true articulations within the joint. This highlights important factors in the current assessment methods carried out by professions including Physiotherapy, Sports Therapy and other physical therapists as they lack reliable outcome measures. From the MRI slides it should also be noted that there were a variety of other factors observed that must be considered when diagnosing PFJ alignment that cannot be assessed purely by the external osseous architecture of the knee. It is therefore controversially recommended that if PFJ malalignment is suspected, a radiological assessment is essential to understand all possible osseous and articular defects that would otherwise go unnoticed. ## **INCIDENCE OF SPORTS INJURIES TO THE LOWER LIMBS IS HIGH IN PHYSICAL EDUCATION STUDENTS AT UNIVERSITY LEVEL**

GOOSSENS, L., WITVROUW, E., DE CLERCQ, D.

*Ghent University*

Incidence of sports injuries to the lower limbs is high in Physical Education students at university level Goossens L., Witvrouw E., De Clercq D. Ghent University, Department for Movement- and Sports Sciences, Department of Physiotherapy Sports injuries are widespread in the general population and especially in adolescents (\*). It was hypothesized that sports injury incidence in Physical Education students at university level is high. A detailed description of incidence, localization and type of injuries could provide us with the rationale for the development of sports injury prevention programs. Study design: 123 Physical Education students were followed prospectively during 14 weeks of classes. An e-mail reminded students weekly to register any injury they were affected by during the last week via an online survey. After complete rehabilitation, they filled out another online survey. At the end of the first semester, they completed a survey with reference to their time of exposure to sports during the course of the last 14 weeks. Results: A total of 43 new injuries in 34 students met the criteria to be a so called sports injury. This equals an injury incidence of 1,64 injuries for every 1000 hours of sports participation (men: 1,53; women: 1,92). There was an absolute risk of 34,9% for having a sports injury. 13 injuries (30,2%) took place during classes at university. 30 injuries (69,8%) were acute, 28 (65,1%) happened in a non-contact situation. Most affected body region was the lower limbs (69,8%). Injuries to the knee were most common (20,9%), followed by the lower leg (18,6%), shoulder (11,6%), ankle and upper leg (9,3% each). Discussion: Our results confirm earlier findings by Lysens (\$) who found an injury incidence of 1,7 in a comparable study group over a period of 4 years. Although this number is rather low in comparison with injury incidence in a general sports population of similar age (4,1)(#), the absolute risk in the present study is comparable with earlier findings (36,69%) in a general sports population with an average age of 27y (\*). This high risk is even more worrying in a population of physical education students since injury will negatively affect their studies and it might even interfere with their professional careers. There clearly is a majority of acute, non-contact injuries to the lower limbs. Preventive programs should focus primarily on these injuries to reduce incidence numbers in this population. ## **POOR BALANCE IS A RISK FACTOR FOR NONCONTACT ANKLE INJURIES IN AMATEUR MALE FOOTBALL PLAYERS**

CALLISTER, R., EVANS, K.L., SNODGRASS, S.J.

*University of Newcastle*

Introduction There is a high ankle injury rate in football but risk factors for noncontact ankle injuries in amateur players are unclear. The aim of this study was to determine whether preseason balance and active and functional dorsiflexion ROM are predictors of ankle injuries in amateur male soccer players. Methods Amateur male football players older than 15 years and playing in local club and area representative teams were recruited. Age, competition level, past injury history, and use of bracing or taping were obtained by questionnaire. Preseason screening assessed ankle dorsiflexion lunge range of motion (ROM), functional strength, balance and ROM by single-leg incline squat on a 10° incline wedge, and 2-legged balance for 20 s on an electronic wobble board. The team trainer or physiotherapist recorded injuries that resulted in a missed training session or game, and the circumstances of injury. Logistic regression was used to determine whether the independent variables ('worst' ankle dorsiflexion lunge, 'worst' single leg incline squat, competition level, age, BMI, previous history of ankle injury, ankle bracing or taping) were predictors of sustaining a noncontact ankle injury. Results Data from 65 players (median age 16.8 y, IQR 16.0-21.7, range 15.2-31.7) were analysed. Only 4 (6.2%) players incurred a noncontact ankle injury and none had a previous ankle injury or preventatively taped or braced. These variables were therefore not included in the model. All other variables (best 'on' balance, 'worst' dorsiflexion lunge, 'worst' single leg incline squat, competition level, age and BMI) were independent of one another with  $r < 0.6$ , except age and BMI ( $r = 0.64$ ), and 'worst' incline squat and 'worst' dorsiflexion lunge ( $r = 0.62$ ), but all were included in the model as these factors were considered important to analysis. The final model retained all variables as it explained a greater percentage of the variance (adjusted  $R^2$  38.7%). Despite the low injury rate, players with poor balance scores in the preseason were at significantly greater risk of incurring a noncontact ankle injury. For every 1.24 s decrease in performance on the balance test (i.e. maintaining the edge of the wobble board off the floor for fewer total seconds) the risk (odds) of being injured increased by a factor of 0.29 (95% CI, 0.12-0.87;  $P = .023$ ). Discussion In amateur male football players, poor pre-season double leg balance, as quantified by the wobble board balance test, is a risk factor for sustaining a noncontact ankle injury during the competition season. Other potential predictors for increased risk of ankle injury including the dorsiflexion lunge test, single leg incline squat test and demographic characteristics were not significantly associated with injury risk. As balance is a modifiable risk factor, improving balance may decrease ankle injury risk.

**DOES A MEDICAL COMPRESSION-SOCK INFLUENCE FATIGUE?**

REER, R.1, ARGUBI-WOLLESEN, A.2, REISCHMANN, M.2, BRAUMANN, K.M.1, MATTES, K.2

UNIVERSITY OF HAMBURG

**Introduction** The fatigue resistance is an essential factor in training and competition in most sports and demanding exercise (Ament et al., 2009). The purpose of this study was to assess if the use of medically prescribed compression-sock (CS) reduces fatigue during intense exercise and positively influences the electromyographic activity of gastrocnemius muscle. **Methods** Forty subjects (20 males and 20 females with a mean age of  $28.7 \pm 7.3$  yrs) performed 60 consecutive maximal toe-raises (plantar flexion). The frequency of plantar flexion lasted about 3s per plantar flexion and was controlled via a metronome and recorded via Optojump (Microgate, Bolzano, Italy) measuring instrument. After 10 min recovery, we conducted the second trial identical to the first trial. During the first trial of 60 plantar flexion exercises, the subject wore the CS on dominant or non-dominant leg. Only one lower leg used the CS and the sequence of first exercise trial was conducted in random order. At the end of first trial we removed the CS from the leg and in the middle of recovery phase (after 5 min) we applied the CS to the opposite leg. The electromyographic measurements were conducted via bipolar surface electrodes measuring both gastrocnemius muscle heads (long and short head). **Results** Our data revealed that electromyographic signals were significantly lower ( $p < 0.05$ ) during both trials as well as during recovery phase with CS on vs. trials without CS. **Conclusion** The reduction in electromyographic signals with CS suggests that there was greater resistance to fatigue compared to no CS. This may be due to an increased venous return that was enhanced via CS and an increased venous circulation that may have influenced the removal of local waste products formed in gastrocnemius muscle (Ali et al., 2007). **References** Ali A, Caine MP, Snow BG (2007). Graduated compression stockings: Physiological and perceptual responses during and after exercise. *J Sports Sci* 25, 413-419. Ament W, Verkerk GJ (2009). **LONGITUDINAL EXCURSION OF THE SCIATIC NERVE DURING THE SLUMP TEST IN A HAMSTRING INJURED ATHLETE.**

FOWLER, E.M.1, HERRINGTON, L.C.2, PEARSON, S.J.2

1: UNIVERSITY OF CENTRAL LANCASHIRE (UK), 2: UNIVERSITY OF SALFORD (UK)

**Introduction** Scar tissue, has been proposed to tether the sciatic nerve in the posterior thigh in athletes presenting with hamstring strains (Turl and George, 1998) subsequently reducing the mobility of the nerve, leading to secondary nerve damage. This case study highlights the effect a hamstring injury has on the longitudinal excursion of the sciatic nerve in the posterior thigh when measured during the slump test. **Method** A 20 year old male, semi-professional rugby union player sustained a posterior thigh injury 11 days prior to participating in this study. An isokinetic dynamometer was used in passive mode to conduct a modified slump test. With the hip and knee placed in 90° and 50° flexion respectively, the athlete maintained thoracic flexion and either cervical flexion or extension. The ankle joint was then passively moved by the dynamometer (10°/sec) 10° into plantar-flexion or dorsi-flexion from a neutral position. B mode ultrasonography was used to record the movement of the sciatic nerve in the posterior thigh during the slump test, in addition to confirming the presence of a muscle strain. An adaptive block matching algorithm using cross-correlation was used to dynamically track the movement of the sciatic nerve, during both isolated movements of the ankle joint. Excursion of the nerve was measured during a total of 20° dorsi-flexion and 20° plantar-flexion. **Results** Evidence of haematoma within the hamstring muscle group was discovered lying in close proximity to the sciatic nerve. During the slump test, the sciatic nerve moved more in the injured limb (0.65mm) than the uninjured one (0.19mm) when the cervical spine was flexed and the ankle dorsi-flexed; a finding also discovered when the spine was extended. When the cervical spine was maintained in flexion and the ankle moved into plantar flexion the sciatic nerve moved a greater longitudinal distance in the injured limb (0.79mm) than its uninjured counterpart (0.29mm). However, the same was not evident when the spine was extended during ankle plantar flexion; a difference which was minimal (0.07mm). **Discussion** In this case study, the presence of hamstring strain did not affect sciatic nerve longitudinal excursion in the posterior thigh during the slump test. The hypothetical tethering of the nerve during hamstring injury must be questioned, as it required significant muscle damage in Carmody and Prietto's (1995) case study to cause entrapment of the sciatic nerve following hamstring injury. **References** Carmody, C. & Prietto, C. (1995). *J Bone & Joint Surg*, 77, 1100-1102. Turl, S.E. & George, K.P. (1998). *J Ortho & Sports Phys Ther*, 27, 16-21.

**Oral presentations****OP-PM43 Muscle and Strength Training****INFLUENCE OF FREQUENCY AND DURATION OF STRENGTH TRAINING FOR EFFECTIVE MANAGEMENT OF NECK PAIN**

ANDERSEN, C.H., PEDERSEN, M.T., RASMUSSEN, A.B., MORTENSEN, O.S., ZEBIS, M.K., SJØGAARD, G., ANDERSEN, L.L.

UNIVERSITY OF SOUTHERN DENMARK

**Introduction** An increasing number of studies provide evidence for the effectiveness of strength training at the workplace in managing musculoskeletal pain. Specific strength training is a promising type of physical exercise for relieving neck and shoulder pain in office workers. However, the optimal combination of frequency and exercise duration remains unknown. This study investigates how a 20-week intervention with one hour of specific strength training for the neck- and shoulder muscles is most effectively distributed over a working-week. **Methods** We performed a cluster randomized controlled trial with 447 working-age office workers who were allocated to one of three intervention groups or a reference group. The first intervention group was offered training for one 60-minute session a week (1WS) ( $n=115$ ), the second was offered training three times 20-minute a week (3WS) ( $n=122$ ), and the third was offered training for nine 7-minute sessions a week (9WS) ( $n=113$ ). The reference group was not offered any training (REF) ( $n=97$ ). The three intervention groups performed high intensity strength training with supervision 50% of the sessions. Participants answered a questionnaire at baseline and follow-up including the Standardized Nordic questionnaire for musculoskeletal disorders. **Results** After 20 weeks all three intervention groups achieved significant reduction in neck pain compared to the REF group. From a baseline pain rating of 3.3 (SD 2.2) 1WS experienced a reduction of 1.5 (95%CI 0.9 to 2.1). From 3.2 (2.4) 3WS experienced a reduction of 1.4 (0.9 to 2.0), and from 3.1 (2.3) 9WS experienced a reduction of 1.4 (0.8 to 2.1). There was no significant difference between any of the intervention groups. **Discussion** A 20-week intervention with one hour of specific strength training is effective for reducing non-specific neck pain in office workers. Further, 1WS, 3WS, and 9WS were equally efficient. This implies a large degree of flexibility for companies and employees regarding time distribution when incorporating specific strength training into a weekly work schedule.

## THE EFFECTS OF STRENGTH AND POWER TRAINING ON PHYSICAL PERFORMANCE IN PREFRAIL COMMUNITY-DWELLING OLDER ADULTS

ZECH, A.1, DREY, M.2, FREIBERGER, E.2, BAUER, J.M.2, SIEBER, C.2, PFEIFER, K.2

1UNIVERSITY OF HAMBURG, 2UNIVERSITY OF ERLANGEN-NUREMBERG

**Introduction** The benefits of regular strength and power exercises on mobility enhancement in older adults have been well established. However, due to the lack of research, it is still unclear which resistance training modalities should be prescribed for older adults in the state of prefrailty or frailty. The aim of the present study was to compare the effects of strength training versus power training on functional performance in prefrail older adults (NCT00783159). **Methods** The trial was based on a prospective randomized controlled single-blind study design. Out of 298 community-dwelling older adults (>65 years) who volunteered for participation, 69 were diagnosed as prefrail according to the definition of Fried et al (2001). The included prefrail participants were randomly assigned into a strength training, power training or control group. The strength and power training comprised a 60min x 2days exercise program over 12 weeks. All participants were supplemented with vitamin D3 orally before entering the intervention period. The primary outcome was the Short Physical Performance Battery (SPPB). Secondary outcomes were muscle power, appendicular lean mass (aLM) measured by DXA and self-reported functional deficit (SF-LLFDI). **Results** Participants in both training groups significantly ( $p=.011$ ,  $p=.012$ ) increased their SPPB score compared to the control group, with no statistical difference among training groups ( $p=.465$ ). No between-group differences were found in changes in aLM ( $p=.660$ ), muscle power ( $p=.294$ ) and SF-LLFDI ( $p=.571$ ). Muscle power significantly increased ( $p=.017$ ) under vitamin D3 intake. **Conclusions** Strength and power training were effective in increasing the physical performance in prefrail community-dwelling older adults. Contrary to the findings in other studies with non-frail older adults, no differences were found between both training modalities. This implies that in the state of prefrailty, strength and power training may be equally effective. However, with regard to drop-out rates, strength training appears to be advantageous compared to power training. ## VOLUME, INTENSITY AND TIMING OF MUSCLE POWER POTENTIATION ARE VARIABLE

BEHM, D.G., CHAOUACHI, A., ABED, M.F., POULOS, N., DRINKWATER, E.J.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

Volume, intensity and timing of muscle power potentiation are variable Behm, D.G.1, Chaouachi, A.2, Abed, M.F.2, Poulos, N.3, Drinkwater, E.J.4 1: Newfoundland, Canada, 2: Tunis Tunisia, 3. Aspire, Qatar, 4. Bathurst Australia **Introduction** Whereas muscle potentiation is consistently demonstrated with evoked contractile properties, the potentiation of functional and physiological measures is more inconsistent. The objective of the study was to compare a variety of conditioning stimuli volumes and intensities over a 15-minute recovery period. **Methods** Twelve volleyball players were subjected to conditioning stimuli that included 10 repetitions of half squats with 70% of 1 repetition maximum (10 x 70%1RM), 5 x 70%1RM, 5 x 85%1RM, 3 x 85%1RM, 3 x 90%1RM, 1 x 90%1RM, and control. Jump height, peak and mean power, velocity and peak force were measured at baseline, 1, 3, 5, 10, and 15 minutes. Data were analyzed with a 2-way repeated measure ANOVA. Further analysis of magnitude-based inferences was conducted on the isolated peaks of each dependent variable. **Results** The ANOVA indicated significant decreases in jump height and velocity at 10 and 15 min recovery with impaired power at 5, 10 and 15 min recovery and no significant change in force. This should not be interpreted that no potentiation occurred. Each dependent variable reached a peak at a slightly different time post-intervention: peak jump height (2.83 min $\pm$ 2.32), mean power (3.62 min $\pm$ 3.01), peak power (2.57 min $\pm$ 1.88), and peak velocity (2.57 min $\pm$ 1.81). Differences in peak times were all trivial or small (i.e.  $d<0.50$ ), though all comparisons with peak force (6.57 min $\pm$ 5.33) were large ( $d>0.80$ ), which is to say the peak force reached its peak substantially later than the other dependent variables. In assessing just the peak data, magnitude-based inference revealed both the 5x70 and 3x85 protocol elicited changes that exceed 75% likelihood of exceeding the smallest worthwhile change (SWC) for peak power (89% and 80% likely respectively) and velocity (77% and 87% likely respectively). The 10x70 also had a substantial likelihood of potentiating peak velocity above the SWC (75% likely). The 5x70 protocol had an 80% likelihood of exceeding the SWC in mean power. **Discussion** Most measures peaked at one-, three-, or five-minutes though this peak was often not greater than the smallest worthwhile change. There was sufficient inconsistency in the timing of the peak that there was no statistically significant potentiation in the repeated measures ANOVA. Magnitude-based inferences revealed that while no protocol had a substantial likelihood of potentiating the peak vertical jump above the SWC, the 5x70 protocol had the most consistent substantial likelihood (i.e. >75%) of increasing the peak of most dependent variables, in particular power as well as peak velocity. We were unable to consistently predict if these peaks occurred at 1-, 3, or 5 minutes post-stimulation though declines after 5 minutes seems probable.

## EFFECT OF 12 WEEKS OF AEROBIC VERSUS RESISTANCE TRAINING ON PERCEIVED APPETITE AND CIRCULATING LEVELS OF APPETITE-RELATED HORMONES

GUELF, K.1, DONGES, C.2, DUFFIELD, R.2

1:THE UNIVERSITY OF WESTERN AUSTRALIA, 2:CHARLES STURT UNIVERSITY

**Introduction** Aerobic exercise training has been shown to improve appetite regulation by leading to more sensitive eating behaviour in response to previous food intake (Martins et al., 2007). However, the role of appetite-related hormones in mediating this response is not clear. Furthermore, it is not known whether similar benefits would be achieved with regular resistance training. Therefore, the purpose of this study was to investigate the effect of 12 weeks of aerobic versus resistance training in previously sedentary volunteers on perceived hunger and satiety, as well as a range of appetite-related hormones in both the fasted state, and in response to a standardised test meal. **Methods** Thirty three previously inactive, overweight males were allocated to either an aerobic-based exercise training group (AER;  $n = 12$ ), a resistance-based training group (RES;  $n = 13$ ) or a control group (CON;  $n = 8$ ). The AER and RES groups participated in 12 weeks of exercise training (3 sessions per week). AER participated in aerobic-based activities such as stationary cycling, treadmill walking and the cross trainer. RES completed a range of resistance-based exercises for each major muscle group of the body. Perceived hunger and satiety, together with a range of appetite-related hormones (active ghrelin, leptin, pancreatic polypeptide and peptide tyrosine tyrosine) were assessed pre and post-intervention in both the fasted state and in response to a standardised test meal. **Results** There was no change in perceived hunger in the fasted state following the intervention period in any group. There was no change in perceived hunger in response to the standardised meal in CON or AER, but perceived hunger was higher 2 hours after the meal post-training in RES ( $p < 0.05$ ). With respect to perceived satiety, there was no difference following the intervention period in CON or RES, while perceived satiety

was higher in the fasted state following AER training ( $p < 0.05$ ). These observations were associated with lower circulating leptin in both AER and RES following training, while levels of active ghrelin, pancreatic polypeptide and peptide tyrosine tyrosine were not altered as a result of training in either the fasted state or following consumption of the test meal. Discussion Regular aerobic exercise training may assist in weight management by stimulating satiety, while an equivalent period of resistance training may stimulate hunger sooner after eating. The role of appetite-related hormones in these changes is unclear and requires further investigation. References Martins C, Truby H, Morgan LM. (2007). *Br J Nutr*, 98, 834-842.

### **SIMILAR HYPERTROPHIC AND STRENGTH GAINS IN YOUNG MEN AFTER TRAINING WITH MAXIMAL SHORTENING OR LENGTHENING CONTRACTIONS MATCHED FOR TOTAL WORK**

MOORE, D.R., YOUNG, M., PHILLIPS, S.M.

*MCMMASTER UNIVERSITY*

Introduction Acute infusion and chronic resistance training studies have suggested that performance of eccentric (lengthening) contractions result in greater increases in protein synthesis and hypertrophy than performance of concentric (shortening) contractions. We aimed to determine whether training-induced increases in muscle size and strength differed between maximal lengthening (LC) and maximal shortening (SC) contractions when total external work is equivalent. Methods Nine healthy young males completed a 9-wk isokinetic (0.79 rad/s) resistance training program of the elbow flexors whereby they performed LC with one arm and an equivalent volume of total external work with the contralateral arm as SC. Results Training increased isometric peak torque for both LC ( $9.6 \pm 5.8\%$ ; mean  $\pm$  SE) and SC ( $20.7 \pm 9.8\%$ ) with no difference between conditions. There were also similar increases in isokinetic peak torque at both slow (0.79 rad/s) and fast (5.24 rad/s) velocities and both shortening and lengthening contractions for both LC ( $\sim 8$ -10%) and SC ( $\sim 9$ -20%). Despite a  $\sim 40\%$  greater work per repetition with LC, training increased work per repetition similarly for both LC ( $17.2 \pm 6.3\%$ ) and SC ( $22.1 \pm 8.9\%$ ). The pQCT-measured increase in muscle cross-sectional area with training was also similar between LC ( $6.5 \pm 0.6\%$ ) and SC ( $4.6 \pm 0.4\%$ ). Discussion Given that we equated both total external work as well as the training intensity (i.e. maximal effort contractions), we hypothesize that the exercise provided a sufficient and equivalent stimulus to induce similar levels of skeletal muscle remodelling and, hence, muscle hypertrophy. Strength gains with maximal LC and SC resistance training were also similar in magnitude. We conclude that increases in muscle size and strength with short-term unilateral resistance training are unrelated to muscle contraction type when matched for both contraction intensity (maximal) and total external work. Funding provided by NSERC.

### **MUSCLE FIBRE HYPERTROPHY AFTER TIME-OF-DAY-SPECIFIC RESISTANCE TRAINING**

SEDLIAK, M.

*FACULTY OF PHYSICAL EDUCATION AND SPORTS COMENIUS UNIVERSITY*

MUSCLE FIBRE HYPERTROPHY AFTER TIME-OF-DAY-SPECIFIC RESISTANCE TRAINING Sedliak, M.1, Cvecka, J.1, Buzgo, G.1, Hamar, D.1, Laczo, E.1, Zelko, A.1, Zeman, M.2, Sedlak, P.3, Ahtiainen, J.P.4, Hakkinen, K.4, Hulmi, J.J.4, Nilsen, T.5, Raastad, T.5 1: FTVS UK (Bratislava, Slovakia), 2: PriF UK (Bratislava, Slovakia), 3: SCHA Kramare (Bratislava, Slovakia), 4: JYU (Jyväskylä, Finland), 5: NIH (Oslo, Norway) Introduction Muscle strength is typically lower in the morning compared to the afternoon but this performance deficit is reduced by regular morning training (Souissi et al., 2002). Much less is known with regards to hypertrophy. The only study performed on humans found a tendency to smaller gains in muscle size, measured by MRI, when repeatedly training in the morning compared to the afternoon (Sedliak et al., 2009). However, no data are available at the level of muscle fibres. This study examined the effect of time-of-day-specific resistance training on muscle fibre hypertrophy. Methods Fourteen untrained men (mean  $\pm$  SD, age  $24 \pm 3$  yrs, body mass  $77.4 \pm 5.82$  kg, height  $181 \pm 8.35$  cm) were pair-matched based on pre-training MVC and BMI index. Thereafter, participants were randomly divided into 2 training groups: Morning (M,  $n=7$ ) and Afternoon (A,  $n=7$ ). M and A trained for 11 weeks 2-3 times a week between 07:30-08:30 h and 16:00-17:00 h, respectively. Both groups underwent identical hypertrophy resistance training with all sessions being supervised. Another 7 subjects served as controls (C). Muscle biopsies were taken from the right vastus lateralis one week prior to and one week after the training. Muscle specimens were analysed for muscle fibre cross-sectional areas (CSA). Results The M and A group increased significantly their CSA from  $5298 \pm 835$  to  $6168 \pm 988$   $\mu\text{m}^2$  (17.6%) and from  $5836 \pm 1001$  to  $7125 \pm 1108$   $\mu\text{m}^2$  (23.0%), respectively. The C group CSA did not significantly change ( $6138 \pm 1016$  to  $5755 \pm 1107$   $\mu\text{m}^2$ , -5.9%). The Wilcoxon Signed rank test showed significant differences between pre- to post training in M ( $p=0.016$ ) but not in A ( $p=0.128$ ) or C ( $p=0.310$ ). Discussion Resistance training increased muscle fibre CSA both in the M and A groups. However, hypertrophic training adaptation was more variable in the M group with 3 out of 7 subjects having no increase in CSA. There was only 1 subject out of 7 in the A group with CSA increase smaller than 10%. Similarly high inter-individual variability in hypertrophic adaptation, when training in the morning, has been reported before (Sedliak et al., 2009) and it could, at least partly, come from diurnal differences in hypertrophic signalling pathways in muscle cells (Sedliak et al., 2010). ### **OP-PM47 Physiology: Brain and Central Fatigue**

#### **EFFECT OF BRAIN NEUROTRANSMITTERS MODULATION ON SUPRASPINAL FATIGUE**

KLASS, M.

*UNIVERSITÉ LIBRE DE BRUXELLES*

Effect of brain neurotransmitters modulation on supraspinal fatigue <sup>1</sup>Klass M, <sup>2</sup>Roelands B, <sup>1</sup>Levenez M, <sup>2</sup>Fontenelle V, <sup>2</sup>Pattyn N, <sup>2</sup>Meeusen R, <sup>1</sup>Duchateau J <sup>1</sup>Laboratory of Applied Biology, Université Libre de Bruxelles and <sup>2</sup>Department of Human Physiology and Sports Medicine, Vrije Universiteit Brussel, Belgium. Introduction Prolonged cycling and running exercises induce a failure of the nervous system to drive the muscle at its maximal capacity ('central fatigue'; Millet and Lepers 2004). Using transcranial magnetic stimulation (TMS), it has been shown that part of central fatigue is due to an insufficient output from the motor cortex ('supraspinal fatigue'; Todd et al 2003; Klass et al 2008). Although, the underlying mechanisms are not yet understood, a few studies suggested that supraspinal fatigue could be related to a change in the brain concentration of dopamine and noradrenaline (Roelands and Meeusen 2010). To investigate the poten-

tial link between neural fatigue and changes in brain concentration of these two neurotransmitters, we combined neurophysiological methods and pharmacological manipulation of brain neurotransmitters. **Methods** Changes in performance of a prolonged cycling exercise (60 min at 55% Wmax followed by a time trial which required the subject to complete a work equal to 30 min at 75% Wmax as quickly as possible) were tested in well-trained subjects after acute oral administration of a placebo, a dopamine or a noradrenaline reuptake inhibitor under normal temperature conditions (18°C). Voluntary activation, corticospinal excitability and excitation-contraction coupling changes were also tested in the knee extensors using TMS and motor nerve electrical stimulation before and after the cycling exercise. **Results** When noradrenaline reuptake inhibitor was administered, more time was needed to complete the time trial (~9%) as compared with the placebo condition, and it was accompanied by a supraspinal fatigue (voluntary activation reduced by ~6%). In contrast, there was no significant effect of dopamine reuptake inhibitor on these two parameters. However, corticospinal excitability was unchanged and excitation-contraction coupling similarly reduced after the time trial in the three conditions. **Discussion** Our results suggest that contrary to dopamine, noradrenaline plays a key role in the development of supraspinal fatigue during prolonged cycling exercise at 18°C. Because corticospinal excitability was not modified after the time trial, noradrenaline appears to affect more specifically the supraspinal circuits "upstream" to the motor cortex. As a consequence, the output from the motor cortex becomes insufficient to drive the muscles optimally. **References** Klass M et al. *J Neurophysiol* 99:1096-1104 (2008) Millet GY and Lepers R. *Sports Med* 34:105-116 (2004) Roelands B and Meeusen R. *Sports Med* 40:229-246 (2010) Todd G et al. *J Physiol* 551:661-671(2003) Supported by a grant of the Fonds National de la Recherche Scientifique of Belgium (FC82578)

### BRAIN ACTIVATION AND PERCEIVED EXERTION DURING CYCLING: A FMRI PILOT STUDY.

FONTES, E.B.1, OKANO, A.H.2, DE GUIO, F.3, SMIRMAUL, B.P.1, SCHABORT, E.4, SPOTTISWOODE, B.S.5, NOAKES, T.D.4

1 STATE UNIVERSITY OF CAMPINAS – BRAZIL; 2 FEDERAL UNIVERSITY OF RIO GRANDE DO NORTE - BRAZIL; 3 NEUROSPIN, CEA, FRANCE; 4 UCT/MRC RESEARCH UNIT FOR EXERCISE SCIENCE AND SPORTS MEDICINE - SOUTH AFRICA

An increased interest has emerged on the magnitude of brain control during exercise. This study aimed to apply functional magnetic resonance imaging (fMRI) to assess whole cerebral function during a cycling exercise, and the relationship to the ratings of perceived exertion (RPE). An MRI compatible cycling ergometer was specifically built for this study (Jaguaré Protótipos Ltda, Brazil) in which the torque generated was transferred through a cardan system and attached to a cycling ergometer (Computrainer, Racemate, Inc., USA) positioned outside the MRI room. Seven healthy male adults were positioned in a MRI scanner (3T Magnetom Allegra, Siemens, Erlangen, Germany), with special care taken to optimize the subjects' comfort in an atypical, horizontal position and to avoid head motion. Structural magnitude prepared rapid gradient echo (MPRAGE) images with a 1x1x1mm<sup>3</sup> resolution were acquired at rest (9 min). Blood oxygen level dependent (BOLD) imaging was then performed as the subjects completed a stochastic cycling block protocol which consisted of a 10 s instruction period, followed by 6 trials of 2 min cycling interleaved with 16 s rest intervals between each trial. Whole brain fMRI data were acquired every 2 s. The workload was determined depending on the fitness level and weight of each participant, and was kept constant during all trials. Subjects were asked to maintain a constant cadence of 60 rpm. In addition, subjects reported their RPE using the Borg scale for perceived exertion (6-20) at 1 min intervals through the audio connection. For data analysis, after motion correction, contrasts were established as cycling vs rest and RPE < 15 vs RPE > 15 using the BrainVoyager software (Brain Innovation, Maastricht, Netherlands). The multi-subject analysis revealed ipsilateral Cerebellum and contralateral Post-central Gyrus activations for cycling vs rest comparison ( $p < 0.001$ ). Cingulate Gyrus and Precuneus were significantly activated in two single-subjects analysis when RPE > 15 were compared to RPE < 15. The findings of the present study propose the possibility of analyzing the activation of brain functional areas during cycling exercise, which could potentially relate to central processes of consciousness of exercise intensity.

### PREVIOUS SHORT-TERM TRAINING INFLUENCES BRAIN ACTIVITY DURING TASK OBSERVATION AT REST

KELLER, M., LEUKEL, C., LAUBER, B., TAUBE, W.

UNIVERSITY OF FRIBOURG

PREVIOUS SHORT-TERM TRAINING INFLUENCES BRAIN ACTIVITY DURING TASK OBSERVATION AT REST Keller, M.1, Leukel, C.1&2, Lauber, B. 2, Taube, W.1 1: UOSS (Fribourg, Switzerland), 2: IFSS (Freiburg, Germany) **Introduction** Previous studies have demonstrated that brain activation is modulated during task observation (Gangitano et al. 2001). Furthermore, motor experience seems to be relevant for brain activation when observing a movement (Orgs et al. 2008). In this context, Aglioti et al. 2008 showed that elite basketball players who observed free shots predicted the success earlier and more precisely than individuals with visual experience and novices. Furthermore, the athletes showed an additional selective increase in motor activation during the observation of non-scoring shots. Therefore, the activity of the motor cortex seems to be dependent whether the observed movement corresponds to the internal representation of this particular movement. In line with this, we hypothesized that the observation of a previously trained fast dynamic plantarflexion results in a different cortical excitability compared to the observation of an unknown tonic plantarflexion task due to the better internal representation of the previously trained task. **Methods** Nine subjects were instructed to train fast concentric plantarflexions in an ankle torque ergometer. After the training session, two videos showing different movements were displayed: first, a video of a fast dynamic plantarflexion and second, a video of an isometric plantarflexion. To test changes in the corticomotoneuronal transmission of monosynaptic and polysynaptic corticospinal pathways to the  $\alpha$ -motoneurons, the soleus H-reflex was conditioned by TMS to the motor cortex (M1). The first detectable facilitation of the H-reflex was determined after M1-conditioning and expressed as percentage of a control stimulus. **Results** The conditioned H-reflexes of the early facilitation, which indicate the contribution of direct corticospinal pathways, were significantly higher when subjects observed the untrained tonic contraction (121 %) compared to watching the dynamic task (108.3%;  $p < 0.04$ ). During action observation no changes in ankle torque and soleus bEMG were observable. **Discussion** The present results suggest that short-term training of a dynamic plantarflexion task leads to augmented brain activation when observing a non-trained tonic plantarflexion instead of the previously trained dynamic one. Therefore, the data suggest that cortical activity increases to a higher extent when subjects observe a movement, which does not correspond to their internal representation. This facilitation might reflect a mental effort to change the observed movement in the direction of the trained one. **References** Aglioti et al. (2008) *Nature Neuroscience*, 11(9), 1109-1116. **CEREBROVASCULAR AND CORTICOMOTOR FUNCTION DURING PROGRESSIVE PASSIVE HYPERTHERMIA**

ROSS, E.1, WILSON, L.2, FAN, J.2, LUCAS, S.2, COTTER, J.2, AINSLIE, P.3

1: UNIVERSITY OF BRIGHTON (UK); 2: UNIVERSITY OF OTAGO (NEW ZEALAND); 3: UNIVERSITY OF BRITISH COLUMBIA OKANAGAN (CANADA)

**Introduction** Hyperthermia has been shown to impair the central nervous systems ability to voluntarily activate muscle and to reduce cerebral blood flow. However, the relationship between this altered cerebrovascular function and supraspinal failure of motor drive has yet to be investigated. **Methods** We examined the integrative effects of passive heating on cerebral perfusion, oxygenation and alterations in central motor drive. Eight subjects underwent passive hyperthermia (0.5°C increments in core [rectal] temperature [T<sub>c</sub>] from normothermia [37 ± 0.3 °C] to the limit of thermal tolerance [T-LIM; 39 ± 0.4 °C]). Cerebral oxygenation, blood flow velocity in the mid cerebral artery (CBFV) and respiratory responses were measured continuously each 0.5°C increase in T<sub>c</sub>. At each level, supramaximal femoral nerve stimulation and transcranial magnetic stimulation (TMS) were performed to assess neuromuscular and cortical function, respectively. Measurements were also made during a period of induced isocapnia (ISO; by administration of 5% CO<sub>2</sub>), which was performed randomly either before or after measurements made at T-LIM. **Results:** CBFV was reduced by ~20% from +0.5°C until T-LIM; however cerebral oxygenation was initially increased until +1.0°C but returned to baseline values thereafter. Maximal voluntary contraction of the knee extensors was decreased at T-LIM (-9 ± 10.3%, P<0.05) and maximal electromyographic (EMG) activity of the Vastus Lateralis was decreased at +1.0°C until T-LIM (-26.6 ± 23.2% at T-LIM, P<0.05), whilst the amplitude of the compound muscle action potential was unchanged. Cortical voluntary activation (VA), assessed by TMS, was decreased at +1.5°C and at T-LIM by 10.8 ± 8.4% and 22 ± 23.3%, respectively (P<0.05). Corticospinal excitability (measured as the EMG response produced by TMS) was unaltered. The reductions in cortical VA were correlated with reductions in CBFV (R<sub>2</sub> = 0.659, P= 0.06), but were not related to changes in end tidal CO<sub>2</sub>. Interestingly, during ISO, MVC and cortical VA were similar to baseline values. During this period, hyperventilation was attenuated (VE decreased towards baseline). Subsequent analysis revealed a correlation between reductions in cortical VA and increases in VE (R<sub>2</sub> = 0.7, P<0.05). **Discussion** These results indicate that descending voluntary drive becomes progressively impaired as T<sub>c</sub> is increased by more than +1.0°C, and this may be brought about, in part, by altered cerebral perfusion. In addition, afferent feedback from increased respiratory work might be integrated upstream of the motor cortex and subsequently modulate cortical output.

**NO EFFECT OF INDUCED BLOOD ALKALOSIS ON CEREBRAL DEOXYGENATION DURING SUPRAMAXIMAL EXERCISE**

PERREY, S.

MONTPELLIER-1 UNIVERSITY, UFR STAPS

**NO EFFECT OF INDUCED BLOOD ALKALOSIS ON CEREBRAL DEOXYGENATION DURING SUPRAMAXIMAL EXERCISE** Perrey, S<sup>1</sup>, Thomas, C.2,3, Delfour, R.3,4, Leprêtre, P.M.5, Dorel, S.4, Bishop, D.6, Hanon, C.3 <sup>1</sup> Movement to Health (Montpellier, France), <sup>2</sup> STAPS department (Evry, France), <sup>3</sup> INSEP (Paris, France), <sup>4</sup> Motricité, Interaction, Performance (Nantes, France), <sup>5</sup> UPJA (Amiens, France), <sup>6</sup> ISEAL (Melbourne, Australia) **Introduction** Identification of the precise roles of the brain in regulating exercise performance in response to metabolic signals produced during exhaustive exercise is elusive. Cerebral oxygenation during very hard exercise drops (Rupp & Perrey, 2008) and may be linked to changes in arterial blood gases (Nielsen, 2003). The aim of this study was to investigate the impact of sodium bicarbonate ingestion on blood-gas variables and cerebral de-oxygenation response to supramaximal cycling exercise. **Methods** Eleven trained male cyclists (age 26.4±3.3 years; body mass 74.3±11.9 kg) took part in the study. On two different visits, they performed 70-s all-out test at fixed pedalling rates (calculated from torque-velocity protocol), 60 min after having ingested i) 0.3 g.kg<sup>-1</sup> body mass of sodium bicarbonate (BIC) or ii) 0.2 g.kg<sup>-1</sup> body mass of sodium chloride (placebo; PLA). The supplements were administered in a blind, randomized order. The initial work rate of Δ50 was sustained constant during the first 20-s, then subject were asked to maintain constant their pedalling rate (isokinetic model). The power Δ50 was defined as the intensity midway between the VO<sub>2</sub>peak (determined during a 20W/min incremental test) and the work requiring 100 % of maximal mechanical power extrapolated from previous torque-velocity tests. During both all-out tests, the cerebral oxygenation was monitored by one pair of continuous-wave infrared spectroscopy (Artinis, Oxymon MKIII, The Netherlands) probe positioned over the left prefrontal cortex between Fp1 and F3, according to international EEG 10-20 system. Blood samples (85 µl) were taken at the earlobe, before and 0, 5 and 8 minutes of recovery for pH, bicarbonates. **Results** The overall performance was significantly improved with BIC compared to PLA conditions (572 W vs. 557 W, P<0.01). With BIC, pH and bicarbonate concentrations values were significantly higher at rest and during the recovery period (P<0.001). For both conditions, cerebral oxygenation decreased significantly over time but no significant difference was observed according to the experimental conditions. **Discussion** While exercise performance was improved, our findings suggest that frontal lobe oxygenation is not modulated by preexercise blood alkalosis. Association between maximal exercise performance and hemodynamics responses in the brain might not be influenced by metabolic strain associated with muscle metabolism. **References** Nielsen HB. (2003). *Scand J Med Sci Sports*, 13, 339-358. Rupp, T, Perrey S. (2008). *Eur J Appl Physiol*, 102, 153-163.

**BRAIN BLOOD FLOW ADAPTATIONS TO INTENSE-INTERVAL COMPARED WITH ENDURANCE TRAINING**

LUCAS, S.J.E.1, PARR, E.B.1, STAVRIANEAS, S.2, GRAHAM, M.J.1, AINSLIE, P.N.3, COTTER, J.D.1

1: OU (DUNEDIN, NEW ZEALAND); 2: WU (OREGON, USA) AND 3: UBC (KELOWNA, CANADA)

**Introduction:** Aerobic fitness and cerebral blood flow (CBF) are positively related. Preliminary evidence indicates that resting CBF and its responsiveness to CO<sub>2</sub>, an important regulator of CBF, is improved following endurance training. Maximal-intensity interval training has recently been shown to match traditional endurance-based training in improving energy metabolism. It is not known whether such intense training may also provide comparable adaptations within the cerebrovasculature. Therefore, the purpose of this study was to examine cerebrovascular adaptations to endurance (END) versus repeat high-intensity interval training (RHIE). **Methods:** Participants were 12 healthy but untrained adults (5 males, 7 females; age 23 ± 4 y; VO<sub>2</sub>max 38 ± 5 mL/min/kg). They were ranked within sex for VO<sub>2</sub>max and assigned in randomised then alternating order to an 8-wk supervised RHIE or endurance cycle ergometer training using established protocols, before a 7-wk washout and crossover. RHIE progressed from four to six 30-s intervals 3 d/wk, whereas END progressed from 40 to 60 min at 65% HRmax 5 d/wk. Middle cerebral artery blood velocity (MCAv, Transcranial Doppler), MAP (Finometer), heart rate (HR), and the partial pressure of end-tidal carbon dioxide (PETCO<sub>2</sub>) were measured at rest before and <3 d after training. In addition, cerebrovascular responses to hypercapnia (5% CO<sub>2</sub>; 3 min) and matched hypocapnia (forced hyperventilation; 2 min) were assessed at rest before and following training. Females were tested on days 4-10 of the menstrual cycle. Inferential analysis was via spreadsheets at [www.newstats.org](http://www.newstats.org). **Results:** Whereas mean (±SD) resting MCAv tended to be higher across END (by 4 ± 14 cm/s) and be lower across RHIE (by -4 ± 6 cm/s), the differential effect of training regime was unclear (95% CI: -19 to +3, P=0.15). Across the training regimes, cere-

brovascular responses to hypercapnia (change:  $-0.03 \pm 1.10$  and  $0.06 \pm 1.20$  cm/s/mm Hg, for END and RHIE respectively) and hypocapnia (change:  $-0.35 \pm 0.96$  and  $0.00 \pm 1.30$  cm/s/mm Hg) were not measurably affected by either training regime. Conclusion: Although fundamentally different forms of training have been shown to improve the endurance phenotype of muscle and its vasculature, the present data do not clearly support an effect of (8 wk) training per se, nor an effect of training type, on cerebrovascular function. Given the link between impaired brain blood flow and many cerebrovascular diseases, further research seems warranted to clearly establish the direct relation between improved cerebrovascular function and exercise, including different exercise modes and regimes.

### OP-PM44 Muscle Activity 1

#### CHANGES IN METABOLIC AND BIOMECHANICAL RESPONSES AFTER HIGH-INTENSE RUNNING EXERCISE

OLIVEIRA, A.S.1,2, SILVA, P.B.3, TIBANA, R.A.2, BARROS, E.S.3

1-AAU (AALBORG, DENMARK), 2-UNIEURO (BRASILIA, BRAZIL), 3-UCB (BRASILIA, BRAZIL)

**Introduction** Few works have described implications of high-intense interval training work on biomechanics and physiology related to such fatiguing demand through the task. These changes are related to decrease in energy offer, muscle activation, and impairments in the excitation-contraction coupling. Consequently, some changes in kinematics, such as stride length (SL) and stride frequency (SF), may impair running technique. In this way, the main objective of the present study was to verify the effects of an interval training session on physiological (blood lactate [LAC], glucose [GLU], heart rate [HR], ventilation [VE], perceived exertion [PE]) and biomechanical parameters (SF, stance phase duration [STA], swing phase duration [SWI]). **Methods** Ten healthy men ( $25 \pm 5$  years;  $173 \pm 5.1$  cm;  $74 \pm 9$  kg;  $11.6 \pm 4.7$  % body fat) performed the following tests on different days: 1) an incremental test in a treadmill (Micromed, Centurion, Brasilia, Brazil), in order to determine maximal aerobic capacity (vMAX) and the anaerobic threshold (AT), by means of ventilatory method (Micromed, FlowMet, Brasilia, Brazil); 2) 5-min running at the AT intensity (PRE); 5 minutes after, a warm up followed by an interval training session (8 x 1min at vMAX, 1 min at a recovery intensity [50%vMAX]). Immediately after the interval training session, a new 5 minutes running at the AT intensity was performed (POST). The two sessions were separated by, at least, 48 hrs between them. During the last 20-seconds of the PRE and POST exercises, 60Hz images were registered. Stride frequency (SF) stance phase (STA) and swing phase (SWI) were accessed by free-software Motion Analysis Tools®, mean values of five strides were considered for analysis. Three-min after the PRE and POST conditions, LAC [LAC] and [GLU] were measured. Other parameters (HR, VE, PE, SF, STA, SWI) were recorded at the last 20-seconds for PRE and POST. The comparisons between PRE and POST were made using a two tailed Students Paired t test set at  $p < 0.05$ . **Results** Significant changes ( $p < 0.05$ ) were found between PRE and POST for [LAC] (PRE =  $2.8 \pm 0.9$  mmol/L; POST =  $8.49 \pm 3.3$  mmol/L) and [GLU] (PRE =  $95 \pm 1$  mg/dL; POST =  $121 \pm 2$  mg/dL). Significant increases in HR (PRE vs POST):  $163 \pm 1$  vs  $182.2 \pm 9$  bpm, VE ( $73 \pm 11$  vs  $89 \pm 14$  /min), RPE ( $11 \pm 2$  vs  $14 \pm 3$ ) and SF ( $82 \pm 3$  vs  $85 \pm 4$  /min) were also found between PRE and POST ( $p < 0.05$ ). However, STA and SWI presented no changes when PRE and POST were compared ( $P > 0.05$ ). **Conclusion** Running interval training exercise performed at maximal intensity presented effects in physiological parameters, as the [LAC] [GLU], HR and VE, as consequence of the increased intensity used (compared to the AT intensity), which leads to higher muscle fatigue. At the same time, the increased RPE supports these changes, since at the same intensity the effort seems to be heavier. In addition, kinematic behaviors, such as for SF, were altered concomitantly, which could be related to difficulties to maintain same performance, through muscle activation and range of motion during running.

#### CONCURRENT FATIGUE AND POTENTIATION IN ENDURANCE ATHLETES

BOULLOSA, D.A., TUIMIL, J.L., ALEGRE, L.M., IGLESIAS, E., PRESTES, J.

UNIVERSIDADE CATÓLICA DE BRASÍLIA

**Purpose:** countermovement jump (CMJ) and maximum running speed over a distance of 20 m were evaluated for examination of the concurrent fatigue and postactivation potentiation (PAP) in endurance athletes after an incremental field running test. **Methods:** twenty-two endurance athletes performed two attempts of CMJ on a force plate and maximum running speed test prior to and following the Université de Montréal Track Test (UMTT). **Results:** the results showed an improvement in CMJ height (3.6%) after UMTT that correlated with the increment in peak power (3.4%); with a concurrent peak force loss (-10.8%) that correlated with peak power enhancement. The athletes maintained their 20 m sprint performance after exhaustion. Cluster analysis reinforced the association between CMJ and peak power increments in responders with a reported correlation between peak power and sprint performance increments ( $r = 0.623$ ;  $p = 0.041$ ); non-responders showed an impairment of peak force, vertical stiffness, and a higher vertical displacement of the center of mass during the countermovement that correlated with lactate concentration ( $r = -0.717$ ;  $p = 0.02$ ). **Conclusions:** it may be suggested that PAP could counteract the peak force loss after exhaustion, allowing the enhancement of CMJ performance and the maintenance of sprint ability in endurance athletes after the UMTT. From these results, the evaluation of CMJ after incremental running tests for the assessment of muscular adaptations in endurance athletes may be recommended.

#### ESTIMATION OF CRITICAL TORQUE DURING INTERMITTENT ISOMETRIC KNEE EXTENSION IN MEN WITH DIVERSE AEROBIC STATUS.

DE RUITER, C.1, MAAS, E.1, WESSELING, M.1, DE HAAN, A.1,2

1 RESEARCH INSTITUTE MOVE, VU UNIVERSITY AMSTERDAM, THE NETHERLANDS 2 INSTITUTE FOR BIOMEDICAL RESEARCH INTO HUMAN MOVEMENT AND HEALTH, MANCHESTER METROPOLITAN UNIVERSITY, MANCHESTER, UNITED KINGDOM

For every exercise there is a critical intensity above which output can not be maintained for a long time (30-60 min) without progressive fatigue. Classically, establishing this critical exercise intensity is time consuming and difficult to perform as it involves a series of exhausting exercise tests at different intensities and days. For repetitive isometric knee extensor contractions, Burnley (2009) published a short alternative test to establish critical torque (CT): 60 maximal contractions (3 s with 2 sec rest in between). In the last 6 contractions torque

was found to be similar to the classically determined CT. He studied 8 healthy (probably untrained) subjects and found little variation in CT (25-35% MVC). In the present study we investigated whether this short test could be used to reveal differences in aerobic training status in 16 male subjects with VO<sub>2</sub>-max ranging from 44.7 to 69.6 mL/kg/min. We expected to find a higher CT than Burnley (2009) and we also expected CT to be positively related to aerobic training status (VO<sub>2</sub>-max). However, we were concerned about the large central fatigue component of the torque decline found by Burnley. Therefore we also included an alternative test on a separate occasion. This test involved six series of 60 sub maximal contractions (3s on, 2 s rest) in total at intensities around the expected CT (40% MVC). Changes in electrically stimulated torque, EMG and tissue oxygenation (near-infrared spectroscopy) of the knee extensor muscles were used as indicators for fatigue during each series and torque was changed (steps of 5 % MVC) to the level where signs of fatigue were absent (CT<sub>submax</sub>). CT<sub>all-out</sub> was 52%  $\pm$  10% MVC (compared to 28.7 $\pm$ 4.3% in Burnley), which was significantly ( $P < 0.05$ ) higher than CT<sub>submax</sub> (39%  $\pm$  8.6% MVC). During the sub maximal test 12 out of 16 subjects, including the seven with the highest CT<sub>all-out</sub>, showed indications of peripheral fatigue at torques comparable to CT<sub>all-out</sub>. Therefore, although CT<sub>all-out</sub> was significantly related to CT<sub>submax</sub> ( $r^2 = 0.93$ ), it seemed to be an overestimation of CT, particularly for subjects with high CT. Moreover, only CT<sub>submax</sub> was significantly related ( $r^2 = 0.43$ ) to VO<sub>2</sub>-max and CT<sub>all-out</sub> was not ( $r^2 = 0.17$ ). We conclude that our sub maximal test, which relates to the aerobic training status and is hardly affected by central fatigue, is more suitable to establish CT than a maximal test. M Burnley (2009) Estimation of critical torque using intermittent isometric maximal voluntary contractions of the quadriceps in humans. *J Appl Physiol* 106:975-983.

## ASSOCIATION BETWEEN MECHANICAL EFFICIENCY AND MUSCLE METABOLISM DURING LEG EXERCISE

LAAKSONEN, M.S., KALLIOKOSKI, K.K., KEMPPAINEN, J., TAKALA, T., KNUUTI, J., NUUTILA, P., KYRÖLÄINEN, H.  
MID SWEDEN UNIVERSITY

Association between mechanical efficiency and muscle metabolism during leg exercise Laaksonen, M.S. (1), Kalliokoski, K.K. (2), Kempainen, J. (2), Takala, T. (3), Knuuti, J. (2), Nuutila, P. (2), Kyröläinen, H. (4) 1: Swedish Winter Sports Research Centre, Mid Sweden University, Sweden, 2: Turku PET Centre, University of Turku, Finland, 3: Oulu Deaconess Institute, University of Oulu, Finland, 4: Dept. of Biology of Physical Activity, University of Jyväskylä, Finland Introduction Mechanical efficiency (ME) may have a crucial role in endurance performance. As ME is affected by several metabolic factors in working muscle it is of interest to clarify how muscle blood flow as well as oxygen, fatty acid and glucose uptakes are associated to ME and further on endurance performance. Methods 17 healthy male subjects with varying training backgrounds were recruited and divided into efficient (EF,  $n=8$ ) (ME $>17\%$ ; age  $24 \pm 1$  yrs, BMI  $23 \pm 1$  kg m $^{-2}$ , VO<sub>2peak</sub>  $53 \pm 3$  mL kg $^{-1}$  min $^{-1}$ ; ME  $20.5 \pm 1.3$  %) and non-efficient (NE,  $n=9$ ) (ME $<17\%$ ; age  $23 \pm 1$  yrs, BMI  $23 \pm 1$  kg m $^{-2}$ , VO<sub>2peak</sub>  $52 \pm 3$  mL kg $^{-1}$  min $^{-1}$ ; ME  $15.4 \pm 0.3$  %) groups. ME was determined during bicycle exercise at 45% of VO<sub>2peak</sub> using indirect calorimetry. During 70-min dynamic knee-extension exercise muscle blood flow (mBF) as well as muscle oxygen (mVO<sub>2</sub>), glucose (mGU) and free fatty acid (mFAU) uptakes in quadriceps femoris muscle were measured using positron emission tomography and arterio-venous blood sampling. Results During knee-extension exercise the delivery of oxygen, glucose and free-fatty acids was similar between the groups (all NS). Respiratory quotient in working muscle averaged  $0.82 \pm 0.16$  and  $0.82 \pm 0.10$  for EF and NE, respectively (NS). The work-load normalized mBF (EF  $35 \pm 14$  vs NE  $34 \pm 11$  mL 100g $^{-1}$  min $^{-1}$ ), mVO<sub>2</sub> (EF  $4.1 \pm 1.2$  vs.  $3.9 \pm 1.2$  mL 100g $^{-1}$  min $^{-1}$ ) and mGU (EF  $31 \pm 18$  vs.  $26 \pm 23$   $\mu$ mol 100g $^{-1}$  min $^{-1}$ ) were all similar between the groups (all NS). However, mFAU was higher in EF group (EF  $3.1 \pm 1.7$  vs. NE  $1.7 \pm 0.6$   $\mu$ mol 100g $^{-1}$  min $^{-1}$ ,  $p < 0.05$ ) and in addition, it was also linearly related to ME ( $r = 0.56$ ,  $p < 0.05$ ) in entire study group. None of the measured variables reported here were correlated to peak power output or VO<sub>2peak</sub>. Discussion According to the present results free-fatty acid uptake is associated to mechanical efficiency in working skeletal muscle. This finding is in line with earlier studies where increased muscle fatty acid uptake has been observed after endurance training (e.g. Kiens et al. 1993). Increased fatty acid uptake in more efficient subjects is likely explained by decreased glycolytic/oxidative capacity ratio (Goldsmith et al. 2010) or increased mitochondrial substrate oxidation with unaltered ATP production (Befroy et al. 2008). References Befroy et al. (2008) PNAS 105(43): 16701-6 Goldsmith et al. (2010) Am J Physiol Regul Integr Comp Physiol 298: R79-R88 Kiens et al. (1993) J Physiol 469: 459-478

## ASSOCIATION BETWEEN FEEDFORWARD AND REFLEX MUSCLE ACTIVITY WITH REACTIVE LEG STRENGTH AND STIFFNESS IN BOYS

OLIVER, J.L., LLOYD, R.S., HUGHES, M.G., WILLIAMS, C.A.  
UNIVERSITY OF WALES INSTITUTE, CARDIFF

INTRODUCTION Previous research has demonstrated a limited amount of common variance between squat and countermovement jump performance with a reactive strength index (RSI) and leg stiffness in children (Lloyd et al., in press). It is speculated that different neural control mechanisms account for this lack of association. Therefore, the aim of the present study was to determine how much of the variance in RSI and leg stiffness could be explained by neural control mechanisms. METHODS Thirty-two boys aged 9-15 years old participated in the study. RSI (jump height/contact time) was calculated during five maximal rebound jumps. Leg stiffness was calculated from contact and flight time during rapid hopping at 2.5 Hz. EMG recordings were collected from the vastus lateralis (VL) and soleus (SOL) of the dominant leg. EMG data was smoothed using a linear envelope employing Butterworth fourth order zero lag filters (20 Hz high pass, 50 Hz low pass). EMG activity was normalized by integrating the processed EMG data over total ground contact time and calculating the contribution during specific phases; feedforward background activity (0-30 ms, BGA) and short (31-60 ms, M1), medium (61-90 ms, M2) and long (91-120 ms, M3) latency reflexes. RESULTS Body mass explained 77.6% of the variance in absolute leg stiffness, with the addition of VL BGA and M2 activity improving this to 87.3%. BGA was the sole predictor of leg stiffness expressed relative to body size, explaining 41.5% of the variance. Up to 56.8% of the variance in the RSI could be explained by an equation including all VL activity (0-120 ms), body mass, VL M3 and VL BGA. The SOL and VL could generally be used interchangeably within the predictive equations without any loss of predictive strength. DISCUSSION Absolute leg stiffness is primarily determined by body mass, influencing peak ground reaction force, with some contribution from feedforward and reflex muscle activity. However, BGA was the sole predictor of relative leg stiffness, explaining 41.5% of the variance. While RSI was related to BGA, performance was also associated with reflex muscle activity. Rapid hopping requires a high rate of force development and this appears to be associated with BGA in boys. Reactive strength during maximal rebounding involves longer contraction times, greater joint displacements and is associated with both feedforward and reflex activity in boys. While feedforward and reflex muscle activity have been shown to account for a reasonable amount of the variance in RSI and relative leg stiffness in boys other unaccounted factors still need to be identified. ## ACUTE NEUROMUSCULAR RESPONSES ASSOCIATED WITH STRENGTH- AND HYPERTROPHY-TYPE WORKOUTS

NICHOLSON, G., BISSAS, A., POLLITT, L., ISPOGLOU, T.

LEEDS METROPOLITAN UNIVERSITY

**Introduction** Hypertrophy-type (HYP) resistance exercise (RE) is typically designed to elicit changes in fibre size whereas strength-type (STR) RE is usually employed to improve strength via mainly neural adaptations. Although previous studies have investigated the acute responses to different RE workouts (McCaulley et al. 2009), the mechanisms responsible for different long-term adaptations are still widely debated. Thus, this study examined the acute neuromuscular responses to STR and HYP workouts which utilised the back squat exercise. **Methods** Seven trained males ( $23.6 \pm 2.7$  years) completed a STR workout (4x6 repetitions at 85%1RM, 5 min rest intervals), a HYP workout (4x10 repetitions at 70%1RM, 90s rest intervals) and a control condition (CON) in a randomised cross-over design separated by at least 48 hours. Subjects performed 3x4s maximal isometric back squats (100o knee flexion), by using a modified squat rack attached to a Kistler force platform (1000 Hz), immediately pre- and post- each workout. Several kinetic performance variables were determined and investigated statistically by using a two-factor within subjects ANOVA. Results Repeated contrast tests showed a greater reduction in Peak Isometric Force following the HYP (-18.06%) than CON condition (-1.21%) ( $p=0.017$ ). Also the HYP workout resulted in greater reductions in the rate of force development (RFD) during the initial 0.05s (-21%,  $p=0.023$ ) and 0.1s (-29%,  $p=0.047$ ) of the force-time curve as well as greater increases in the time required to produce 500N (92%,  $p=0.018$ ) when compared with the CON condition. The STR workout was characterised by a greater reduction in RFD during the initial 0.2s of the force-time curve (-0.19%,  $p=0.034$ ) as well as greater increases in the time required to produce 250N (28%,  $p=0.025$ ) when compared to the CON condition. No significant differences were observed between the STR and HYP conditions for any variable. **Discussion** Both workouts resulted in acute neuromuscular fatigue possibly via different pathways. The acute reductions in RFD following the STR workout may have resulted from central fatigue whereas the reductions in RFD and PF following the HYP workout may be indicative of central and peripheral fatigue (Hakkinen et al. 1994; McCaulley et al. 2009). Although STR and HYP workouts are typically prescribed in order to emphasise different long-term adaptations, marked differences in the acute neuromuscular responses were not observed. Such findings may question the future prescription of similar workouts when aiming to elicit distinctly different neuromuscular stimuli. **References** Hakkinen, K. ### OP-SH09 Sport Management

#### A PROPOSED ADAPTATION OF THE EFQM TO PHYSICAL ACTIVITY PROGRAMMES FOR THE ELDERLY – DEVELOPMENT OF A SELF-ASSESSMENT TOOL USING A MODIFIED DELPHI PROCESS

MARQUES, A.I.1, SANTOS, L.2, SOARES, P., SANTOS, R.I.3, MOTA, J.I, CARVALHO, J.I

1. RESEARCH CENTRE IN PHYSICAL ACTIVITY, HEALTH AND LEISURE - FACULTY OF SPORTS / U.PORTO; 2. DEPARTMENT OF INFORMATION SYSTEMS - U. MINHO; 3. MAIA INSTITUTE OF HIGHER EDUCATION, PORTUGAL

**Background:** There has been a growing concern in designing physical activity (PA) programmes for elderly people, because evidence suggests that such health promotion interventions may reduce the deleterious effects of the ageing process. The Physical Activity and Health Branch of the Centers for Disease Control and Prevention holds that complete programme evaluations are a necessary prerequisite to continuous quality improvements. The development and efficient use of quality assessment tools requires considerable resources - human, temporal and financial. Being able to refine, adapt and create tools that are suited to the realities and contexts of PA programmes for the elderly, to support its continuous improvement is, therefore, crucial. Thus, the aim of this study was to develop a self-assessment tool for PA programmes for the elderly. **Methods:** A 3-round Delphi process was conducted with 43 national experts in PA for the elderly, management and delivery of PA programmes for the elderly, sports management, quality management and gerontology, asking experts to identify the propositions that they considered relevant for inclusion in the self-assessment tool. All rounds were conducted via the Internet. Experts reviewed a list of proposed statements, based on the criteria and sub-criteria from the European Foundation for Quality Management Excellence Model (EFQM) and PA guidelines for older adults. They rated each proposition from 1 to 8 (disagree to agree) and modified and added propositions. After each round, we calculated the percentage of agreement on each statement and provided these data in the next round. Propositions receiving either bottom or scores of greater than 70% were considered to have achieved consensus to drop or retain, respectively. **Results:** In round 1, of the 196 originally-proposed statements (best practice principles), the experts modified 41, added 1 and achieved consensus on 93. In round 2, they were presented with 104 propositions, of which they modified 39 and achieved consensus on 53. In the last round, of 51 proposed statements, the experts achieved consensus on 19. After 3 rounds of rating, they had not achieved consensus on 32 propositions. The resulting tool consisted of 165 statements that assess nine management areas involved in the development of PA programmes for the elderly: five criteria assess Enablers (Leadership, Policy & strategy, People, Partnership & resources and Processes), and four criteria assess Results (Customer results, People results, Society results and Key performance results). **Conclusion:** Based on experts' opinions, a self-assessment tool was found in order to assess quality of PA programmes for the elderly. Information obtained with evaluations would be useful to organizations seeking to improve their services, customer satisfaction and, consequently, adherence to PA programmes.

#### THE CHINESE ELITE SPORT DEVELOPMENT: CENTRALISED PLANNING MEETS THE MARKET

TAN, T.C.

NATIONAL TAIWAN NORMAL UNIVERSITY

**Introduction** The paper locates the PRC's current policy toward global sport and the Olympic Movement in its historical context. In order to analyse the behaviour of the Chinese state we adopt Houlihan's (1994: 370) concepts of 'reach' and 'response' which focus attention on global actors and pressures external to the country and state and the capacity of states to determine their response. The article examines the extent to which, and the manner in which, the Chinese government managed its relationship with the Olympic following its re-engagement with international elite sport competition in the mid 1970s. **Methods** Data were collected from a number of sources including official government documents, news media, a series of 40 interviews from China's sport administrative system including General Administration of Sport (GAS), Chinese Olympic Committee (COC) and six national sport associations and 16 Chinese sports academics from

inside and outside China between 2005 and 2010. Results As regards the "reach" of global culture in the Chinese context, it has been a case of China reaching out to bring in global influences rather than global influences pushing their way in. This is seen especially in the slogan - "Sending human capital out and bringing foreign resources in" by which athletes, coaches, managers and scientists were dispatched to learn new knowledge and skill from the outside world, and foreign experts, sponsors and companies were welcomed into China to bring new resources to promote the Chinese elite system. Discussion To a large extent, China has been enthusiastic about absorbing those international influences and, rather than seeing them as a threat, they have seen them as a resource. According to GAS (2003: 5) "after winning the bid to host the 2008 Beijing Olympics in 2001, we will promote China's economic and social development in the new era, open China's doors more widely and deeply, and raise China's status on the international scene. All of these will have a huge impact on China's future." This assessment echoed Deng's 'open door' policy which implied not only an economic involvement with the capitalist world - through trade, investment and technology transfer - but also an opening up to carefully selected ideas and cultural forms originating in the west. The foregoing discussion indicates that the government of the PRC has been effective, so far at least, in controlling the extent and impact of greater commercialisation at the Olympic elite level. However, China's involvement in global commercialised Olympic sport has been relatively brief and it remains to be seen whether the government will be able to maintain its control over the extent of engagement over the longer term. ## **MEASURING AND MODELING ORGANIZATIONAL SOCIAL CAPITAL IN SPORT ORGANIZATION ISLAMIC REPUBLIC OF IRAN**

KHODADAD KASHI, S., GOODARZI, M.

*KHAJENASIR UNIVERSITY, UNIVERSITY OF TEHRAN*

Introduction Social capital which is embedded in social interactions and resources of plays is currently a very important research era in sports and sports organizations. Therefore, Measuring social capital and designing model of social capital in Sport organization of Islamic Republic of Iran are makeup of the ultimate goals of this study. Method We used descriptive research method in order to describe the current situation of social capital in the population conducting a survey of staff. The instrument was constructed and validated in the study in three phases: pilot, semifinal, and the final phase which was aimed to validating. For modeling social capital the mathematical model of structural equation modeling was used by Lisrel(8.50) software. Result Using a reliable and valid research tool which was checked in this study, Social capital in the Sport Organization was measured. Level of social capital was significantly lower than moderate level (from 97.83 in 2010). Scores related to the dimensions of social capital in the Sport organization except for 'organizational citizenship behavior' were lower than average. For modeling social capital in Sport Organization three models based on three perspectives which were community-oriented, institutional, and networks was tested using structural equation modeling. Finally, due to the Lisrel good fit parameter outcome institutional model parameters were better fit than network model, and community-oriented in Sport Organization (Chi Square=1.79 P-value=0.18, RMSEA=0.052). Discussion Considering there was no relationship between each of the dimensions of social capital and its importance, there was any inference that the Sport Organization currently benefits their social capital to become continuous (Krishna, 2001). Due to the institutional model of social capital concluded that the main source of social capital in Sport organization of Iran is institutional trust which means that that continued good corporate function such as, reliability, competence and accountability towards their community, causes internal consistency (North 1998). ## **EQUESTRIANISM AND GENDER DURING THE 20TH CENTURY. A COMPERATIVE STUDY UK AND SWEDEN**

HEDENBORG, S.

*MALMÖ UNIVERSITY*

The aim of this chapter is to analyze changing gender and social class patterns in equestrian sports in Sweden and Great Britain during the 20th century. 100 years ago equestrian sports were strongly connected to men and masculinity. Men worked together with and used horses in agriculture, forestry, in the transport sector and in the army. A real man was a "horse man". It is also important to recognize that very few people used the horse for riding as horses were mainly used as draught animals. In Sweden horse riding was connected to the army and to the upper class. In today's Sweden equestrianism is strongly connected to women, girls and femininity on all levels (Hedenborg 2007, 2008, 2009). Furthermore the contemporary equestrian sector is of great economic importance (as important as the dairy sector, or cattle sector) to Swedish economy and horse riding is popular and not only restricted to members of the upper class. Less is known about the development in Great Britain, despite the fact that Great Britain has since long been seen as a very important place for the development of equestrian sports. In order to understand the process of changing gender codes and the growth of the sector in Sweden and to explore and understand the development in Great Britain in the 20th century, this chapter examines articles on the equestrian competitions of the Olympic games in 1912, 1924, 1932, 1936, 1948, 1952, 1956, 1964 and 1972 in Swedish and British magazines (Hästen, Idrottsbladet, Horse & Hound).

## **MANAGEMENT CONTROL IN SWEDISH SPORT**

ERFORS, A.

*KRISTIANSTAD UNIVERSITY*

Swedish sport involves nearly 3 million out of a total of 9 million inhabitants. The Swedish Sports Confederation (RF), which is the highest decision-making organization, has 70 different sport associations which in turn together contain about 20 000 clubs, all with different roles and situations. Sport in Sweden is essentially based on a non-profit idea with voluntary leadership. The main financing comes from state and municipal grants, membership fees, competition and training fees, lottery incomes and incomes from entrance fees. In some types of sports, especially where the elite sport performers have high financial compensation (as soccer and icehockey), sponsorship is

getting a more and more important source. However, the number of professional athletes is just a small part of the total number of Swedish athletes. Instead, we can talk about sport in Sweden as a broad people movement with collaboration between elite activities and sport for all. The Swedish Sports Confederation has in the policy declaration "Sport will" pointed out a range of statements, which together creates a form of norms and values for all associations and clubs under the umbrella of RF. They present a vision and talk about the idea of sport as an activity to enjoy ourselves, to feel good and to get fitter. They also point out that sport consists of training and fun, competition and display. Moreover, sport promotes physical, psychological, social and cultural development. In "Sports will" four important core values are also presented: a) enjoyment and community, b) democracy and participation, c) everyone has the right to take part, and d) fair play. As we can note, sport in Sweden is a big and important movement including a great number of socially related goals. The extent to which these norms and values emerge in a clear way in the associations' goals and activity plans has been studied (Söderholm, 2007). In the 58 studied associations, Söderholm could identify 396 different goals, which were grouped into six categories. The most common goals were related to organizational challenges. Not until in fifth place came socially oriented goals. The foregoing leads us to the following research questions: 1. To what extent do the sport associations act in order to follow the sport movement's overall norms and values? 2. What type of management control tools are used to ensure high achievement? The results reported in this presentation are based on document studies and interviews in five strategically selected sport associations. One interesting result is that the sport movement uses management control tools, originally developed and used in the Business Community. According to a theoretical framework built on the so-called New Institutional Theory we can see this as an example of how different types of ideas flow between different organizational fields or sectors.

## THE SPECIALIZATION PROCESS IN PORTUGUESE AND BRAZILIAN SOCCER CLUBS: A HOLISTIC APPROACH

CAVICHIOILI, F.

UNIVERSIDADE FEDERAL DO PARANÁ - BRAZIL

THE SPECIALIZATION PROCESS IN PORTUGUESE AND BRAZILIAN SOCCER CLUBS: A HOLISTIC APPROACH Cavichioli, F.1, Gonçalves, C.E.2, Maoski, D.1, Cheluchinhak, A.1, Sperotto, R.1, Joay, A.1 1: UFPR/ CAPES (Curitiba, Brasil), 2: FCDEF (Coimbra, Portugal) Introduction The specialization process of the young soccer players is studied using the holistic model, identifying and analyzing the opinions and interventions of the managers and coaches of youth teams of two soccer clubs, from Portugal and Brasil. The aim of the study is to research the path to specialization as a process of teaching and learning, seeking to improve and discipline both the body and the athletes' ways of thinking and acting. Methods Two managers and eight coaches from youth teams (from 10-18 years) of two top clubs, one from Portugal, the other from Brazil, were interviewed. Ten semi-structured interviews were performed, to identify professional structure, recruiting, education, security and citizenship. Content analysis was used to examine the interviews. A field diary was also kept, to identify the ecological dimension of education and the power relations inside the club and with other clubs, and training methods: 32 observations of games, practices and social activities were performed. Results Results show a real concern to educate the athletes under a multi-dimensional perspective, targeting specific skills, academic achievement and citizenship. Players are instructed to more active in tactical interpretation of the game and in life outside sport. To train athletes to reach the professional level is seen as a process essentially pedagogic. Discussion The opinions of managers and coaches show their intention to optimize the players natural abilities, but also to follow a planned process to foster the incorporation of a soccer habitus. While the portuguese club sees the sell of the players to other professional clubs as a possible consequence of a long-term process, for the brasilian club, to sell the players is the main goal. There is a convergence relating the control, discipline and rationalization aiming to create a professional ethos since early ages. References BOURDIEU, P. O poder simbólico. 2. ed. ### OP-SH07 Athlete and Coach Psychology

#### COACHES' REFLECTIONS ON INCIDENTS OF ATHLETE EMOTIONAL ABUSE

STIRLING, A.

UNIVERSITY OF TORONTO

COACHES' REFLECTIONS ON INCIDENTS OF ATHLETE EMOTIONAL ABUSE Stirling, A. E. Faculty of Physical Education & Health, University of Toronto, Canada Introduction Concern for athlete well-being has long existed, however research specifically on relational athlete maltreatment has emerged only recently. The majority of athlete maltreatment research has explored athletes' perspectives on experiences of abuse in sport (Stirling, 2009). A few studies have been conducted to-date examining coaches' perspectives on sexually abusive coach-athlete relations (Bringer, Brackenridge, & Johnston, 2002; 2006; Toftegaard-Neilson, 2001), but no research has yet examined coaches' perspectives on the perpetration of emotionally abusive coaching behaviours. The purpose of this study therefore, was to explore coaches' reflections on incidents of emotional abuse in sport. Methodology and Methods The methodological approach used for the study was a constructivist and symbolic interactionist approach to grounded theory. Participants included nine elite coaches, seven male and two female. Coaches ranged in age from 38-68 years of age, with 18-47 years of coaching experience. In-depth semi-structured interviews were conducted with each participant, and data were coded using open, axial, and selective coding techniques. Results The following themes emerged from the raw data; coaches' care for the athletes, the nature of the coach-athlete relationship, previous incidents of harmful coaching behaviour, and perceived reasons for use of these harmful coaching practices. Discussion Coaches' reflections about the reasons for choosing to use emotionally abusive behaviours in the coach-athlete relationship are interpreted to suggest two distinct origins for the perpetration of this behaviour. Applied and theoretical recommendations are discussed. References Bringer, J. D., Brackenridge, C. H., & Johnston, L. H. (2002). **EXPLORING THE RELATIONSHIP BETWEEN PASSION AND ATHLETIC PERFORMANCE**

PETERS, D.

AUSTRALIAN CATHOLIC UNIVERSITY

Exploring the Relationship Between Passion and Athletic Performance Darren Peters Australian Catholic University Introduction Passion is the highest or strongest form of emotion (Frijda, 2007). Passion towards an activity can be defined as a strong inclination toward an activity which is liked, important, consumes a significant amount of personal time and energy, and becomes internalised into a person's identity (Vallerand et al., 2003). There are two forms of passion, obsessive and harmonious. Passion has been indirectly and positively associated with performance through a mastery orientation, and indirectly and negatively associated with performance through an avoidance orientation (Vallerand et al., 2008). The aim of this study was to determine if athletes with high and obsessive passion are less successful in sport. Methods Two separate survey research studies were conducted. Participants were a sample of elite (n=56) and non-elite (n=105) Australian athletes. The Sport Environment and Passion Scale were used. Passion Scale items derived from the Gambling Passion Scales (Rousseau et al., 2002). Exploratory Factor Analysis (EFA) and Confirmatory Factor Analysis (CFA) were conducted to validate scale items. Descriptive statistics were used to indicate the incidence of Passion by type. Structural Equation Modelling, using total data-set, was used to determine relationships between passion and performance. Results Overall, the EFA and CFA analyses indicated internal consistency and support for the two factor Passion structure proposed by Vallerand et al (2003). Some harmonious passion items required attention. Passion was found to have a direct and positive influence on practice, and direct and negative influence on performance. Discussion Motivation is required for an initial and prolonged involvement in sport. Being over motivated can lead to poor performance (Davis, 2009). This small study confirms this general direction, albeit by inference rather than experimental control. It is the first to declare a direct and negative relationship exists between a person's passion and their performance. This type of finding supports a general view that emotions are an important factor in human performance. References Davis, H. **ATHLETE MALTREATMENT: WHEN DOES THE PRACTICE OF PHYSICAL CONDITIONING BECOME A FORM OF ABUSE?**

KERR, G., STIRLING, A.

UNIVERSITY OF TORONTO

Athlete Maltreatment: When Does the Practice of Physical Conditioning Become a Form of Abuse? The purpose of this presentation is to raise questions about the use of excessive physical activity and physical punishment within the framework of athlete maltreatment. Needless to say, pushing one's body physically is not only an inherent part of sport training but is a requirement for skill acquisition and performance enhancement. Moreover, it is the coach's role, in part, to encourage athletes to push themselves out of their 'comfort zone' physically and psychologically in order to become more fit or skilled. Apart from legitimate uses of physical conditioning for athlete development however, there are also anecdotal examples of the use of physical conditioning for the purposes of punishment. Directing a team to engage in exhausting conditioning as punishment for poor performance or undesirable behaviors such as arriving late for practice or missing curfew are some examples. In such cases, physical conditioning is used for the sole purpose of punishment and is unrelated to the enhancement of an athlete's physical condition. It is the supposition of this presentation that under certain conditions the use of physical conditioning represents a form of physical and perhaps emotional abuse. Interestingly, despite a substantial body of literature on sexual abuse within the coach-athlete relationship and emerging literature on emotional abuse, no empirical research exists on physical abuse and neglect. This is perplexing given sport's emphasis on the body and physicality, its focus on disciplining of the body, and the commonplace use of physical conditioning practices. In this presentation, we will explore the conditions under which the coach's implementation of physical conditioning represents a form of maltreatment versus a legitimate method for performance enhancement and athlete development.

**TEAM-REFERENCED PERCEIVED COACHING ENVIRONMENT, NEEDS SATISFACTION, AND WELL-BEING IN ELITE HOCKEY PLAYERS: AN EXTENSION OF BASIC NEEDS THEORY.**

MERRETT, C., DUDA, J.L., QUESTED, E.

UNIVERSITY OF BIRMINGHAM

Introduction. Studies testing the tenets of Basic Needs Theory (BNT; Deci & Ryan, 2002) have focused on individual-defined views regarding the social environment, reported need satisfaction and indices of athlete welfare (Reinboth & Duda, 2006). No research to date has taken a systematic approach to measuring the relevant motivational processes and well-being dimensions when referenced at a group level. Moreover, there has been limited testing of BNT in elite youth athletes and teams (Adie, Duda & Ntoumanis, 2008). Assessing whether predictions emanating from BNT are supported when defined in terms of perceived team-based perceptions may assist future research aimed at developing our understanding of the complexity of motivation in team sports. This study aimed to i) explore the interplay between perceptions of the coaching climate evident on the team, BN satisfaction for the team as a whole, and positive and negative indicators of team "health", and ii) test the role of BN satisfaction in mediating the relationship between dimensions of the coaching climate and team well- and ill-being indices. Method. Cross-sectional design. 224 (M age =17.59 years) elite junior field hockey players completed a multi-section questionnaire assessing perceptions of the autonomy supportive and controlling features of the coach-created team environment, satisfaction of the needs for team competence and autonomy, and perceived relatedness in terms of coach and teammates, and indicators of team well-being (subjective vitality) and ill-being (physical and emotional exhaustion). Results. Preliminary analyses using structural equation modeling partially support a model indicating satisfaction of the team-referenced BNs to be positively predicted by perceptions of an autonomy supportive coaching environment. Competence, relatedness to coach, and relatedness to teammates emerged as positive predictors of vitality. The model demonstrated reasonable fit to the data (Chi-squared =1125.3, p <0.01; RMSEA=.07; CFI=.90; TLI=.89). Tests of mediation on the BNs aim to reveal their role in explaining the relationships between perceived coaching climate and well- and ill-being outcomes. Discussion. Initial findings partially support the tenets of Basic Needs Mini-Theory when the central constructs are group rather than individual-referenced, and indicates the importance of particular needs in promoting aspects of team emotional health. ### DRIVE FOR MUSCULARITY: ROLE OF EXERCISE STATUS AND PHYSICAL SELF-BELIEVES

BORKOLES, E., POLMAN, R.C.J.

VICTORIA UNIVERSITY

Men have reported significant discontent with their bodies. Associated with this dissatisfaction is the desire to attain a more muscular physique. The Drive for Muscularity (DFM) in men has been associated with poor self-esteem and higher levels of depression. DFM may be interpreted as dissatisfaction with current levels of muscularity but can be an expression of concerns with performing behaviours aimed toward increasing muscularity. This study investigated the role of physical self-description in predicting levels of DFM in a sample of men who were either engaging in weight training, aerobic exercise or were sedentary. Participants were 564 males aged between 18 and 55 years (M age = 26.24 years, SD = 7.93). Of these 216 were classified as regular weight trainers, 148 as regular exercisers and 200 as sedentary. The study was approved by a University Research Ethics Committee and participants provided informed consent prior to participating. The participants completed the Drive for Muscularity Scale (DMS) the Physical Self-Description Questionnaire (PSDQ) and the Balanced Inventory of Desirable Responding (BIDR). Regression analysis for the DMS Attitude scale showed that the PSDQ factors health (beta = .12), physical self-concept (beta = .29), endurance fitness (beta = .18), and self-esteem (beta = -.22) explained 7.3% ( $P < .001$ ) of the variance. For DMS Behavior scale physical activity (beta = -.46), body fat (beta = -.15), sport competence (beta = -.15), strength (beta = -.23) and self-esteem (beta = .26) explained 25.2% ( $P < .001$ ) of the variance. The MANOVA for DFM was significant ( $P < .001$ ;  $\eta^2 = .17$ ) as were the follow-up ANOVAs (Attitude:  $P = .01$ ;  $\eta^2 = .02$ ; Behavior:  $P < .001$ ;  $\eta^2 = .31$ ). Tukey post-hoc comparisons revealed a significant higher score for the active group in comparison to the weight training group for attitude and behavior. The MANOVA for the PSDQ was significant ( $P < .001$ ;  $\eta^2 = .44$ ). Follow-up ANOVA show significant differences for all 11 scales of the PSDQ. Post-hoc comparisons confirmed that the sedentary group scored significantly lower on all scales in comparison to the weight training and active groups. The weight training group scored higher on health, physical activity, and strength than the active group which in turn scored higher on endurance fitness. DFM seems to be influenced by exercise status. Men mainly engaging in aerobic exercise reported a significantly higher DFM than those who weight trained. Therefore, DFM is also a concern for men who do not weight train, not just those who actively try to change their muscular structure. Furthermore, different physical self-descriptors as measured by PSDQ underlie the Attitude and Behavior scales of the DMS. Behavioral intervention targeting men's self perceptions need to be cognizant of exercise status and the different aspects of the physical self-descriptions and their interplay to be effective in changing negative attitudes and behaviors towards the self.

### THE EFFECT OF DEHYDRATION AND MODERATE ALCOHOL CONSUMPTION ON COGNITIVE FUNCTION AND REACTION TIMES

IRWIN, C.G.1, LEVERITT, M.1, SHUM, D.2, DESBROW, B.1

1. SCHOOL OF PUBLIC HEALTH & RESEARCH CENTRE FOR CLINICAL AND COMMUNITY PRACTICE INNOVATION, GRIFFITH HEALTH INSTITUTE, GRIFFITH UNIVERSITY, GOLD COAST, AUSTRALIA

Cognitive function and neurological reaction times are important for many aspects of daily living. Extensive literature exists on the deleterious effects alcohol consumption has on these variables. Studies examining the impact of dehydration on human cognitive function however have not always demonstrated performance decrements. No literature currently exists investigating cognitive performance when moderate alcohol intake is combined with mild/moderate levels of dehydration. This study examined the impact of mild and moderate dehydration on the effects of alcohol induced cognitive impairment. Nine healthy males (age,  $22.6 \pm 3.8$ y; mean $\pm$ SD) participated in 4 randomised, single-blind trials (separated by 7d) designed to induce dehydration through exercise for a target of 2.5% body mass loss. Following a 1h recovery period in a thermo-neutral environment (23deg, 67% RH) a 4-task Cambridge Neuropsychological Test Automated Battery (CANTAB), mood rating questionnaires and subjective estimates of alcohol-related symptoms were completed (test 1). Participants were then either provided with no water (D), a small amount of water equivalent to 50% body mass loss (P) or a large amount of water equivalent to 150% body mass loss (F) over a 2h period. Following the rehydration phase, participants consumed a set volume of alcohol (A) or placebo (P) to incorporate the conditions DP, DA, PA, and FA. The alcoholic beverage was consumed over 10min in a volume individually calculated and intended to raise breath alcohol concentration to  $\sim 0.05$  g/100ml. Following an absorption period (30min), participants completed a second rating of symptoms and the CANTAB test battery (test 2). Differences between test 1 and test 2 CANTAB mean responses were compared for all trial conditions. No significant differences were observed in mean CANTAB scores of choice reaction time, executive functioning and response inhibition between any of the trial conditions. No differences were observed between trial conditions for ratings of alcohol intoxication however subjective impairment responses revealed differences between trial conditions, with participants declaring a greater willingness to operate a motor vehicle after alcohol ingestion in fluid replacement conditions (PA & FA) compared to the dehydration condition (DA). Rehydration following exercise resulting in fluid loss may impact on alcohol related risk-taking behaviour and may pose implications for post match fluid replacement if a moderate amount of alcohol is also consumed

### OP-PM38 Vibration

#### WHOLE BODY VIBRATION AND OXIDATIVE STRESS

LARK, S., WADSWORTH, D.

MASSEY UNIVERSITY

Introduction Oxidative stress following exercise is derived via the mass action of reactive oxygen species formed by the elevated oxygen consumption and metabolism, phagocytotic activity e.g., with muscle damage, ischemia-reperfusion, and mechanical stress (1). The exercise Whole Body Vibration (WBV) causes mechanical stress, and increases blood flow and oxygen consumption (2). However, the

level of any exercise or oxidative stress damage induced by WBV is unknown although it is being proposed as an effective neuromuscular-training and therapeutic tool. This study was designed to determine the acute and chronic level of oxidative stress induced by WBV in comparison to muscle damage inducing exercise, and a metabolic equivalent exercise. Methods Twenty-one untrained females (age  $23.9 \pm 5$  years; height  $1.65 \pm 0.08$  m; mass  $70.1 \pm 15.8$  Kg) were randomised to one of three training groups: WBV (26Hz; Galileo plate; 1min vibration/1min rest; 5mm amplitude;  $20^\circ$  knee flexion), Downhill Running (DHR;  $-10.5\%$ , 11 K/h) or a Walking control (W; 4.5 km/h). They completed 3x20min weekly supervised sessions for 8 weeks. Baseline venous blood samples were collected for acute; pre-, immediately post, 24-h post, and chronic effects; after 8 weeks. Creatine Kinase (CK) and Isoprostane (lipid peroxidation) activity and percentage change from baseline were compared between groups at the different measurement points via Repeated Measures ANOVA. Paired analysis between final and baseline values was performed to determine any training effects. Results The CK for DHR was significantly elevated ( $p=0.02$ ) compared with WBV and W at 24h post exercise, but not between W and WBV. Overall WBV was always higher than W but not significantly so. Significant Group ( $P<0.05$ ) and Measurement Period ( $P<0.05$ ) main effects were seen for the percentage changes of CK. There was also a significant ( $P<0.05$ ) main effect for the Measurement Period for percentage change of Isoprostane, but no difference between groups. All groups showed an increase in Isoprostane immediately post-exercise, but lower than baseline at 24h and 8 weeks. There were significant ( $P<0.05$ ) Measurement Period and Group main effects for Isoprostane activity, for which for WBV always appeared slightly higher than W and less than DHR, but was the most stable between measurement periods. Isoprostane measured at 8 weeks was not different from baseline for any of the groups. Conclusions An acute bout of WBV does not incur significant muscle damage. Lipid peroxidation increased immediately post-exercise and decreased by 24h, but no significant training effect was seen. WBV had a consistently higher level of lipid peroxidation and muscle damage compared to the metabolic equivalent exercise of walking, but less than DHR. References 1. Urso et al. ### THE EFFECTS OF A 6-WEEK NEUROMUSCULAR TRAINING PROGRAM ON KNEE JOINT MOTOR CONTROL DURING SIDECUTTING IN HIGH-SCHOOL FEMALE ATHLETES

WAXMAN, J., TUTALO SMITH, S., WALSH, M., NOYES, F.

MIAMI UNIVERSITY

The Effects of a 6-Week Neuromuscular Training Program on Knee Joint Motor Control During Sidecutting in High-School Female Athletes Waxman, J.1, Tutalo Smith, S.2, Walsh, M.1, and Noyes, F.2 1: Miami University (Oxford, OH, USA) 2: Cincinnati Sportsmedicine Research and Education Foundation (Cincinnati, OH, USA) Introduction Anterior Cruciate Ligament (ACL) injuries occur 4 to 8 times more frequently in female athletes than in male athletes, causing increased focus on the prevention of ACL injury in female athletes. A majority of these injuries occur in non-contact situations that involve landing, sidecutting, or sudden deceleration. The medial hamstring muscles have been found to play an important role in resisting anterior-directed shear on the tibia and in protecting against movements that commonly cause excess valgus. Current research has demonstrated that prophylactic neuromuscular training induces a positive change in the pattern of neuromuscular activation of the hamstring muscles during sidecutting, potentially reducing the risk of ACL injury. The purpose of the current study was to implement a 6-week neuromuscular training program prior to the athlete's upcoming competitive season and to experimentally analyze the neuromuscular adaptation mechanisms elicited by this type of training during a standardized sidecutting maneuver known to be associated with non-contact ACL injury. Methods Twenty-five healthy female athletes were included in the current study. The athletes were split into two groups, those that previously participated in the training program (previous participants) and those that have not (first time participants). All participants were tested for electromyography (EMG) activity in the vastus medialis (VM) and lateralis (VL), rectus femoris (RF), semitendinosus (ST), and biceps femoris (BFcl) during a standardized sidecutting maneuver pre and post a 6-week prophylactic neuromuscular training program. The RMS EMG amplitude was obtained at time periods of 10 and 50 milliseconds both before and after foot strike on the target area. RMS EMG amplitude was then normalized to the peak RMS EMG amplitude recorded during the sidecutting maneuver. The mean of five trials was calculated for each participant. Results A series of mixed-design ANOVAs examined each muscle group at pre and post training, controlling for training experience. There were significant differences found in the VM and VL in the 50-ms time interval before foot strike, the VL 10-ms before foot strike, and in the ST 50-ms after foot strike. Discussion The neuromuscular training program used in this study was shown to elicit changes in EMG activity. However, the observed neuromuscular adaptation during sidecutting conflicts with previous research, which has used a training program longer in duration. These findings suggest that 6-weeks may not be enough time to induce neuromuscular adaptations that could potentially reduce the risk for non-contact ACL injury.

### HEMODYNAMIC RESPONSES TO VIBRATION IN HUMAN CALF MUSCLE

ZANGE, J., ILLBRUCK, A., MOLITOR, S., KOHL-BAREIS, M., RITTWEGER, J.

DLR, GERMAN AEROSPACE CENTER

HEMODYNAMIC RESPONSES TO VIBRATION IN HUMAN CALF MUSCLE Zange, J.1; Illbruck, A.1,2; Molitor, S.1; Kohl-Bareis, M.2; Rittweger, J.1 1: DLR, Institute of Aerospace Medicine, (Cologne, Germany); 2: University of Applied Technology Koblenz, Rhein-Ahr-Campus (Remagen, Germany) Introduction During whole body vibration training leg muscles moderately increase their energy turn-over (Zange et al. 2009) and absorb part of the kinetic energy by conversion into heat (Cochrane et al. 2008). This entails the need for appropriate blood supply. The present study focuses on the hemodynamic response to passive vibration in terms of blood content and blood oxygenation in the unloaded calf muscle exploring the relative contribution of the arterial and the venous compartment. The hypothesis was that venous restriction would prevail over arterial vasodilatation. Methods The subjects ( $n=12$ , male) sat in front of a vibration platform with their bare right foot affixed to the platform. The test included 2 intervals of 3 min vibration at either 15Hz or 25Hz (permutated order,  $\pm 2.5$  mm amplitude), followed by 3 min recovery. Near infra-red spectroscopy (Geraskin, 2009) was used for measuring hemoglobin oxygen saturation ( $SmO_2$  in %) and the concentrations of oxygenated, desoxygenated, and total hemoglobin ( $HbO_2$ ,  $HbH$ ,  $tHb$ ) in the m. gastrocnemius medialis. EMG was recorded for the detection of reflex responses. Results Within the first 30s of vibration  $SmO_2$  increased from  $56 \pm 7\%$  to  $68 \pm 4\%$ . After having reached this maximum,  $SmO_2$  slowly decreased until it reached a steady state at  $63 \pm 5\%$  after almost 1.5 min of vibration. In the recovery phase  $SmO_2$  linearly decreased back to base line. No significant differences were found for frequency and the order of vibration intervals. The initial increase of  $SmO_2$  corresponded to a large decrease in  $HbH$ , a small increase in  $HbO_2$ , and a decrease in  $tHb$ . The EMG was super-imposed by artefacts at the vibration frequency and its harmonics and did not reveal any evidence of muscular activity. Furthermore, there was no evidence for a reflex contraction by visual observation or subjects' sensation. Discussion These observations suggest that in the unloaded calf muscle 15 and 25 Hz vibration initially cause a mechanical removal of predominantly desoxygenated blood from the capillaries and venules. Afterwards a moderate mismatch between oxygen supply and consumption was indicated by the decrease in  $SmO_2$  followed by a steady state indicating a balance. After vibration full recovery was reached

within 3 min without indications of a reactive hyperemia. Of note, all these very clear changes occurred in the absence of EMG activity. The responsible mechanisms could e.g. be related to vasomotor responses or to basic muscle tone and need to be established by further studies. ### EFFECT OF WHOLE BODY VIBRATION ON THE H-REFLEX IN NORMAL GRAVITY AND MICROGRAVITY

RITZMANN, R., KRAMER, A., GOLLHOFER, A.

UNIVERSITY OF FREIBURG

**Introduction:** During space flights, astronauts suffer from structural (bone and muscle loss) and functional changes (impairment of balance and movement control in response to changes within the neuromuscular system). Space agencies are exploring the suitability of whole body vibration (WBV) as a training regimen for astronauts to counteract the degeneration caused by weightlessness. However, the effect of weightlessness on the neuromuscular system and the interaction of microgravity and WBV have not been studied yet. Therefore, the purpose of this study was to investigate (1) how weightlessness affects Ia afferent transmission with respect to the soleus (SOL) and gastrocnemius medialis (GM) muscles and (2) if gravitational alterations modulate Ia afferent transmission during WBV. **Methods:** Fourteen subjects participated in this experiment that was conducted during a parabolic flight campaign with exposure to microgravity (0g) and normal gravity (1g). Ia afferent transmission was evaluated in four different conditions: 1g and 0g without WBV; 1g and 0g with WBV. For that purpose, H-reflexes were elicited by peripheral nerve stimulation. H/M recruitment curves were recorded in SOL and GM in each of the four conditions and Ia afferent transmission was assessed by their corresponding Hmax/Mmax-ratios. **Results:** (1) SOL (0g:  $0.45 \pm 0.10$ ; 1g:  $0.47 \pm 0.12$ ) and GM Hmax/Mmax-ratios (0g:  $0.29 \pm 0.12$ ; 1g:  $0.27 \pm 0.10$ ) were statistically equal and showed no changes due to different gravity levels. (2) In 1g, SOL and GM Hmax/Mmax-ratios showed a distinct reduction (SOL -58%  $p < 0.05$  and GM -51%  $p < 0.05$ ) during WBV compared to conditions without WBV. Likewise in 0g, SOL and GM Hmax/Mmax-ratios were highly decreased (SOL -57%  $p < 0.05$  and GM -44%  $p < 0.05$ ) compared to conditions without WBV. **Discussion:** The main findings were: (1) WBV causes drastic reductions in Ia afferent transmission and (2) these reductions are independent of the gravitational condition. It has been shown that WBV induces stretch reflex responses that cause muscle contractions (Ritzmann et al. 2010). This contractile stimulation has been successfully utilized in training programs to compensate for disuse in long term bed rest studies (Belavý et al. 2009). Based on the finding that Ia afferent transmission is not affected by gravitational changes, it might be concluded that vibration-induced benefits typically observed in 1g might also be achieved in 0g. For space conditions, WBV could be recommended as a training modality, either applied alone or in combination with strength training to counteract atrophic muscle deteriorations effectively. **References:** Ritzmann R, Kramer A, Gruber M, Gollhofer A, Taube W. (2010). *Eur J Appl Physiol* 110(1):143-51. Belavý DL, Miokovic T, Armbrecht G, Rittweger J, Felsenberg D. (2009). *J Musculoskelet Neuronal Interact* 9(4):225-35.

### EFFECTS OF DETRAINING AFTER RESISTANCE TRAINING WITH WHOLE BODY VIBRATION ON MUSCLE FITNESS IN UNTRAINED ADULTS

OSAWA, Y., OGUMA, Y.

KEIO UNIVERSITY

**Introduction** Various physiological aspects of detraining (that is, complete cessation of training) effects after resistance training (RT) have been investigated. Recently, RT combined with whole-body vibration (WBV) has become popular for untrained middle-aged populations. Several reports have demonstrated that RT with WBV enhances muscle power and strength (Marin et al. 2010a; Marin et al. 2010b). However, the effects of detraining after RT combined with WBV on muscle fitness in untrained individuals have not been demonstrated. The present study investigates the effects of 5-week detraining after 13-week of RT coupled with or without a WBV program on muscle strength and power. **Methods** Thirty-two participants (22-49 years of age) were randomly assigned to groups that performed RT with (RT-WBV,  $n = 16$ ; Frequency, 35 Hz; Amplitude, 2mm; Power Plate® Next Generation) or without (RT,  $n = 16$ ) WBV. Training intensity was progressively increased by using external loading. We investigated the effects of 5-week detraining after a 13-week exercise program with WBV by measuring maximal isometric and isokinetic knee extension, as well as isometric lumbar extension strength, countermovement-jump height, knee extension endurance and sit-ups. **Results** Maximal isometric and concentric knee extension strength was significantly higher in the RT-WBV, than in the RT group after the training. However, decreases were significant only in the RT-WBV ( $-11.5 \pm 9.2\%$  and  $-19.9 \pm 18.0\%$ , both  $p < 0.05$ ), whereas maximal isometric and concentric knee extension strength was retained in the RT group after detraining. Maximal isometric lumbar extension strength increased significantly more in the RT-WBV, than in the RT group, and neither group lost a significant amount of strength after detraining. **Discussion** Although knee extension strength was lost in the RT with WBV group, maximal isometric lumbar extension strength was retained in both groups after the detraining. Exercises for back extensor muscles in the present study were performed at a lower training intensity than for the lower extremities. Taking the results of maximal isometric knee and lumbar extension strength and the possibility that skeletal muscle groups might respond differently to detraining into consideration, muscle strength losses might depend in part on training intensity and the specific muscle group examined in RT coupled with WBV. **In conclusion**, these results suggest that high plasticity of gains in muscle strength might occur in response to detraining RT combined with WBV in healthy untrained adults. **References** Marin et al. (2010a) *J Strength Cond Res*, 548-556. Marin et al. (2010b) *J Strength Cond Res*, 871-8.

### THE EFFECTS OF WHOLE-BODY VIBRATION TRAINING ON BALANCE AND GAIT IN THE ELDERLY: A PILOT STUDY

ROGAN, S.1, RADLINGER, L.1, SCHMIDTBLEICHER, D.2, DE BIE, R.A.3, DE BRUIN, E.D.4

1: BERN UNIVERSITY OF APPLIED SCIENCES (SWITZERLAND), 2: FRANKFURT UNIVERSITY (GERMANY), 3: MAASTRICHT UNIVERSITY (THE NETHERLANDS), 4: IBWS ETH (ZURICH, SWITZERLAND)

**Introduction** A human is in stable posture as long as the line of action of the person's weight vector passes within the base of support. For effective maintenance of postural stability during standing, functional activities and gait, quick coordinated responses to environmental perturbations are important. Since aging is associated with a decline of balance, muscle mass, and mobility, it impacts on postural control. Some 80% of falls in the elderly are caused by balance disturbances during everyday movements. Exercise programs that include a balance-training component have shown to be effective in preventing falls (Sherrington et al., 2008). In the last decade whole-body vibration (WBV) has become a therapeutic modality to train postural control of elderly (Merriman & Jackson, 2009). However, the effects of this intervention are not always clearly documented. Consequently the aim of this study was to assess the effects of a four-week

stochastic resonance whole-body vibration (SR-WBV) training program on balance and gait in the elderly. **Methods** Twenty elderly volunteers aged 65 to 90 years (78.46 sd. 7.4 years) were randomly assigned to intervention (IT) and sham-training (ST) groups exercising 3 times a week during four weeks with a minimum of one day rest in between. All participants stood on the device with slightly flexed knees. IT (n=7) received 5 sets of 1 minute SR-WBV (5Hz, Noise 4) with 1 minute of rest in between whereas ST (n=10) received 5 sets of 1 minute SR-WBV (1Hz, Noise 1) with 1 minute of rest in between. All participants performed pre- and post-training tests of dynamic balance the Extended Timed Get Up-and-Go Test (ETGUG; Wall et al., 2000). Gait (20 m walk) was assessed under standardized single task (ST) and dual task (DT) conditions. **Results** Two dropped out of knee pain and one of personal reason. Baseline comparisons revealed no significant differences for demographic variables. Pretests showed only for ETGUG 12-18m ( $p=0.045$ ) a borderline significant difference between groups. Following the four-week training period, ETGUG indicated a significant decrease in the time needed to perform the walking parts of the test for IT: 2-8m (-14.6%,  $p=0.018$ ), 12-18m (-7.9%,  $p=0.018$ ). ST conditions showed no changes in this test. **Discussion** The results indicated a beneficial effect of SR-WBV with 5Hz vibration frequency on dynamic balance in contrast to those training with a 1 Hz frequency. Low volume SR-WBV exercises over 12 units with 5 Hz might provide a sufficient stimulus to the nerve-muscle system to improve dynamic balance at the ETGUG. These findings warrant further research in deconditioned elderly populations with postural control impairments.

## Oral presentations

### OP-PM35 Physical Activity Ageing

#### ACTIVE OLDER ADULTS ARE LESS AFFECTED BY THE FEAR OF FALLING

MACHADO, M., CARNIDE, F., MONIZ-PEREIRA, V., ANDRÉ, H., RAMALHO, F., VELOSO, A.

*FACULTY OF HUMAN KINETICS - TECHNICAL UNIVERSITY OF LISBON*

**BACKGROUND AND PURPOSE:** Fear of fall (FoF) is a major health problem among elderly, restricting their mobility and independence. The purpose of this study was to determine the impact of FoF in the activities of daily living (ADLs) in elderly. **SUBJECTS AND METHODS:** A cross-sectional study was designed to determine the effect of FoF and its consequences regarding perception of health (PH), falls prevalence (FP), physical activity (PA) and functional fitness (FF) among 160 Portuguese older adults (73.4±6.2 yrs; 71.9% women). FoF, PH and FP, were assessed by specific questionnaire. PA was calculated through YPASI[1]. FF was evaluated by UG and CS tests from SFT[2], and balance obtained through "item 4, 5, 6 and 7" of FAB Scale[3]. Mann-Whitney and Chi-Square test were done to identify differences between PH, PA, FF, FP according to FoF and how it affects the ADLs. Logistic regression analyzes (forward conditional) were performed. **RESULTS AND DISCUSSION:** FoF was reported by 50.0% and associated avoidance of activity by 21.1%. The factors related with FoF are: Women ( $x^2 = 26.00$ ;  $p = 0.000$ ), poor PH ( $x^2 = 7.06$ ;  $p = 0.008$ ), visual health perception (VHP) ( $x^2 = 8.43$ ;  $p = 0.004$ ), FP ( $Z = 0.342$ ;  $p = 0.001$ ), medications ( $Z = -2.96$ ;  $p = 0.003$ ), poor FF, namely agility ( $Z = -2.51$ ;  $p = 0.012$ ), lower limb strength ( $Z = -2.41$ ;  $p = 0.013$ ) balance ( $Z = 4.87$ ;  $p = 0.000$ ) and PA energy expenditure in household activities ( $Z = -2.21$ ;  $p = 0.028$ ) and walking ( $Z = -2.58$ ;  $p = 0.010$ ). The factors related with impediment to ADLs are: Women ( $x^2 = 4.64$ ;  $p = 0.031$ ) as poor PH ( $x^2 = 8.43$ ;  $p = 0.004$ ), VHP ( $x^2 = 11.15$ ;  $p = 0.001$ ) and hearing health ( $x^2 = 14.63$ ;  $p = 0.006$ ), age ( $Z = -2.02$ ;  $p = 0.044$ ), FP ( $Z = 2.36$ ;  $p = 0.018$ ), fractures ( $x^2 = 4.43$ ;  $p = 0.0035$ ), sitting time ( $Z = 2.24$ ;  $p = 0.25$ ) and walking time ( $Z = -3.40$ ;  $p = 0.001$ ), recreational activities time ( $Z = -2.34$ ;  $p = 0.018$ ), and balance ( $Z = -3.78$ ;  $p = 0.000$ ). The logistic regression model for the outcome FoF shows that men (OR = 0.071; 95% CI -0.020-0.246), good balance (OR = 0.795; 95% CI -0.700-0.903) and VHP (OR = 0.178; 95% CI -0.178-0.850) are protective predictors of FoF. Male gender and good balance are also protective predictors to the impediment outcome (OR = 0.240; 95% CI -0.059-0.982; OR = 0.808; 95% CI -0.726-0.899, respectively). **CONCLUSION:** Men seem to be protected for FoF and its impact in ADLs. However, be more active especially by increasing walking and achieve good balance could have a positive effect on autonomy of the elderly. **References:** [1] Dipietro, et al (1993) MSSE 25(5), 628-642; [2] Rikli & Jones (2001) SFT Manual. #### RELATIONSHIP BETWEEN FUNCTIONAL FITNESS, BMI, BLOOD PRESSURE AND SELF-RATED HEALTH IN ELDERLY INVOLVED IN AN INTERVENTIONAL EXERCISE PROGRAM

MARTINS, C., FIGUEIRAS, T., SANTANA, P., SANTOS, R., POVOAS, S., CARVALHO, C.

*HIGHER EDUCATION INSTITUTE OF MAIA*

**INTRODUCTION:** Physical activity is directly associated to an increased quality of life among elderly people by increasing their functional capacity and independence. Thus, the aim of this study was to analyze the relationship between self-rated health (SRH) and functional fitness, BMI and blood pressure of elderly involved in an interventional exercise program. We hypothesized that subjects who obtained better results in functional tests tend to have a better SRH and low levels of BMI and blood pressure. **METHODOLOGY:** These are preliminary results of an interventional program developed in Maia/Portugal, comprised of 900 subjects, aimed to evaluate the effects of different training methodologies. Our sample consists of 167 subjects, aged 60 to 74. The functional capacity was measured by Rikli & Jones (1999) functional fitness battery. The SRH was evaluated by the international questionnaire Medical Outcome Study – 36 items from health survey- short version (SF-36). BMI and blood pressure were evaluated according to international procedures. Statistical analysis was performed using SPSS (Windows version 17.0) and the level of significance was set up at  $p \leq 0.05$ . **RESULTS:** SRH was significantly associated with four different functional tests ( $p \leq 0.05$ ). Subjects who belong to the 4th quartile in tests related to locomotion correspond to those subjects who had the best perception of health and the lowest levels of BMI blood pressure. **CONCLUSION:** We observed that SRH, BMI and blood pressure are associated to functional fitness, especially in those tests related to locomotion capacity.

#### CORRECTNESS OF HOME EXERCISE PERFORMANCE IN OLDER ADULTS

HINRICHS, T.1, BUCCHI, C.1, BRACH, M.2, MOSCHNY, A.1, VOLKE, J.1, TRAMPISCH, U.1, WILM, S.3, PLATEN, P.1

**Introduction** Due to low costs and high accessibility home-based exercise seems to be an appropriate alternative to supervised exercise to preserve functional status in old age. However, the concept of home-based exercise relies on the belief that exercises are performed correctly so that they are likely to be effective and do not harm the participants. A home-based exercise program, approaching and supporting community-dwelling elderly via their general practitioner (GP) and an exercise therapist (ET), has been developed (HOMEfit). A

feasibility study was conducted to allow modifications before entering the next phase of research. To assess suitability of exercises for the program, correctness of exercise performance was assessed. Methods The 12-week intervention (single arm trial) included home exercises (walking for exercise plus a choice of strength, flexibility and balance exercises from a given set of 16) and consultations provided by an ET in the GP's practice and via telephone. Based on the participant's abilities, needs and experiences the ET set up an individualized program. Selected exercises were taught within 4 personal consultations. Participants received a pictorial guidebook. At the end of the intervention all exercises practiced within the course of the program were rated by the ET (Friedrich et al. 1996): grade 1 - the exercise is performed correctly and the treatment goal is reached; grade 2 - the exercise is not performed correctly and the goal is not reached but no negative impact is to be expected; grade 3 - the exercise is performed incorrectly, the goal is not reached and there is reason to believe that the exercise might have harmful effects. Results Correctness of exercise performance was assessed in 74 participants (median age 76 (70-86) years; 58% females). Between 67 and 100% (mean 85%) performed the respective exercise correctly (grade 1). Only 1 patient performed 1 exercise in the way that it might have harmful effects (grade 3). From the given set of exercises, 3 were performed by less than 10% of patients within the course of the program. Conclusion The present evaluation permitted us to select the most appropriate exercises for the consecutive study. An additional personal consultation might improve correctness of exercise performance. Reference Friedrich, M., Cermak, T., Maderbacher, P. (1996) The effect of brochure use versus therapist teaching on patients performing therapeutic exercise and on changes in impairment status. *Physical Therapy*, 76, 1082-88. ### **MULTIPLE JOINT FUNCTION WITH AGEING: FORCE-VELOCITY AND POWER-VELOCITY RELATIONSHIPS**

ALLISON, S.J., BROOKE-WAVELL, K., FOLLAND, J.P.

LOUGHBOROUGH UNIVERSITY

Introduction Previous studies have documented the decline in neuromuscular function, particularly muscular power, of single joints with ageing. However, the extent to which force or velocity are responsible for the loss in power is equivocal. Furthermore, multiple joint movements (e.g. simultaneous extension of the ankle, knee and hip) may be more relevant to mobility and locomotion, but have received little attention. This study compared the neuromuscular function of young vs. older men during a multiple joint leg press action. The force-velocity and power-velocity relationships were assessed and the contribution of force and velocity to the decline in power evaluated. Methods Twenty-one older men (OM, 66 ± 3 yrs) and twenty-three young (YM, 24 ± 2 yrs) completed a familiarisation session followed by two main trials which involved assessment of the non-dominant leg with a leg press dynamometer instrumented to record force (Kistler 92868A, force plate, London, UK) and displacement (linear transducer, Micro-epsilon Ltd, Ortenburg, Germany). During the first main trial participants completed a series of maximum and explosive isometric contractions followed by an assessment of 1RM lifting strength. During the second main trial, participants completed maximum dynamic contractions, 3 attempts at each of 5 different loads of 60, 45, 30, 15 and 0 % of their 1RM. For these contractions displacement was used to derive velocity and calculate power. The highest instantaneous peak power achieved at each load and the associated force and velocity values were used to plot the force-velocity and power-velocity relationships, and these were fitted with a quadratic function. For the power-velocity relationship this facilitated the calculation of maximum power (Pmax) and of the optimal velocity (Vopt) and optimal force (Fopt) as the co-ordinates of the optima of the quadratic function. Results The force-velocity relationship was lower for the OM as reflected by their 21% lower maximum isometric strength compared to the YM (2053 ± 284 vs. 2585 ± 487 N; p<0.001). The power-velocity relationship was also lower for the OM compared to the YM, as shown by the 30% reduction in Pmax (1136 ± 176 vs. 1663 ± 278 W; p<0.001), the 12% slower Vopt (1.43 ± 0.16 vs. 1.62 ± 0.32 m.s<sup>-1</sup>, p<0.05) and 22% lower Fopt (797.4 ± 93.6 vs. 1025.8 ± 220.5 N; p<0.001). Explosive isometric strength (peak rate of force development) was 24% lower for the OM compared to the YM (9340 ± 2723 vs. 11605 ± 3655 N.s<sup>-1</sup>, p<0.05). Discussion Older men had substantially lower power during a functionally relevant multiple joint leg press movement than younger men, and whilst force and velocity were both lower in older men, the decrease in force contributed more to the decline in power.

### **IDENTIFICATION OF SARCOPENIC OBESITY IN POSTMENOPAUSAL WOMEN: A CUTOFF PROPOSAL**

LIMA, R.M., BOTTARO, M., JÚNIOR, J.T., FARINATTI, P.V.T., BEZERRA, L.A., OLIVEIRA, R.J.

UNIVERSIDADE DE BRASÍLIA (UNB)

Introduction: Sarcopenic obesity has been pointed as an important cause of frailty among older adults but lack of clear criteria for its identification leads to limitation in clinical and research settings. The purposes of the present investigation were: 1) to develop an approach for identifying postmenopausal women who are deficient in fat-free mass (FFM) relative to their fat mass (FM) and height (i.e., sarcopenic obesity); 2) to calculate the prevalence of inadequate FFM in that population; and 3) to examine whether there are associations between the proposed classification and health-related phenotypes. Methods: A total of 607 women were included in this cross sectional study and were categorized into two subsets: 1) Older women with mean age of 66.8 years (n = 258) and 2) 349 young women aged 18-40 years. All volunteers underwent body composition assessment through dual energy x-ray absorptiometry. The proposed cutoff value corresponded to an index of FFM relative to FM and height two standard deviations below the mean of the young reference group. Results: Definition of older women presenting sarcopenic obesity was conducted based on comparison of FFM index distribution in the young reference group versus the older volunteers. The proposed classification generated a sarcopenic obesity prevalence of 19.8% that was associated with reduced absolute and relative muscle strength and aerobic fitness indexes among the older participants. Conclusions: These results demonstrate reduced functional capacity for those below the proposed cutoff and suggest applicability of the approach as a definition for sarcopenic obesity. Future studies should further investigate its potential use in clinical settings and examine its association with other clinical outcomes such as cardiovascular and metabolic risks.

### **SKELETAL MUSCLE SIZE, STRENGTH AND 'QUALITY' IN UNTRAINED YOUNG AND ELDERLY MEN, AND IN ELDERLY ATHLETES**

MCPHEE, J.S., MADEN-WILKINSON, T.M., CAMPBELL, E.L., NARICI, M., JONES, D.A., DEGENS, H.

MANCHESTER METROPOLITAN UNIVERSITY

Introduction Elderly people can develop problems of mobility, in part due to age-related loss of muscle mass and strength. Strength, however, deteriorates at a faster rate than muscle mass, resulting in reduced specific force (strength when normalised to muscle size) (Goodpaster et al 2006). Maintaining high levels of exercise throughout adulthood and into old age does not prevent the age-related loss of muscle strength (Aagaard et al 2007), but we hypothesised that highly active elderly would show some preservation of muscle specific

force. Methods Knee extensor maximum voluntary isometric contraction torque (MVC) was measured using dynamometry and muscle architecture was measured by ultrasound scanning at the mid-point of each of the quadriceps (Quads) muscles in 11 young (Y: age  $22 \pm 1$  years) and 15 old men (O: age  $72 \pm 1$ ) with average levels of physical activity, and in 11 master-athlete runners (MA: age  $76 \pm 2$ ) who were competing in the European Veteran Athletics Championships in 2010. Muscle specific force was expressed as MVC normalised to the sum of muscle thickness of the Quads muscles (Qt), as measured from ultrasound scans. Data are mean  $\pm$  SEM. Results MVC was higher in Y compared with O and MA ( $272 \pm 43$ ,  $175 \pm 39$  and  $192 \pm 39$  Nm, respectively  $P < 0.0005$ ), but was not significantly different between O and MA ( $P = 0.551$ ). The Quads thickness was also greater in Y compared with O and MA ( $102 \pm 12$ ,  $86 \pm 7$  and  $81 \pm 12$  mm, respectively;  $P = 0.006$ ), but was not significantly different between O and MA ( $P = 0.532$ ). MVC was positively correlated with Qt ( $r = 0.629$ ;  $P < 0.0005$ ). Specific force (MVC/Qt) was higher in Y compared with O, but did not differ significantly between Y and MA ( $2.7 \pm 0.3$ ,  $2.1 \pm 0.5$  and  $2.4 \pm 0.5$  Nm/mm in Y, O and MA, respectively). Quads fascicle length was similar in all groups and only minor differences were seen between groups in pennation angles. Discussion Many years of exercise in elderly people does not prevent the deterioration in muscle size and strength, but does preserve muscle quality in terms of its strength normalised to muscle size. The results suggest that exercise training could be a way to combat the age-related deterioration of muscle quality, which is an important component of the overall loss of muscle function. #### ACUTE METABOLIC RESPONSE TO LOW-VOLUME, HIGH-INTENSITY CONTINUOUS OR INTERVAL WORK-MATCHED EXERCISE

COCHRAN, A., CERMAK, N., GILLEN, J., PERCIVAL, M., TARNOPOLSKY, M., GIBALA, M.

MCMMASTER UNIVERSITY

Introduction High-intensity interval training (HIT) induces skeletal muscle remodeling similar to traditional endurance training despite a markedly lower total exercise volume and training time commitment (1,2). However, the relative importance of the "pulsed" nature of the HIT stimulus remains unclear. Our purpose was to determine whether a single bout of all out exercise would elicit similar acute metabolic changes as compared to an intermittent maximal cycling protocol matched for total work. We hypothesized that performing a given amount of work at maximal intensity would result in similar acute metabolic changes in human skeletal muscle, regardless of whether the exercise was performed in a continuous or interval manner. Methods Eight men ( $22 \pm 1$  y,  $48 \pm 2$  mL $\cdot$ kg $^{-1}\cdot$ min $^{-1}$ ) performed two exercise trials in random order at least 1 wk apart. During one session, subjects performed 4 x 30 s all out sprints separated by 4 min of rest (repeated Wingate tests; INT). In the other trial, subjects performed an isovolumetric amount of work ( $67.0 \pm 2.4$  kJ) but as a single continuous all-out effort (ISO). Skeletal muscle biopsies were taken before and immediately after each trial and analyzed for various metabolites and signaling proteins linked to mitochondrial biogenesis. Results Mean power averaged over the 4 sprints was  $557 \pm 16$  W, whereas mean power during the single bout was  $287 \pm 18$  W. Total exercise time was  $3:58 \pm 0:09$  (range: 3:23-4:30 min:s) in ISO, compared to 4 x 30 sec = 2 min over a 14 min training time commitment (including recovery) in INT. Both INT and ISO resulted in similar changes in muscle glycogen (net decrease: INT =  $140 \pm 39$ ; ISO =  $121 \pm 32$  mmol $\cdot$ kg dry wt $^{-1}$ ) and lactate contents (net increase: INT =  $57.5 \pm 6.7$ ; ISO =  $48.7 \pm 8.2$  mmol $\cdot$ kg dry wt $^{-1}$ ) (all main effects for time,  $P < 0.05$ ). Similar main effects were found for the phosphorylation status of signaling proteins p38 MAPK (increased 3-fold), ACC (increased 2-fold), and Akt (decreased 50%), with no difference between treatments. Discussion A few minutes per day of very intense exercise induces similar metabolic disturbances and activation of signaling pathways linked to skeletal muscle remodeling, regardless of whether that work is performed continuously or in an interval manner. These data add to the growing body of evidence that suggests very intense exercise training is extremely potent and time-efficient. It remains to be determined whether chronic training using an ISO-based protocol induces adaptations similar to traditional high-volume endurance training, as we have previously shown after an INT-based protocol (1,2). #### COMPARABLE EFFECTS OF MODERATE INTENSITY EXERCISE ON CHANGES IN ANORECTIC GUT HORMONE LEVELS AND ENERGY INTAKE TO HIGH INTENSITY EXERCISE

YOSHIKAWA, T., UEDA, S.

OSAKA CITY UNIVERSITY GRADUATE SCHOOL OF MEDICINE

There is growing interest in effects of exercise on plasma gut hormone levels and subsequent energy intake (EI) but the effects of mode and exercise intensity on anorectic hormone profiles on subsequent EI remains to be elucidated. We aimed to investigate whether circulating peptide YY3-36 (PYY3-36) and glucagon-like peptide-1 (GLP-1) levels depend on exercise intensity which could affect subsequent EI. Ten young male subjects (mean  $\pm$  S.D., age;  $23.4 \pm 4.3$  years, body mass index;  $22.5 \pm 1.0$  kg/m $^2$ , and maximum oxygen uptake (VO $_2$  max);  $45.9 \pm 8.5$  ml/kg/min) received a standardized breakfast, which was followed by constant cycling exercise at 75% VO $_2$  max (high intensity session), 50% VO $_2$  max (moderate intensity session), or rest (resting session) for 30 min. At lunch, a test meal was presented, and the EI was calculated. Blood samples were obtained during three sessions for measurements of glucose, insulin, PYY3-36 and GLP-1 which includes GLP-1 (7-36) amide and GLP-1 (9-36) amide. Increases in blood PYY3-36 levels were dependent on the exercise intensity (effect of session:  $P < 0.001$  by two-way ANOVA), whereas those in GLP-1 levels were similar between two different exercise sessions. Of note, increase in area under the curve (AUC) values for GLP-1 levels was negatively correlated with decrease in the EI in each exercise session (High:  $P < 0.001$ , Moderate:  $P = 0.002$ ). The present findings raise the possibility that each gut hormone exhibits its specific blood kinetics in response to two different intensities of exercise stimuli and might play differential roles in regulation of EI after exercise.

## THE SOLUTE CARRIER FAMILY 22 GENE RS2457571 POLYMORPHISM DOES NOT INFLUENCE OXYGEN UPTAKE RESPONSES TO A SIX WEEK AEROBIC TRAINING PROGRAMME

DAY, S., WILLIAMS, A., TURNER, M., MCPHEE, J.

MANCHESTER METROPOLITAN UNIVERSITY

**Introduction** Timmons et al. (2010) used RNA expression profiling and previously published QTL analyses to identify 11 single nucleotide polymorphisms (SNP) accounting for 23% of the interindividual variance in endurance-training induced gains in maximal oxygen uptake in the HERITAGE Family study (Bouchard et al. 1995). Most of these polymorphisms had not previously been associated with exercise responses and hence represent a novel set of exercise response mediators that need independent replication. Here we present preliminary data regarding the potential association between one of those polymorphisms, the solute carrier family 22 gene (SLC22A3 rs2457571 SNP), and data derived from McPhee et al. (2009). **Methods** 61 previously sedentary women followed a 6 week supervised cycle training programme. 1 legged cycling peak oxygen uptake (1LVP) and 2 legged cycling maximal oxygen uptake (2LVM) were measured before and after the training programme. DNA was extracted from 200 µL whole blood using spin columns (Qiagen, Crawley, UK). Genotyping was performed via real-time PCR using a Chromo4 machine (BioRad, Hemel Hempstead, UK) and a pre-designed Taqman® SNP genotyping assay (Applied Biosystems, Warrington, UK). **Results** Mean 1LVP increased from 1.9 L/min to 2.1 L/min (delta 1LVP = 0.2 L/min), and 2LVM increased from 2.4 L/min to 2.7 L/min (delta 2LVM = 0.3 L/min) (both  $P < 0.0005$ ). Following univariate analysis and analysis of covariance using baseline body mass and physical activity as covariates for baseline data and training data respectively, no significant association between the SLC22A3 rs2457571 SNP (CC=14, CT=32, TT=15) and baseline values or changes in any of the functional measures was observed (e.g.  $P=0.562$  for the interaction between genotype and delta 2LVM). **Discussion** Our study failed to show any association between the functional data and the SLC22A3 rs2457571 SNP. However, very recent work by Bouchard et al. (2011), using precisely the same data set as Timmons et al. (but different methods to identify candidate genes), also fails to replicate the findings. In that context, it is unsurprising that we fail to replicate the Timmons et al. observation in a completely independent cohort with different training intensity and volume. **References** Bouchard C, Leon AS, Rao DC, Skinner JS, et al. ## EFFECTS OF 12-H MECHANICAL VENTILATION ON FIBRE-SPECIFIC EXPRESSION OF ALPHA-ACTININ-3 PROTEIN IN RAT DIAPHRAGM

ICHINOSEKI-SEKINE, N.1, YOSHIHARA, T.1, OGURA, Y.2, SUGIURA, T.3, POWERS, S.K.4, NAITO, N.1

1: JUNTENDO UNIVERSITY(IINZAI, JAPAN), 2: ST. MARIANNA UNIVERSITY SCHOOL OF MEDICINE (KAWASAKI, JAPAN), 3: YAMAGUCHI UNIVERSITY (YAMAGUCHI, JAPAN), 4: UNIVERSITY OF FLORIDA (GAINESVILLE, USA)

**Introduction:** Alpha-actinin-3 protein and its gene expression become a focus of attention on athletic performance since alpha-actinin-3 protein is restricted to fast fiber in mammalian skeletal muscle. We recently reported that hind-limb unloading increases alpha-actinin-3 expression with slow-to-fast muscle fiber shift in the atrophied rat soleus muscle (Ogura et al., 2009). We have been also reported that mechanical ventilation (MV) rapidly induces muscle atrophy in rat diaphragm which is mainly composed of fast fibres (Powers et al., 2009). Those observations indicate that atrophic stimuli with MV may cause a different response of alpha-actinin-3 protein in diaphragm. Thus, the purpose of this study was to examine the effects of 12-h mechanical ventilation on fibre-specific expression of alpha-actinin-3 protein in rat diaphragm. **Methods:** Adult Wistar rats were randomly divided into either a control (n=8) or a 12-h of MV (n=8) group. Mechanically ventilated animals were anesthetized, tracheostomized, and ventilated with 21% O<sub>2</sub>. Animals in the control group were acutely anesthetized but were not exposed to MV. After the treatment, diaphragms were removed and immunohistochemical detection of muscle fiber type (Type I, Type IIa and Type IIb/dx) and alpha-actinin-3 expression were performed. **Results:** MV resulted in fibre selective atrophy of Type II b/dx in the cross-sectional area (CSA). Percentage of CSA did not change in Type I fibre, whereas that of type II b/dx decreased ( $P < 0.05$ ) after MV. Type I fibres did not express alpha-actinin-3 in all animals. In contrast, alpha-actinin-3 expressed in all of Type II b/dx fibres. Interestingly, alpha-actinin-3 expression were observed in 14% of Type IIa fibres, and this percentage did not change regardless of MV. **Conclusion:** Our results indicated that 1) 12-h of MV has caused selective atrophy of the Type II b/dx fibre, and 2) expression pattern of alpha-actinin-3 protein was not effected by 12-h of MV. **References** Ogura Y, Naito H, Kakigi R, Akema T, Sugiura T, Katamoto S, Aoki J. ## EFFECTS OF CONTINUOUS AND INTERVAL AEROBIC EXERCISE UPON EXPRESSION OF PGC-1 $\alpha$ AND FOXO1 IN HUMAN SKELETAL MUSCLE

POPOV, D.1, ZINOVKIN, R.2, KARGER, E.2, NARYCHEVA, I.1, TARASOVA, O.1, VINOGRADOVA, O.1

1: SRC OF RF – INSTITUTE FOR BIOMEDICAL PROBLEMS RAS (MOSCOW, RUSSIA), 2: A. N. BELOZERSKY INSTITUTE OF PHYSICO-CHEMICAL BIOLOGY (MOSCOW, RUSSIA)

**Introduction** Choosing an optimal aerobic exercise protocol for improving aerobic performance is an important task for endurance training and rehabilitation. The aim of the present study was to compare expression of master regulator of mitochondria biogenesis – PGC-1 $\alpha$ , FOXO1 and PDK4 mRNA in human skeletal muscle after continuous (CE) and interval (IE) aerobic exercise sessions. **Methods** For this purpose the 12 physical active men performed CE (workload at lactate threshold (LT), 50 min) and IE (3 min 81% LT + 2 min 127% LT) x 10 equalized in duration and mean power output. The subjective perception of exertion was evaluated and capillary blood were drawn before and during exercise session for determination of lactate, glucose and free fatty acid concentration. Biopsies were taken from m. vastus lateralis before and 10 min, 1, 3, 5 h after the exercise. **Results** Mean workloads per body weight in CE and IE session were  $2.25 \pm 0.16$  and  $2.23 \pm 0.15$  W (kg of body weight)<sup>-1</sup> accordingly. In IE lactate concentrations just after intensive bout at the 20-th, 30-th, 40-th and 55-th min were significantly higher than lactate concentrations at the same time points in CE. No differences were found between CE and IE in subjective perception of exertion as well as in blood concentrations of glucose and FFA. PGC-1 $\alpha$  mRNA abundance rapidly rose after the first hour of recovery for both CE and IE sessions and did not change between 3 and 5 h after exercise. The increment of PGC-1 $\alpha$  mRNA abundance 3 h after IE session was significantly higher than after CE ( $p < 0.05$ ):  $8.4 \pm 1.0$ - and  $5.6 \pm 0.8$ - fold correspondingly. Significant increments of FOXO1 mRNA were revealed 3h after IE and CE:  $2.1 \pm 0.3$ - and  $1.6 \pm 0.2$ - fold correspondingly. At the 1st h of recovery FOXO1 mRNA abundance after IE was higher than after CE ( $p < 0.05$ ). PDK4 mRNA abundance did not change after both CE and IE sessions. **Discussion** The current study demonstrated that at the transcriptional level IE had higher potential for improvement of mito-

chondrial biogenesis than CE equalized in duration and mean workload. The expression of PGC-1 $\alpha$  mRNA after CE positively correlated with relative workload indicating that the relative intensity of CE is of major importance for exercise-induced rise of PGC-1 $\alpha$  mRNA expression.

**Introduction** In patients with heart failure (HF), the gradient of the slope relating minute ventilation to carbon dioxide production (VE/VCO<sub>2</sub> slope) is greater than normal, so that for a given volume of carbon dioxide production, the ventilatory response is greater.(1-4) Another way of characterising the relation between VE and VCO<sub>2</sub> is the instantaneous ratio of ventilation to carbon dioxide production, the ventilatory equivalent for CO<sub>2</sub> (VEqCO<sub>2</sub>). In normal subjects, VEqCO<sub>2</sub> falls at the outset of exercise and rises toward the end. Patients with mild heart failure exhibit a similar pattern, although those with more severely affected patients, VEqCO<sub>2</sub> increased from the start of exercise.(5) We hypothesised that the time to VEqCO<sub>2</sub> nadir may be an important prognostic marker in patients with HF. **Methods** Left ventricular function was determined from 2D echocardiography and left ventricular systolic dysfunction (LVSD) was diagnosed if LVEF was  $\leq 45\%$ . Patients underwent a symptom-limited, treadmill maximal CPET. We included a healthy control group who had no evidence of cardiorespiratory disease. Results 423 patients with HF (mean age  $63 \pm 12$  years; 80% males; left ventricular ejection fraction  $36 \pm 6\%$ ; peak oxygen uptake  $22.3 \pm 8.1$  mL $\cdot$ kg<sup>-1</sup> $\cdot$ min<sup>-1</sup>; VE/VCO<sub>2</sub> slope  $34 \pm 8$ ) were included in the study. Seventy eight healthy participants (62% males; age  $61 \pm 11$  years) were recruited as controls. One hundred and eighteen patients died during follow-up with a median follow up of  $8.6 \pm 2.1$  years in survivors. Time to VEqCO<sub>2</sub> (nadir) was shorter in patients than controls ( $327 \pm 204$ s v  $514 \pm 187$ s;  $P=0.0001$ ). Time to VEqCO<sub>2</sub> (nadir) was similar as a percentage of the total exercise duration ( $55 \pm 23\%$  v  $60 \pm 17\%$ ;  $P=0.077$ ). The strongest univariable predictors of all-cause mortality were: VEqCO<sub>2</sub> (nadir) ( $\chi^2 = 47.9$ ), peak oxygen uptake ( $\chi^2 = 53.0$ ), VE/VCO<sub>2</sub> slope ( $\chi^2 = 31.7$ ), and time to VEqCO<sub>2</sub> (nadir) ( $\chi^2 = 23.7$ ). In multivariable Cox regression VEqCO<sub>2</sub> (nadir) ( $\chi^2 = 8.8$ ), peak systolic blood pressure ( $\chi^2 = 6.0$ ), age ( $\chi^2 = 6.6$ ) and time to VEqCO<sub>2</sub> (nadir) ( $\chi^2 = 3.8$ ) were the strongest independent predictors of all-cause mortality. **Discussion** The time to VEqCO<sub>2</sub> (nadir) following maximal exercise testing provides additional prognostic information in patients with HF. **References** 1. #### EFFECTS OF INSTITUTIONAL REHABILITATION VERSUS HOME-BASED INTERVAL TRAINING ON PEAK OXYGEN UPTAKE AND HEALTH RELATED QUALITY OF LIFE IN CORONARY ARTERY BYPASS PATIENTS

MOHOLDT, T.1, BEKKEN VOLD, M.2, GRIMSMO, J.2, SLØRDAHL, S.A.1,3, WISLØFF, U.1

1:NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2: THE FEIRING HEART CLINIC, 3: ST.OLAV'S HOSPITAL

**Introduction** Rehabilitation after coronary artery bypass grafting (CABG) is commonly organized as either institutional or home-based exercise training. Aerobic interval training has been shown to be effective in increasing peak oxygen uptake (VO<sub>2</sub>peak) in subjects with cardiovascular disease. We determined the effect a standard institutional rehabilitation program (IR) versus home-based interval training (HINT) upon VO<sub>2</sub>peak. **Secondary outcome measures** were health related quality of life (QoL) and blood markers of cardiovascular disease. **Methods** CABG (n = 26) patients were randomised to either IR (n = 14) or HINT (n = 12), 7.5 (SD 2) weeks postoperatively. VO<sub>2</sub>peak was tested on treadmill at baseline and again six months later. We used the heart disease specific Mac New questionnaire of health related quality of life (QoL). Blood was sampled after overnight fasting. The IR group stayed at a rehabilitation centre for four weeks and followed a standard rehabilitation program of exercise and education about healthy lifestyle. At discharge they received individualised home exercise prescriptions and were telephone monitored twice during the follow up period. The HINT group received information on how to do aerobic interval training at home (4 x 4 minutes of exercise with 85-95% of individual heart rate maximum, 3 times per week for six months). They were asked to register the amount and intensity of exercise. HINT received no formal supervision during follow up. **Results** Both groups increased VO<sub>2</sub>peak ( $p < 0.005$ ); IR from  $25.6$  (SD  $4.0$ ) mL/min/kg to  $30.2$  (SD  $4.3$ ) mL/min/kg and HINT from  $23.8$  (SD  $5.4$ ) mL/min/kg to  $27.7$  (SD  $6.5$ ) mL/min/kg with no significant difference between the groups ( $p = 0.51$ ). The physical and social domains of QoL increased significantly in both groups, with no differences between the groups. High density lipoprotein (HDL) increased significantly only after IR, from  $1.1$  (SD  $0.3$ ) mmol/l to  $1.4$  (SD  $0.2$ ) mmol/l ( $p=0.03$ , group difference  $p = 0.021$ ). In the HINT group all patients reported to have exercised 4.0 (range 2-7) times per week, 41% of these exercise sessions was interval training with high intensity. **Conclusion** IR and HINT gave equal increases in VO<sub>2</sub>peak and QoL six months after baseline. HDL increased more after IR. This study implies that CABG patients may administer a home-based exercise program of aerobic interval training and that compliance is good.

#### COMPARISON OF BASELINE VALUES OF TOTAL SERUM NITRITE/NITRATE IN SEDENTARY OBESE AND PRE-OBESE MALE SUBJECTS, WITH OR WITHOUT TYPE 2 DIABETES

KRAUSE, M.1,2, O'HAGAN, C.3, RODRIGUES-KRAUSE, J.1,2, DE VITO, G.3, BOREHAM, C.3, NEWSHOLME, P.2,3, COLLERAN, G.1, MURPHY, C.1

1BIOMEDICAL RESEARCH GROUP, DEPARTMENT OF SCIENCE, ITT DUBLIN, IRELAND; 2SCHOOL OF BIOMOLECULAR AND BIOMEDICAL SCIENCE CONWAY INSTITUTE AND 3INSTITUTE FOR SPORT AND HEALTH, UCD, IRELAND

**Introduction** It is now widely accepted that hypertension and endothelial dysfunction are associated with an insulin resistant state, and thus with the development of Type II diabetes mellitus (T2DM). Insulin signalling is impaired in target cells and tissues, indicating that common molecular signals are involved. Nitric oxide (NO) regulates cell metabolism, insulin signalling and secretion, vascular tone, neurotransmission and immune system function. NO<sub>2</sub> synthesis is essential for vasodilation, the maintenance of blood pressure and glucose uptake. Consequently, reduced NO<sub>2</sub> results in insulin resistance and hypertension. Therefore, the aim of this study was to com-

pare metabolic parameters and tNOx levels (an indirect measurement of NO<sub>1</sub> synthesis) in obese and pre-obese individuals with and without T2DM. Methods Fourteen sedentary male subjects [6 obese controls (C) vs. 5 obese and 3 pre-obese T2DM; age 54±9 years] were selected according to their BMI [≥30kg/m<sup>2</sup> for obese and 25-27kg/m<sup>2</sup> for pre-obese subjects (WHO, 2004)] and were evaluated for fasted values of blood glucose, HbA1c, lipid profile, plasma glycerol levels, serum insulin, CRP and tNOx. Body composition was measured by DEXA and VO<sub>2</sub>max was estimated with a submaximal incremental treadmill test. Results Fasting glucose (C=5.2±1.2 vs. T2DM=7.0±0.89 mmol/L), HbA1c (C=6.0±0.2 vs. T2DM=7.3±0.5%) and serum insulin (C=11.1±5.4 vs. T2DM=30.9±12.5 µU/L) were higher in T2DM, as expected. Obese T2DM demonstrated lower levels of tNOx (C=21.1±2.4 vs. T2DM=12.7±3.5 µM). Interestingly, in pre-obese T2DM a higher level of tNOx was observed when compared with controls and obese T2DM (33.8±7.2 µM). No differences in glycerol, CRP and estimated VO<sub>2</sub>max were found. Discussion The fact that pre-obese T2DM have higher while obese T2DM have lower levels of tNOx could, at least in part, provide a link between obesity, T2DM, insulin resistance and hypertension as previously hypothesized [1]. Our preliminary results indicate that elevated nitric oxide levels associated with pre-obese individuals may counter the adverse affects of adipose tissue derived inflammatory factors which are major factors in the development of cardiovascular complications, insulin resistance and beta-cell failure in associated with obesity. This hypothesis is now under investigation. References 1. Newsholme P, Homem De Bittencourt PI, O'Hagan, C., De Vito G, Murphy C, Krause MS. Clin Sci (Lond) 118: 341-349, 2010.

### EFFECT OF AEROBIC TRAINING ON PLASMA ADIPONECTIN CONCENTRATIONS IN OBESE WOMEN.

LAKHDAR ATTIA, N., DENGUEZLI, M., BENAÏSSA, N., ZBIDI, A., TABKA, Z., BOUASSIDA, A.

LABORATORY OF CARDIO-CIRCULATORY, RESPIRATORY, METABOLIC AND HORMONAL ADAPTATIONS TO MUSCULAR EXERCISE, FACULTY OF MEDICINE IBN EL JAZZAR, 4002 SOUSSE

Introduction Adipose tissue secretes multiple proteins known as adipocytokines that modulate various biological functions. One of these adipocytokines is adiponectin, which is reduced with obesity, which increases insulin resistance, dyslipidaemia and diabetes. (Mujumdar et al. 2011). Hence, the aim of this study was to analyse the effect of aerobic training for 12 weeks on plasma adiponectin concentrations and metabolites. Methods Twenty-four obese women (age, 35-41 years; BMI, 32.2 ± kg/m<sup>2</sup>) took part to the study. Participants were divided in three groups: diet group (D; -500 kcal.day<sup>-1</sup>, n=8), aerobic exercise group (E; n=8), aerobic exercise + diet group (E+D; n=8). Subjects underwent a 12 week training program (4days/week, 60 min.day<sup>-1</sup>) at 50-70 % of VO<sub>2</sub> peak. Fasting plasma levels of adiponectin and lipids were measured in all subjects before and after the program. 3 Result In the three groups we showed a decrease in body weight (P<0.05), BMI (P<0.05), % Fat (P<0.05), HDL-cho (P<0.05) but we detect an increase in VO<sub>2</sub> max in group E (21.18%; P<0.05) and in group E+D (25.19 %; P<0.05). Adiponectin levels increased significantly in the D (P<0.05), E (P<0.05) and E+D groups (P<0.01). In the subjects of the E+D group, adiponectin levels exhibited a significant negative correlation with body mass (-0.52; P<0.01). Furthermore in the D group, significant correlations were observed between adiponectin levels and body mass (r=-0.42; P<0.05) and between the TC/HDL-C ratio and body mass (0.36; P<0.05). Discussion Our results are in agreement with the results of the study of Nuamo et al. (2010), who have shown that aerobic exercise intensity alters adiponectin concentrations in middle-aged obese men. Elloumi et al. (2009) demonstrated also that exercise training combined with energy restriction increases adiponectin levels. On the other hand, several authors have shown that circulating adiponectin did not change whereas a decrease in body mass, fat mass and an increase in cardio respiratory fitness were noticed (Dvorakova-Lorenzova et al. 2006). These findings show that the combined program of diet restriction and aerobic exercise training is necessary to improve body mass loss, adiponectin levels, as well as metabolic parameters in obese women. ### IMPACT OF EXERCISE TRAINING AND/OR DIET ON THE LIPOPROTEIN-LIPID PROFILES IN YOUNG OVERWEIGHT MALES

SABBAGHIAN RAD, L.1, LOTFIPOUR, M.2

(1) SHARIF UNIVERSITY OF TECHNOLOGY, TEHRAN, IRAN (2) TEHRAN UNIVERSITY, TEHRAN, IRAN

This study examined the independent and combined effects of exercise training, weight loss and changes in dietary quality on the serum lipid profile in sedentary, healthy and overweight young men. 106 men 18-25 y with BMI>25 were randomly assigned to four groups, Control (C), Diet (D), Exercise (E) and Exercise and Diet (ED). Height, weight, percent body fat (BF%), TC, HDL-C, TG and LDL-C were measured before and after an 8-week intervention period. Subjects in the two exercise groups walked five times a week, 45 minutes per session, at 60-80% of maximum heart rate (MHR). Duration and intensity of exercise were gradually increased over a three week period from 25-30 minute/sessions at 60% to 65% of MHR during week 1 to 45 minutes at 70% to 80% MHR from weeks 4 through 8. Subjects in the two non-walking groups (control and diet) reported to the exercise facility five days per week for 45 minutes of stretching and mild range of motion calisthenics. The intent was to keep heart rate below 100 beats per minute. One-way ANOVA was the statistical test (α= 0.05). Relative to control group, the ED and D groups displayed a 4.6% and 3.9% reduction in body mass, 10 and 7% reduction in BF%, 31 and 28% reduction in TG. LDL-C fell by 14% in ED group. For each kg of weight loss there was a decrease of 0.06, 0.03 and 0.017 mg/dL in TC, LDL-C and TG respectively. No change of body mass occurred in E group. Exercise alone was insufficient to stimulate change in any lipid or lipoprotein measures. These results demonstrated that weight loss mostly was due to diet, because the exercise was the same in groups E and ED. The lipid profile improved and body mass decreased.

#### WORKLOAD AND RACE STRATEGY: A COMPARISON BETWEEN THREE DIFFERENT COMPETITIONS LASTING THREE TO SEVEN DAYS.

WEYDAHL, A., CALOGIURI, G.

FINNMARK UNIVERSITY COLLEGE

WORKLOAD AND RACE STRATEGY: A COMPARISON BETWEEN THREE DIFFERENT COMPETITIONS LASTING THREE TO SEVEN DAYS. Weydahl, A. 1, Calogiuri, G. 1 1: HiF (Alta, Norway) Introduction Finnmarksløpet (FL) is Europe's longest sled dog races, with a 1000km and 500km category. The race lasts up to 7-days; the 'mushers' are physically active most of the time, with little and fragmented rests. The same is the situation in the 700km biking event OffroadFinnmark (OF), taking about 5-days. The intensity and distribution of activity and rests (race strategy) determine the success in the race. Physical training that aims to improve the special abilities required, increase the chance of winning and reduce the risks of accidents, injuries, and avoid overloading the dogs. The aim of this study was to describe the athletes' workload in these competitions (FL500km, FL 1000km, and OF 700km), and the strategy that they used in the race. Methods Heart rate (HR) was continuously recorded using HR-monitor in 5 participants at the FL500km, 5 at the FL1000km, and 6 at the OF700km. Maximal oxygen consumption and peak HR were measured about a week before the competitions started. The HR data were processed using Microsoft Excel. The official race reports have been used for separating the 'active parts' (AP= while the athletes were active on the trail and working with the equipment) from the 'resting parts' (while the athletes were resting in the check-points). The data have been studied macroscopically at first, observing the distribution of the effort across the different tracks of the race. Student's t-test has been used to compare parameters describing the workload in the different competitions Results The bikers (OF) spent shorter time in the check-points (22% of the total race time) compared with the mushers (FL) (ab. 40%). The OF had long rests (>3-hours) in 31% of the check-points, while the FL500km and FL1000km had long rests in 67% and 75% of the check-points. Nevertheless in all the races the participants had the chance to sleep for about 3/4-h per day. The overall HR (mean±SD) in AP, was significantly higher for the OF and the FL500km ( $62.42 \pm 10.34$  and  $60.36 \pm 5.47$  respectively) than the FL1000km ( $50.78 \pm 2.67$ ). The FL500km had a higher range of HR in AP ( $8.61 \pm 0.66$ ) compared with the OF ( $5.92 \pm 1.22$ ), no significant difference was found compared to the FL1000km ( $9.08 \pm 3.80$ ). In all the races, the HR decreased across the competition, the closer to the arrival the lower the HR values. Discussion These competitions present big differences in terms of race-strategy and type of workload. It is not clear if the reduction of the HR values across the competitions is caused by physiological adaptation, physical exhaustion or reduction of motivation because the placing is obvious because of the distance to the closest competitor. This study provides information about HR in response to strenuous tasks as well as helpful indications in order to plan training and race strategy.

#### EFFECTS OF LOW AND HIGH-CADENCE INTERVAL TRAINING ON POWER OUTPUT IN FLAT AND UPHILL CYCLING TIME-TRIALS

NIMMERICHTER, A.1,2, ESTON, R.1, BACHL, N.2, WILLIAMS, C.1

1UNIVERSITY OF EXETER, 2AUSTRIAN INSTITUTE OF SPORTS MEDICINE

Introduction The majority of interval training studies are conducted on ergometers to control external variables and exercise intensity. The differences between laboratory and outdoor cycling have been discussed recently (Jobson et al., 2007) suggesting different physiological demands. With the use of mobile power meters, exercise intensity can be monitored in the field, which improves the ecological validity of the measurements. This study tested the effects of low-cadence (60 rpm) uphill (Int60) or high-cadence (100 rpm) level-ground (Int100) interval training on power output (PO) during 20-min uphill (TTup) and flat (TTflat) time-trials as well as on performance during a laboratory graded exercise test (GXT). Methods Eighteen male cyclists ( $\text{VO}_{2\text{max}}$ :  $58.6 \pm 5.4$  mL/min/kg) were randomly assigned to Int60, Int100 or a control group (Con). The interval training comprised of two training sessions per week over 4 weeks, which consisted of 6x5 min at the PO corresponding to the respiratory compensation point (RCP). For the control group, no interval training was conducted. During the interval training sessions and the time-trials, PO was measured with mobile power-meters (SRM). Results A two-factor ANOVA revealed significant increases on performance measures obtained from GXT ( $P_{\text{max}}$ :  $2.8 \pm 3.0\%$ ;  $p < 0.01$ ; PO and  $\text{VO}_2$  at RCP:  $3.6 \pm 6.3\%$  and  $4.7 \pm 8.2\%$ , respectively;  $p < 0.05$ ), with no significant group effects. Significant interactions between group and uphill and flat time-trial, pre vs. post-training on PO were observed ( $p < 0.05$ ). Int60 increased PO during both TTup ( $4.4 \pm 5.3\%$ ) and TTflat ( $1.5 \pm 4.5\%$ ). The changes were  $-1.3 \pm 3.6\%$ ,  $2.6 \pm 6.0\%$  for Int100 and  $4.0 \pm 4.6\%$ ,  $-3.5 \pm 5.4\%$  for Con during TTup and TTflat, respectively. PO was significantly higher during TTup than TTflat ( $4.4 \pm 6.0\%$ ;  $6.3 \pm 5.6\%$ ; pre and post-training, respectively;  $p < 0.001$ ). Discussion The performance improvements during TTup and TTflat have shown specific adaptations in response to the interval training sessions and indicate the ecological validity of the time-trials. The application of higher pedaling forces via low cadences provides a potentially higher training stimulus with a cross-over effect to flat time-trials. When evaluating power output data or prescribing training zones, it is important to note that trained cyclists are able to produce higher power outputs during uphill compared to flat time-trial conditions. #### RELATION BETWEEN LACTATE MINIMUM AND MAXIMAL LACTATE STEADY STATE IN RUNNING AND CYCLING: A MATTER OF MUSCLE MASS?

PERRET, C.1, HARTMANN, K.2

1INSTITUTE OF SPORTS MEDICINE, SWISS PARAPLEGIC CENTRE, NOTTWIL

Introduction: The heart rate-based lactate minimum test (LMT-HR) is a highly reproducible exercise test to determine individual training intensity zones based on heart rate recommendations (Strupler et al., 2009). However, in contrast to wheelchair athletics (Perret et al., 2007), it is still not clear what the relation between the lactate minimum (LM) determined by a LMT-HR and the maximal lactate steady state (MLSS) in running and cycling is and if this relationship depends on exercising muscle mass involved. The aim of the present study was to specify these circumstances. Methods: 12 healthy, endurance trained male subjects (age:  $38 \pm 6$  y; height:  $181 \pm 5$  cm; weight:  $77 \pm 6$  kg; training volume:  $9 \pm 3$  h/wk) participated in the study. They performed a LMT-HR on a treadmill and on a cycle ergometer. Addition-

ally, several endurance exercise tests were performed to determine exercise intensity at MLSS for both modes of exercise. Data for heart rate, power output, lactate, oxygen uptake and rating of perceived exertion at LM, MLSS as well as at maximal performance level were used for analysis. Results: All measured parameters (heart rate, power output, lactate, oxygen consumption, rating of perceived exertion) revealed significantly higher values at MLSS compared to LM for both types of exercise. However, significant correlations between MLSS and LM for heart rate (running:  $r=0.809$ ,  $p<0.01$ ; cycling  $r=0.830$ ,  $p<0.01$ ) and power output (running:  $r=0.813$ ,  $p<0.01$ ; cycling:  $r=0.818$ ,  $p<0.01$ ) were found. Peak heart rate and peak oxygen uptake were significantly higher for running compared to cycling. However, the amount of exercising muscle mass seemed to have no influence on relative (expressed as percentage of maximal values) heart rate at LM in running and cycling ( $88.6\pm2.2$  vs.  $87.2\pm2.1\%$ ,  $p=0.099$ ) in contrast to relative power output data ( $70.0\pm3.3$  vs.  $55\pm4.2\%$ ,  $p=0.002$ ). Discussion: Using different exercise modes the amount of exercising muscle mass seems to influence peak heart rate and peak oxygen uptake, but not the relationship of relative heart rate values between LM and MLSS. In conclusion, the LMT-HR seems to be a helpful tool to accurately determine exercise intensity at MLSS for running and cycling with one single exercise test and allows the determination of individual training intensity zones and training recommendations. For daily clinical practice it can be assumed that heart rate at MLSS is 10-12 bpm above heart rate at LM. References: Perret C, Labruyère R, Mueller G, Strupler M. ## EFFECTS OF 12-MONTH ENDURANCE TRAINING ON HAEMOGLOBIN MASS IN 16, 21, AND 28-YEAR-OLD ELITE ENDURANCE ATHLETES

STEINER, T., WEHRLIN, J.P.

SWISS FEDERAL INSTITUTE OF SPORTS (SFISM)

**Introduction** It is well known that elite endurance athletes are characterised by considerably higher levels of relative haemoglobin mass (Hbmass) than untrained subjects. However, it is unclear whether these high levels are due to several years of endurance training, are due to a manifestation of optimal inherited characteristics, or a combination of both. Since lower Hbmass levels for 16-year-old athletes in comparison to adult elite athletes were observed, it has been suggested that the age period from 16 to 21 years is a sensitive phase to elevate Hbmass with endurance training (Steiner & Wehrlin, 2011). The aim of this study was, therefore, to study the effects of a 12-month endurance training period on haemoglobin mass in 16, 21 and 28-year-old athletes. **Methods** Hbmass (CO-rebreathing) was assessed three times (T1-T3) with a time span of 6 months between the measurements in elite cross-country skiers and elite triathletes in an age-stratified sample: AG16 (athlete group with mean age 16),  $n=14$ , 6.6 h/week endurance training; AG21,  $n=12$ , 13.9 h/week; AG 28,  $n=14$ , 13.6 h/week. The same measurements were also performed in 3 age-matched control groups (CG16,  $n=14$ ; CG21,  $n=14$ ; CG28,  $n=15$ ) with < 1 h/week endurance training. **Results** Relative Hbmass (g/kg) at T1 did not differ between AG16 ( $12.4 \pm 0.8$ ) and CG16 ( $12.1 \pm 1.0$ ). AG21 ( $14.3 \pm 1.1$ ) and AG28 ( $14.7 \pm 1.2$ ) disclosed higher Hbmass levels than AG16 ( $p<0.01$ ). Hbmass levels of CG21 ( $12.6 \pm 1.0$ ) and CG28 ( $12.2 \pm 1.0$ ) did not differ from CG16. Overall, absolute and relative Hbmass increased ( $p<0.01$ ) over the 12-month period but the changes in relative Hbmass (g/kg/year) did not differ statistically among the 6 subgroups. They were +0.57 (AG16), +0.29 (CG16), +0.08 (AG21), +0.26 (CG21), +0.29 (AG28), and +0.15 (CG28). Higher changes in absolute Hbmass from 16 to 17 years of age were observed than in adult subjects ( $p<0.05$ ). The change rates were highly individual, especially among the 16-year-old subjects. **Discussion and Conclusion** Absolute Hbmass of 16-year-old subjects did not increase more than could be explained by increased body weight due to maturation. High endurance training volumes appeared to have no additional influence on the development of Hbmass over a one-year training period, irrespective of age and initial Hbmass levels. However, it is unclear whether a longer time period of observation, especially between 16 to 21 years of age, would have shown a training effect on Hbmass. High increase rates of Hbmass around age 16 (due to yet unknown factors) seem to play an important role to develop high Hbmass levels in adulthood. **References** Steiner T and Wehrlin J (2011). *Med. Sci. Sports Exerc.* (Epub: February 8, 2011; in press).

## OXYGEN CONSUMPTION AND ENERGY EXPENDITURE DURING ENDURANCE TRAINING IN TEAM SPORT ATHLETES

FRANKE, J., HINRICHS, T., PLATEN, P.

RUHR-UNIVERSITY BOCHUM

**Introduction:** The importance of aerobic endurance in team sports has frequently been evaluated. Two commonly used training methods in this context are long-lasting endurance runs as well as high intensity interval runs. Results of interventional studies comparing the two methods showed equal effects on endurance performance enhancement. The aim of this study was to analyse oxygen consumption and energy expenditure as possible factors of aerobic adaptation to both training methods. **Methods:** 43 players (22 male, 21 female) from 3 team sports (12 basketball, 10 soccer, 21 handball) were investigated. They completed a VO<sub>2</sub>max-Test (including determination of maximal heart rate (HR<sub>max</sub>)) and a field test for calculating run velocity at 4 mmol l<sup>-1</sup> lactate (v<sub>4</sub>). From these results individual training regimes for extensive run training (ET, 45 min at 75% of v<sub>4</sub>) and high intensity interval training (IT, 4x4 min at 95% of HR<sub>max</sub>) were defined. Each player completed one training session ET and one training session IT in a randomised order. Training intensity was controlled via heart rate measurement. During both training sessions O<sub>2</sub> and CO<sub>2</sub> were continuously measured using a portable spirometry system. Energy expenditure (EE) was calculated using the modified de Weir equation:  $EE = 3.94VO_2 + 1.11VCO_2 - 2.17 UN$  (Takala & Meriläinen 1991). **Results:** VO<sub>2</sub>max (ml min<sup>-1</sup>kg<sup>-1</sup>) values for the players were: male:  $45.3\pm3.5$ ; female:  $41.6\pm6.1$ , v<sub>4</sub> (ms<sup>-1</sup>) were: male:  $3.7\pm0.3$ ; female:  $3.3\pm0.2$ . There was no effect concerning the sport the players belonged to. Mean oxygen consumption (VO<sub>2</sub>) was significantly higher for 45 min ET ( $133.0\pm25.5$  l-l) compared to 32 min IT ( $86.0\pm15.3$  l-l). Calculated EE was also significantly higher in ET ( $620\pm121$  kcal) compared to IT ( $401\pm75$  kcal). Significant differences persisted when comparing the two training methods for the same amount of time (50 min, warm up included). A slight decrease of VO<sub>2</sub> while exercising was observed for men and women in both training methods. **Conclusion:** ET expends more VO<sub>2</sub> and higher EE compared to IT. As previous studies have shown a similar effect of the two methods on endurance performance, VO<sub>2</sub> and EE do not seem to be the major influencing factors for adaptation. Other parameters (e.g. time spent at VO<sub>2</sub>max) seem to be superior. Because of decreasing VO<sub>2</sub> during exercise, intensity control via HR seems to be questionable. The sympathetic nervous activation induces less effort for the player to reach the given heart rate zone after the first interval. **References:** Takala, J. & Meriläinen, P. (1991). ## RESPIRATORY MUSCLE TRAINING DOES NOT IMPROVE SIMULATED SKIING PERFORMANCE IN PARALYMPIC NORDIC SKIERS

BHAMBHANI, Y.1, CRAVEN, B.2, FORBES, S.1, FORBES, J.1, ROGERS, C.3

1: U OF A (EDMONTON, CANADA), 2: SMSCS (SASKATCHEWAN, CANADA), 3: U OF S (SASKATCHEWAN, CANADA)

**Introduction** Respiratory muscle strength and endurance training has been reported to improve ventilatory capacity and endurance performance in competitive wheelchair racers (Litchke et al., 2007; Mueller et al., 2008). Currently the effects of respiratory muscle endurance training (RMET) on endurance performance in Paralympic Nordic Skiers (PNS) have not been examined. This study tested the hypothesis that RMET would significantly improve ventilatory capacity and simulated Nordic skiing performance in PNS. **Methods** Six Canadian PNS (2 paraplegia, 1 visually impaired, 1 guide and 1 amputee) completed a: (1) spirometric evaluation, (2) 12 min respiratory muscle capacity test (RMC), and (3) 12 min simulated Nordic skiing performance test (SNSP) prior to and after a 12 weeks RMET performed at 60% MVV, 2 to 3/week using a Spirotiger (Fact Canada Consulting Ltd.). Cardiorespiratory responses were monitored during SNSP while sitting or standing on a double poling ergometer (Alsobrook & Heil, 2009) depending upon the disability. Near infrared spectroscopy was used to noninvasively measure muscle oxygenation of the Triceps (Tmox) and serratus anterior (SAmox) during the RMC and SNSP. Finger prick blood lactate (BLa) was measured 3 minutes post exercise. **Results** Average RMET frequency was 1.8 sessions/week. There was no significant ( $P > .05$ ) improvement in spirometric variables post training. Although RMET significantly ( $P < .05$ ) increased RMC by 11%, there was no significant ( $P > .05$ ) improvement in SNSP. RMET significantly ( $P < .05$ ) decreased SAmox (greater extraction) during the RMC by 14%. Oxygen uptake ( $\dot{V}O_2$ ), heart rate (HR),  $\dot{V}E/\dot{V}O_2$  ratio, BLa, Tmox and SAmox during SNSP were unchanged ( $P > .05$ ) post training. **Discussion** Although RMET significantly improved RMC and SAmox, the greater respiratory capacity did not translate into enhanced SNSP in these Paralympic athletes. The fact that  $\dot{V}O_2$ , HR,  $\dot{V}E/\dot{V}O_2$  ratio and BLa were unchanged implies that overall cardiorespiratory and metabolic efficiency was unaltered by RMET. These observations are in contrast to previous findings (Mueller et al., 2008) which showed significant improvements in wheelchair racing performance in paraplegics following RMET. The lack of improvement in performance in this study could be due to the athletes' forward crouching posture during the simulated race which compromised their ability to fully inflate the lungs during the SNSP. **Acknowledgments** Funding: Own The Podium, Canadian Olympic Committee, 2007. **References** Alsobrook N G & Heil D P. ### IS-BN07 Soccer Footwear and Surface: Performance and Injury

#### KICKING MECHANICS IN SOCCER: HOW DOES IT CHANGE AFTER FATIGUE?

NUNOME, H.

NAGOYA UNIVERSITY

**Introduction** Kicking is the most widely studied skill in soccer. However, the kicking mechanics: kinematics and kinetics has been obscured by inadequate data treatment around ball impact [2,3]. On the other hand, the ball kicking action itself can be categorized as having a significant injury risk [4]. It can be assumed that an induced leg muscle fatigue towards the end of the match somehow disturbs maximal kicking performance and also leads to a less coordinated kicking motion, thereby making players more susceptible to injury. Our research group made a series of attempts to conduct a comprehensive analysis of the kicking mechanics and how it changes when soccer players are fatigued [1]. **Methods** A series of experiments was conducted: 1) The motion before, during and immediately after ball impact was captured (1000 Hz) and smoothed by a modified version of a time-frequency filtering to illustrate a comprehensive shank kinematics. 2) The muscle moment and motion-dependent interactive moment were computed to demonstrate the segmental interaction of the kicking leg. 3) To extract the effect of fatigue on kicking motion, a comparison was made for the kicking leg kinetics between before and immediately after leg muscle fatigue was induced. **Kinematics** In contrast to conventional data, the shank was still angularly accelerating until ball impact. The data strongly supports coaches' practical advice of kicking such as 'kick through the ball'. **Kinetics** Immediately before ball impact, the knee muscle moment decreased rapidly and began to exhibit a reverse moment. In contrast, the motion-dependent interactive moment increased rapidly in magnitude until ball impact. It can be assumed that this moment is a key to angularly accelerate the shank during the final phase of kicking. **Effect of fatigue** A reduced leg swing speed was most likely due to a significantly reduced muscle moment and motion-dependent interactive moment during kicking. These results suggest that muscle fatigue not only diminished the ability to generate force, but also disturbed the effective action of the interactive moment leading to poorer inter-segmental coordination. This could be caused by a reduced eccentric action of the knee flexors immediately before ball impact. This might increase the susceptibility to injury. **References** 1. Aprianono, T., et al. #### INJURY OCCURRENCE AND FOOTWEAR PERFORMANCE ON ARTIFICIAL SOCCER TURF

STERZING, T.

LI NING SPORTS GOODS CO., LTD.

**INJURY OCCURRENCE AND FOOTWEAR PERFORMANCE ON ARTIFICIAL SOCCER TURF** Sterzing, T. Li Ning Sports Science Research Center (Beijing, P.R. China) **Background** Since the 1960s artificial soccer turf (AST) has been controversially discussed in relation to game characteristics, injuries and, recently, also with respect to footwear. The structure of current AST (3rd generation) is characterized by a sand and rubber infilled fiber carpet covering an elastic bottom layer. In 2004 AST was included in the FIFA rules of the game as official match play surface, subject to compliance with FIFA 2star performance standards. **Injury Occurrence** Increased injury occurrence in game and practice used to be major problem of the earlier generations of AST (Arnason et al. 1996). In contrast, research shows no differences with respect to injury frequency and severity on 3rd generation AST. However, it is reported that injury types may differ as Ekstrand et al. (2006) observed more ankle sprains on AST. Thus, further investigations with respect to injury occurrence and injury type are required. **Footwear Performance** Athletic footwear function highly depends on the surface on which it is used. Hence, the implementation of AST forced the footwear industry to initiate corresponding research, especially with respect to potentially new requirements for outsole traction. **Innova-**

tive AST shoes were shown to provide superior athletic performance and biomechanical characteristics which was matched by players' perception (Sterzing et al. 2010). Additionally, the innovative footwear decreased ankle eversion joint moments during soccer specific turning movements compared to firm and soft ground shoes designed for natural grass (Müller et al. 2010). Based on those findings, it is suggested that AST footwear should use a rather high number of relatively low stud elements. Discussion Soccer injuries, AST and footwear characteristics are often directly related to each other in the public discussion. However, prospective scientific studies that investigate and provide proof of these relationships are missing. Therefore, injury risk and lower extremity loading in soccer as well as their potential interaction need to be further examined. Thereby, the concept of mechanically available versus biomechanically utilized friction during shoe ground interaction plays an important role. It illustrates the sensory motor skills of athletes to adapt their sport specific movement patterns according to varying circumstances. ## **SOCCER SHOE DESIGN AND ITS INFLUENCE ON KICKING ACCURACY AND MAXIMUM BALL SPEED**

HENNIG, E.M.

UNIVERSITY OF DUISBURG-ESSEN

Introduction Soccer is the most played, most watched and most revenue-generating sport. For players to be successful they need high skill levels in handling the ball. Quickness on the field has become increasingly important in recent years. Footwear plays a central role in helping the player to perform fast movements on the field, providing comfort, and protecting the foot. Performance Criteria of Soccer Shoes A questionnaire, sent out to 250 male soccer players, revealed the most desirable features that soccer players expect from their shoes (Hennig, 2006). Comfort was the most wanted shoe quality, followed by traction, and shoe stability. Surprisingly, protection against injuries had a low priority in the catalogue of desired shoe features. It appears that players are much more concerned about performance aspects of the shoe rather than protection. Therefore, light weight and low cut shoes, which provide good traction for fast movements, are best liked by players in modern soccer. Few soccer players, however, believe that a shoe can improve their kicking accuracy and/or maximum ball velocity. Influence of Shoe Design on Maximum Ball Velocity Several shoe features influence maximum ball speed during full-instep kicks in a complex manner. In a series of studies Sterzing and Hennig (2008) showed that maximum ball speed is influenced by the type of shoe. Surprisingly, soccer players achieve equal or even higher maximum ball velocities with their bare feet. Cinematographic analyses show that players have an increased foot plantarflexion during barefoot kicks, thus allowing a stronger mechanical coupling between the foot and lower leg. The increased effective impacting mass of the lower leg may explain this finding. Shoe Design and Kicking Accuracy It is common knowledge that an increased string tension of a tennis racket results in a better accuracy of ball placement on the tennis court. However, few soccer players believe that their shoe could also help them to perform kicks with more precision. In a series of studies we could show that shoe design has an influence on kicking accuracy. Whereas barefoot kicking resulted in least precision, certain shoe upper features provided an improvement in kicking accuracy. A more homogenous pressure distribution between the shoe upper and the ball was identified as the main factor for an improvement of kicking precision. Conclusion Footwear design can influence maximum ball velocity and kicking accuracy. Especially, an increased precision of passing and for kicks on goal will help soccer players to improve their performance on the field. ## **Invited symposia**

### **IS-PM11 ACSM Exchange symposium: Sports Specialization in Children, When Do We Start?**

#### **U.S. PERSPECTIVE: IS THE MICHAEL PHELPS TRAINING MODEL 'ALL WET'?**

MILLARD-STAFFORD, M.

GEORGIA INSTITUTE OF TECHNOLOGY

Over the past several decades in the United States, there has been a paradigm shift in both the philosophy and organization of competitive youth sports. Following World War II and the evidence that American youth were unfit compared to their European counterparts, youth sport leagues became increasingly available within many sectors (e.g. religious affiliated youth leagues, boys' and later girls' organizations, and the educational system). However, with the decline of both the quality and quantity of physical education in the school systems across all levels (elementary through secondary education), opportunities for sport participation in American youth has become increasingly limited to sport-specific clubs. Sport clubs are administered by their respective sport governing organization, each of which may differ dramatically in their respective requirements for coaching licensure and rules governance for the sport. No central governing body (such as the US Olympic Committee) or federal governmental agency provides support or direct oversight for clubs. Therefore, as clubs rely upon athletes' paid dues to remain financially solvent, it is commonplace for club coaches to demand sport specialization at increasingly early ages (8-10 yrs). The rise of youth sport specialization is fuelled by successful case studies (e.g., Michael Phelps at age 11 accurately identified by his coach as a future Olympic superstar), potential for financial rewards (from major sponsorships to college scholarships), overzealous parents who invest in the philosophical approach espoused by coaching dogma related to early skill acquisition and training volume. The pressure for the child to "select" their sport well before puberty appears to be the new norm in American Youth Sport culture. The key question is: what is the evidence that early sport specialization is safe, effective or advantageous? The evidence related to health and safety of youth athletes who specialize prior to growth and maturation is primarily limited to sports where maturation adversely affects performance (e.g. girls' gymnastics), overuse injuries related to growth plates (e.g. pitch counts in Little League baseball). New areas of concern have emerged such as long term exposure to chloramine gas and a link with asthma in elite swimmers. Data regarding generational trends in Masters' swimmers will be presented. There is clearly a need to provide empirical data on safe training practices in youth related to specific limits relative to volume, intensity, and frequency of training (Adolescent Athlete and the Team Physician: A Consensus Statement, *Med. Sci. Sports Exerc.* 2008) and competition to prevent overtraining and psychological "burn-out". The obesity epidemic in the US calls for a re-examination of this paradigm shift back towards a broader base of opportunity and support for children to reap health benefits of participation and skill-development across multiple sports.

**YOUTH COMPETITIONS: OPTIMAL DEVELOPMENT OF THE YOUNG ATHLETE?**

CAPRANICA, L.

*UNIVERSITY OF ROME FORO ITALICO*

Worldwide young athletes participate in sport academies and only a select few will achieve elite level due to both innate talent and deliberate practice. The psycho-physiological load and the technical aspects of youth performance vary in relation to the age and technical level of the young athletes. Therefore, it is not possible to generalize information gathered on elite athletes to young ones. In considering that competitions pose a high load on athletes, the main principle adhered to in most sport Federations is to preserve children from an excessive psycho-physiological strain. For this reason, youth competitions might apply simplified rules and reduced match duration in relation to the age of the children. However, there is a need of information on the actual requirements of different youth codes and to develop strategies aimed to promote the potential of children. Thus, the examination of youth athletes during their actual match play might increase the relevance and the applicability of the results. Because several parameters essentially influence performance, individual and team sport official youth competitions have been examined using a multidisciplinary approach, which included technical-tactical, psychological, and physiological contributions to the youth performance. Independently from match duration and pitch dimension, findings indicate that youth matches pose a high load on youth competitors similar to that observed in elite athletes. However, situational and contextual factors vary considerably between matches played by young and elite athletes. Thus, notational and match analyses that consider a wide multiplicity of movement patterns and decision-making aspects proved to be effective in providing advances in the understanding of youth sport and guidance for coaches in directing training goals. In particular, the hypothesis that competitions organized with a reduced number of players and pitch dimensions facilitate the technical and tactical aspects of play and enhance the development of sport-specific skills of players is not always substantiated. Surely, further studies on different youth competitions could provide researchers and coaches a better understanding of the development of sport-specific skills and give also insights for other youth sports. Another important issue in the development of young athletes involves their capability to combine high-level sports training and good quality education. Because in Europe the improvement of talented young athletes is the main concern of Sport Clubs and Federations, recently the European Commission promoted actions on dual careers for young athletes to encourage a dialogue between the sport and education sectors.

#### IS-PM12 Respiratory Limitations to Exercise

##### EXERCISE-INDUCED RESPIRATORY MUSCLE FATIGUE: CAUSES AND CONSEQUENCES

ROMER, L.M.

BRUNEL UNIVERSITY

There is convincing evidence that the respiratory muscles fatigue in response to sustained exercise at intensities  $>85\%$   $\dot{V}\text{O}_2\text{max}$ . For example, the transdiaphragmatic pressure evoked by supramaximal stimulation of the phrenic nerves (1-100 Hz) is reduced 15 to 50% below pre-exercise baseline in subjects with a broad range of fitness and takes about 2 h to recover. That diaphragmatic fatigue is prevented when inspiratory work is reduced throughout exercise using a mechanical ventilator suggests that exercise-induced diaphragmatic fatigue is in part due to the high levels of diaphragmatic work that must be sustained throughout heavy exercise. Diaphragmatic work is not sufficient to explain all of the diaphragmatic fatigue, however, because when the resting subject mimics the magnitude and duration of diaphragmatic work incurred during exercise, fatigue does not occur. The explanation for why the diaphragm is more susceptible to fatigue during exercise may be because the diaphragm competes with the locomotor muscles for the available blood flow during heavy exercise, thereby promoting inadequate  $\text{O}_2$  transport and fatigue of the diaphragm. Exercise time-to-exhaustion is increased when the respiratory muscles are partially unloaded during exercise using either reduced density gas mixtures or mechanical ventilation, although such improvements are observed only during heavy sustained exercise ( $>85\%$   $\text{VO}_2\text{max}$ ). Furthermore, time-to-exhaustion during heavy sustained exercise is decreased when the respiratory muscles are fatigued prior to the exercise. These effects of respiratory muscle work and/or fatigue on exercise tolerance may be mediated via changes in dyspnoea. Another aspect of respiratory muscle work that might limit exercise tolerance is a reflex effect from fatiguing respiratory muscles that increases sympathetic vasoconstrictor outflow and compromises perfusion of limb muscle, thereby limiting its ability to perform work. Indeed, fatiguing contractions and accumulation of metabolites in the respiratory muscles activate metabosensitive Type III/IV afferents which, in turn, reflexively increase sympathetic vasoconstrictor activity to several vascular beds, including the working limb muscles. Concomitant increases in vascular conductance and blood flow to locomotor muscles have been observed when the normally occurring work of breathing is reduced using a mechanical ventilator during maximal exercise, but not during exercise at 50 or 75%  $\text{VO}_2\text{max}$ . Moreover, relieving much of the respiratory muscle work during heavy exercise attenuates the severity of quadriceps muscle fatigue. Such changes in quadriceps fatigue likely play a pivotal role in determining performance during heavy exercise both through direct effects on muscle force output and through feedback effects on sensory input to the CNS.

##### CONVECTIVE $\text{O}_2$ TRANSPORT EFFECTS ON PERIPHERAL AND CENTRAL FATIGUE

AMANN, M.

UNIVERSITY OF UTAH

Acute and/or chronic exposure to hypoxia places a substantial challenge on the exercising human and burdens the respiratory system with the consequence of compromised convective  $\text{O}_2$  transport. Although central and peripheral fatigue may develop independent of alterations in convective  $\text{O}_2$  transport, reductions in  $\text{O}_2$  supply exacerbate and increases attenuate the rate of accumulation. It appears that across the range of hyperoxia to severe-hypoxia the major determinant of central motor drive (CMD) and endurance performance switches from a predominantly peripheral origin to a hypoxic-sensitive central component of fatigue. We found that peripheral locomotor muscle fatigue (pLMF) is the prevailing factor limiting CMD and therefore exercise performance from hyperoxia to moderate hypoxia ( $\text{SaO}_2 >75\%$ ). In these levels of arterial hypoxemia, the development of pLMF is confined to a certain limit which varies between humans. In contrast, pLMF does not develop to this limit in severe hypoxia ( $\text{SaO}_2 <70\%$ ) and exercise is prematurely terminated presumably to protect the brain from insufficient  $\text{O}_2$  supply. Based on the observations from hyperoxia to moderate hypoxia, we outlined a model linking CMD with the  $\text{O}_2$  transport-sensitive metabolic milieu within the working locomotor muscles. Our model suggests that the metaboreflex/somatosensory feedback (group III/IV muscle afferents) from the working muscles imposes inhibitory influences on the magnitude of CMD "chosen" by the working human during high intensity endurance exercise with the purpose to regulate and restrict the level of exercise-induced pLMF. To experimentally test this model, we pharmacologically blocked somatosensory pathways originating in the working limbs during cycling exercise in normoxia. After initial difficulties with a local anesthetic (epidural lidocaine) and associated loss of locomotor muscle strength we switched to an intrathecally applied  $\mu$ -opioid agonist (fentanyl). These experiments were the first ever to selectively block group III/IV locomotor muscle afferents during high-intensity cycling exercise without affecting maximal locomotor muscle strength. In the absence of  $\mu$ -opioid receptor-sensitive neural feedback from the working limbs, CMD was increased and end-exercise pLMF substantially exceeded, for the first time, the individual critical. The outcome of these latter studies indicate that, from hyperoxia to moderate hypoxia, convective  $\text{O}_2$  transport effects on central fatigue are mediated via the impact on peripheral fatigue (intramuscular metabolic milieu) and associated effects on limb muscle afferents and the resulting CMD inhibition.

##### PULMONARY PHYSIOLOGY OF WOMEN: LIMITATIONS AND ADVANTAGES

SHEEL, W.

UNIVERSITY OF BRITISH COLUMBIA

Studies examining pulmonary gas exchange during exercise have primarily focused on young healthy males, while the female response has received limited attention. Evidence is accumulating that the response of the lungs, airways and/or respiratory muscles to exercise is

less than ideal and this may significantly compromise oxygen transport and exercise performance in certain groups of otherwise healthy male subjects. Females may be even more susceptible to exercise induced pulmonary limitations than height matched males, by virtue of their smaller lung volumes, lower maximal expiratory flow rates, and smaller diffusion surface areas. We, and others, have found that exercise induced-arterial hypoxaemia (EIAH; arterial oxygen desaturation of 3-15% below resting levels) is more prevalent and occurs at relatively lower fitness levels in females compared to males. However, few mechanisms have been identified to explain why females may be more susceptible to EIAH than males and the prevalence remains controversial. Using high resolution computed tomography we have shown that when males and females are matched for lung size, the airway luminal areas of the larger conducting airways in females are significantly smaller (14-25%) than in males. These are important observations when considering that resistance to airflow is inversely proportional to airway radius to the fourth power. This becomes physiologically relevant under conditions where ventilation is high such as exercise. We have shown that young athletic females experience expiratory flow limitation more frequently and at a lower level of ventilation than males. At rest and during very low intensity exercise the work of breathing is the same between the sexes. However, with modest increases in exercise intensity the work of breathing, for the same level of ventilation, increases more rapidly in females. This is due to a higher resistive work of breathing in females and is associated with expiratory flow limitation and a greater relative dynamic hyperinflation. Based on the abovementioned anatomical and functional sex differences in pulmonary physiology we asked whether the female diaphragm is more prone to exercise-induced fatigue. However, we found that fewer females developed diaphragmatic fatigue and that the magnitude of fatigue was significantly greater in males. This suggests that the female respiratory system that might have a distinct advantage relative to males. That is, women may be more resistant to exercise-induced diaphragmatic fatigue and the sympathetically mediated metaboreflex that originates from fatiguing inspiratory muscles.

### IS-PM13 Optimising Recovery in Sports (sponsored by Nestle)

#### DIETARY PROTEIN FOR RESTORATION, REPAIR, AND ADAPTIVE ADVANTAGE IN EXERCISE RECOVERY IN OLD AND YOUNG

PHILLIPS, S.M.

*MCMMASTER UNIVERSITY*

Protein consumption in the post-exercise period synergistically interacts to bring about increases in the synthesis of new muscle proteins more than either stimulus alone. Collectively, the summed increases in protein synthesis change the phenotype of the muscle. Our classical thinking is that if we practice high intensity resistance work the training-induced phenotype is hypertrophy and by contrast repetitive dynamic work results in expansion of mitochondrial proteins. However, recent data from our lab has caused us to question this dogma. Measurement of short-term responses using stable isotope tracers reveals far more overlap and redundancy between the two forms of exercise versus differences. The signals leading to hypertrophy are still largely unknown and those leading to mitochondrial biogenesis, while some progress has been made, are also less than clear. Rather than disparate signalling pathways the thesis that muscular contraction in dynamic or resistance work is a common stimulus to both conditions and is largely a generic stimulus. What modifies this stimulus causing it to impact on various protein 'pools' (i.e., dynamic = mitochondrial and resistance = myofibrillar) is still largely unknown, but we are beginning to make some progress in this regard. Discussion will focus on factors that differentiate protein pool-specific responses in skeletal muscle and how those are modified by nutrition and aging.

#### OPTIMISING RECOVERY POST-EXERCISE: THE ROLE OF CARBOHYDRATE AND FAT

HAWLEY, J.

*RMIT UNIVERSITY*

The major disruptions to cellular homeostasis occur during exercise, being largely dependent on the relative exercise intensity and prevailing substrate availability to the active muscles. In contrast, the post-exercise period is characterised by a general homeostatic recovery phase which includes the resynthesis of fuel stores, free radical quenching, repair of free radical-mediated damage and the restoration of intracellular electrolyte concentrations and pH. Post-exercise macronutrient intake (carbohydrate, fat and/or protein) rapidly alters the concentration of blood-borne substrates and hormones that, over time, cause marked perturbations in the storage profile of skeletal muscle and other insulin-sensitive tissues. In the hours immediately after substrate-depleting exercise, there is both a time- and fuel-dependant activation of several stress-activated protein kinases, accompanied by the up-regulation of multiple genes: these events may ultimately provide the stimulus for the chronic intracellular adaptations that occur over months and years of repeated contractile activity (i.e. training adaptation). This talk will provide a contemporary perspective of how post-exercise nutrient provision (or lack of) has the potential to activate or inhibit many biochemical pathways with putative roles in training adaptation.

#### WATER AND ELECTROLYTES FOR RECOVERY AFTER EXERCISE

MAUGHAN, R.

*LOUGHBOROUGH UNIVERSITY*

Exercise, especially in hot and humid environments, results in loss of water and electrolytes, primarily sodium, in sweat. If these losses are substantial and are not replaced before the next exercise bout, the subjective perception of effort is increased and performance is likely to be impaired. Replacement of losses requires restoration of body water volume, but ingestion of large volumes of plain water will result in a fall in plasma sodium concentration and osmolality, leading to a diuresis that may prevent full restoration of body water content. Addition of sodium in amounts equal to or greater than the sweat losses can reduce this diuresis and increase the retention of ingested fluid. The sodium may come from drinks or from ingested foods. Sweat sodium concentration is invariably less than plasma sodium concentration, but may range from about 10-80 mmol/l in healthy individuals: sweat sodium content is influenced by a number of factors, including sweating rate, acclimation status and diet, but there remains a substantial individual variability. The post-exercise diuretic response will also be influenced by other factors such as the rate of fluid ingestion and the presence of macronutrients that will slow gastric emptying. Athletes who wish to ensure effective recovery after exercise should be aware of the extent of their water and salt losses and should have a strategy in place to ensure their replacement.

## IS-BN08 Neuro-muscular system and tendons across the lifespan

## NEUROMUSCULAR FUNCTION OF THE AGEING MOTOR SYSTEM

DUCHATEAU, J., KLASS, M., BAUDRY, S.

UNIVERSITE LIBRE DE BRUXELLES

Senescence is accompanied by a marked decline in the performance of the motor system. In addition to the decrease in muscle mass (sarcopenia), there is a loss of motor neurones that reduces the number of motor units. However, surviving nerve cells can reinnervate some denervated muscle fibres, increasing the innervation ratio of the remaining motor units. Although this profound motor unit remodelling, voluntary muscle activation does not seem to contribute greatly to the weakness commonly observed in elderly adults. Even if differences in the techniques and muscles tested may explain some discrepancies between studies, the deficit in voluntary activation during an isometric maximal voluntary contraction (MVC) is often similar in physically active elderly and young adults (Klass et al., 2007). Furthermore, it was reported that when a deficit in activation is observed in elderly adults, it can be rapidly reduced with practise (Jacoby & Rice, 2002). The observation of a limited deficit in muscle activation can be surprising at first because the maximal motor unit discharge rate is significantly reduced in elderly adults during an MVC (Connelly et al., 1999). However, this age-related reduction in discharge rate is usually accompanied by a slowing of muscle contraction that shifts the muscle force-frequency relation leftward and would permit to attain maximal performance with a lower motor units discharge rate. In contrast, the age-related reduction in motor unit discharge rate at the onset of a fast (ballistic) contraction appeared to be more affected than a slow MVC (Klass et al., 2008). This decrease in instantaneous discharge rate tends to be progressively greater for the successive interspike intervals of the discharge train. These data indicate that the slowing of motor unit discharge rate likely limits, in addition to the slowing of muscle contractile properties, the maximal rate of torque development in elderly adults. Therefore, healthy ageing appears to involve neural impairments that influence the maximal capacity of motor neurones to discharge at very high frequencies. In conclusion, the age-related decline in motor unit discharge rate does not have a profound effect on the force produced during an MVC but seems to affect more substantially the performance of fast voluntary contractions. This may alter the reactive responses to nociceptive stimuli or balance perturbations, and as a consequence, makes elderly adults more vulnerable to quick changes in their surrounding environment. Physiol. 100: 543-551, 2007 Klass M., Baudry S. & Duchateau J. J. Appl. Physiol. 104: 739-746, 2008

## MUSCULO-SKELETAL CHANGES WITH AGEING OF MASTER ATHLETES

NARICI, M.V., CAMPBELL, E.L., MCPHEE, J., SEYNNES, O.R., RITTEWEGER, J.

MANCHESTER METROPOLITAN UNIVERSITY

Introduction Ageing of the musculoskeletal system is characterised by a loss of muscle mass and strength. Typically, between 20 and 70 years of age, about 20% of muscle mass and 40% of muscle strength are lost (Narici & Maffulli 2010). Although some of this structural and functional decline is due a progressive denervation and loss of motor units, reduced physical activity and lifestyle factors exacerbate to these changes. It is thus of great interest to study lifelong trained individuals to find out whether regular physical activity affords protection against ageing of the musculo-skeletal system. Thus the aim of investigation was to compare skeletal muscle structural and functional characteristics of young adults, older sedentary individuals and lifelong trained athletes (master athletes). Methods The investigation was performed on 23 young untrained (YU) individuals aged 18-35 years, on 26 elderly untrained (EU) individuals aged 67-82 years and on 24 master athletes (MA) (sprinter and endurance runners) aged 65-81 years. Vastus lateralis muscle thickness and pennation angle were measured by ultrasonography, maximum knee extensor force was assessed by dynamometry and maximum jumping power was measured on a force platform. Data are reported as means  $\pm$ SD, statistical differences were tested with ANOVA followed by the Tuckey's post hoc test. Significance was set at  $P < 0.05$ , n.s.=non-significant. Results Muscle thickness was  $21.2 \pm 3.7$  mm in the YU,  $16.1 \pm 3.1$  mm in the EU (EU vs YU, -24%,  $P < 0.02$ ) and  $17.5 \pm 3.0$  mm in the MA (MA vs EU, +9% n.s., MA vs YU, -18%  $P < 0.02$ ). Pennation angle was  $14.6 \pm 2.9$  deg in YU (EU vs YU, -23%,  $P < 0.02$ ),  $11.3 \pm 2.6$  deg in EU, and  $13.1 \pm 2.6$  deg in MA (MA vs EU, +16% n.s., MA vs YU, -10%, n.s.). Maximum isometric force was  $273.8 \pm 51.4$  Nm in YU,  $154.4 \pm 42.7$  Nm in EU (EU vs YE, -44%,  $P < 0.001$ ) and  $193.6 \pm 41.3$  Nm in MA (MA vs EU, +26%  $P < 0.01$ , MA vs YU, -29%  $P < 0.001$ ). Maximum explosive power was  $3487.8 \pm 730$  watt in YU,  $1880.3 \pm 663.1$  watt in EU (EU vs YU -46%,  $P < 0.001$ ) and  $2478.7 \pm 670.2$  watt in MA (+32% MA vs EU,  $P < 0.001$ , MA vs YU, -29%,  $P < 0.01$ ). Discussion These findings clearly show that life-long training mitigates the loss of muscle mass, force and power in old age. The reduction in muscle thickness and pennation angles, known markers of sarcopenia (Narici et al. 2003), is significantly smaller in master athletes, indicating that life-long training (running) is effective in preserving muscle mass in old age. Distinct benefits in muscle function are also afforded by life-long training. In fact, master athletes not only show smaller decrements of muscle function but they also display considerably greater values of force (+26%) and power (+32%) with respect to untrained peers. This preservation of force and power should be viewed as a major advantage for maintaining mobility and independence in old age. References Narici MV, Maffulli N. (2010). Br Med Bull, 95, 139-59. ## MUSCLE-TENDON CHANGES AND LOCOMOTOR FUNCTION IN THE ELDERLY

ARAMPATZIS, A.

HUMBOLDT-UNIVERSITY BERLIN

Several studies reported that ageing is associated with a decrease of muscle strength [4], tendon stiffness [8] and alterations in muscle architecture [9]. However old adults are able to adjust task demand on their reduced muscle-tendon capacities while performing different locomotion activities such as level walking [2,7] running [6] and stair climbing [10]. An age-related muscular readjustment may affect the joint moments in the other two planes, causing abnormalities in the knee joint loading during daily activities. Osteoarthritis is the most common form of arthritis among people over the age of 60, affecting most frequently the weight-bearing joints such as the knee [3]. Recent studies give evidence that the magnitude of the external adduction moment at the knee joint, as experienced during daily activities, results in knee pain and osteoarthritis in the elderly [1]. Stair negotiation is, next to level walking, one of the most frequently performed locomotion activities. During stair negotiation the peak compressive loads at the knee joint are approximately 28% higher than during level walking [5]. Therefore, identifying abnormalities in the mechanical loading of the knee joint within the elderly population during stair

negotiation may be important for an early diagnosis of potential risks and, thus, for the application of early therapeutic interventions. We examined the joint kinetics in the lower extremities of 28 old and 16 young adults while ascending and descending stairs. We found that old adults showed a higher external adduction moment at the knee joint ( $P < 0.05$ ) compared to the young ones indicating an increased mechanical load at the medial knee compartment. The reason for the higher knee adduction moment in the old adults was an altered control strategy during stair negotiation, probably initiated by the age-related reduction in muscle strength and tendon stiffness in the lower extremities. The higher knee adduction moment in the elderly while ascending stairs was related to a shift of muscular output towards the stronger, proximal hip musculature. The control strategy leading to the higher knee adduction moment while descending stairs was a shift of the demand from the leading to the trailing limb because of the higher muscle force potential of the trailing leg. ### IS-BN09 Evidence-based Sports Physiotherapy

#### EVIDENCE-BASED EXERCISE TRAINING IN THE PREVENTION AND REHABILITATION OF SPORTS INJURY

BANZER, W., HÜBSCHER, M.

UNIVERSITY OF FRANKFURT

Sports and recreation injuries constitute a major public health burden in developed countries. The most common sports injuries are sprains, dislocations, and ligament ruptures occurring at the ankle and knee as well as at the hand, elbow, and shoulder. Particularly, severe injuries such as anterior cruciate ligament (ACL) ruptures or ankle sprains are often associated with increased morbidity (e.g. early development of joint osteoarthritis) and long-term disability. Therefore, measures to prevent and treat these injuries are of particular interest. In view of appropriate intervention strategies, the prevention of injuries must be considered a primary goal. On the basis of previous research, it is hypothesized that proprioceptive and neuromuscular abilities in particular have a certain impact on injury risk. Furthermore, sport-related joint injuries tend to result in severe and long-term alterations in proprioceptive and neuromuscular functions that can further increase the risk of persisting functional deficits and recurrent injury. The aim of my presentation will be first to review the current evidence on specific exercise programs aimed at improving proprioception and neuromuscular function to reduce the incidence of acute sports injuries (e.g. Hubscher et al. 2010). Furthermore, I will review the effectiveness of neuromuscular rehabilitation programs for the posttraumatic or postsurgical treatment of sports injuries (e.g. Zech et al. 2010). #### EVIDENCE-BASED STRENGTH TRAINING FOR THE PREVENTION OF NECK/SHOULDER MUSCLE PAIN IN THE WORKING POPULATION.

SJØGAARD, G.

UNIVERSITY OF SOUTHERN DENMARK

Workers with neck/shoulder pain have often been demonstrated to present lower strength in this body region than those without pain 7. Further, strength training of patients with chronic neck pain has resulted in clinically significant reduction in their pain 8. These findings lead to the hypothesis that strength training of muscles in the neck/shoulder region may relieve and prevent neck/shoulder pain among workers with monotonous repetitive work tasks including computer work. A systematic review has presented evidence for strength training to be successful in reducing pain given the training was intensive, lasted at least 10 weeks and was supervised 5. Even a preventive effect has been demonstrated 4. Mechanisms of training effect have been studied to reveal biomechanical as well as morphological key factors 2, 6. Ongoing studies will reveal the acceptable variability of training regarding mode of exercises 1 as well as time wise planning of exercises 3. References 1. #### EVIDENCE-BASED PRACTICE IN TREATMENT OF ARTHRITIC AND NON-ARTHRITIC PATELLOFEMORAL PAIN

CALLAGHAN, M.,

CENTRE FOR REHABILITATION SCIENCE

Patellofemoral pain can be a debilitating and painful problem in the arthritic and non-arthritic knee joint. Treatment for both conditions are usually non-surgical with physiotherapy providing the mainstay of treatment. Physiotherapy has been proven to be successful in the

majority of cases of patellofemoral pain. This presentation outlines the evidence base for the rehabilitation strategies for both conditions to be treated successfully

### IS-SH09 Football as an Agent of Social Change

#### THE FAMILY AND FOOTBALL: ENABLING POSITIVE HEALTHFUL BEHAVIOURS

RICHARDSON, D., BURGESS, T., NEWLAND, T., WATSON, L., BINGHAM, D., PARNELL, D.

LIVERPOOL JOHN MOORES UNIVERSITY

The family is a significant social group which is regarded as the primary source of a person's social activity (Nam, 2004). The family unit is a key influence in the lifestyle, including health and non health behaviours, of its members. Understanding the complexity of the family unit is critical in order to facilitate appropriate health enhancing behaviours. This presentation offers a series of interactions of a range of practitioners engaged in encouraging positive health behaviours within a Premier League football club based family centre. The Everton Active Family Centre (EAFC) is family health promotion unit located in the grounds of Everton Football Club. The presentation draws on a range of health practitioner experiences working with families at EAFC over a period of 12 months. Practitioners (n=5) engaged in a range of formal and informal interactions with individuals and families. Furthermore semi-structured interviews and focus groups were undertaken with individuals and with collective families. Practitioners adopted the principles of ethnography (Hammersley and Atkinson, 2007) and observational research (Hammersley and Atkinson, 1983) throughout and were encouraged to collate field notes and reflective diaries. The experiences of the practitioners are presented using a series of narrative vignettes and real experiences to capture the complex day-to-day challenges that the family experiences in adopting healthful behaviours. The findings describe the challenges that families face in understanding and engaging in health behaviours such as changes in diet and physical activity. The presentation alludes to the value of targeting the family as a whole unit alongside the targeting of younger family members to influence and sustain behaviour change. Furthermore, the presentation recounts the broad and eclectic practitioner skill base required in order to initiate and sustain behaviour within the family.

#### THE INITIAL FINDINGS FROM THE EVALUATION OF THE PREMIER LEAGUE MEN'S HEALTH PROGRAMME

PRINGLE, A., MCKENNA, J., ROBERTSON, S., SMITH, A., WHITE, A., ZWOLINSKY, S.

LEEDS METROPOLITAN UNIVERSITY

Introduction In the UK, groups of men are at risk from cardio-vascular diseases (CVD), diabetes, fat related cancers and poor mental health (White & Holmes, 2006). Concerns also exist over men's adoption of primary health care and there is a need to reach this group with health interventions using alternative channels (White and Robertson, 2010). One such channel are professional football clubs and offer a rich opportunity to reach male audiences with health promotion interventions. With that in mind, this research examined the pre-intervention health profiles of men adopting Premier League Health (PLH), a national programme of men's health delivered in English Premier League (EPL) football clubs and targeted at men 18-35 years. Methods Interventions were delivered by clubs (N=16) including, educational activities on match days, weekly healthy lifestyle classes and outreach with local communities of men. Interventions were delivered at stadia, club training venues and community facilities. Activities were run by health trainers who received specific training on men's health and behavioral change activities. Following ethical clearance, men completed adapted and validated measures for demographics and lifestyle behaviors, including physical activity, consumption of fruit and vegetables, smoking, weight/height, alcohol intake and perception of health. Data collection by health trainers occurred pre-intervention and was independently analyzed by researchers. Data were used to assess participant adoption and pre-intervention health profiles. Results N=946 adopted PLH, but mode of engagement led to variations in sample size. Demographics showed that 89% (N=783/875) were 18-44 years. 78% (N=685/878) were white British. 43% (N=173/403) were unemployed and 26% (N=157/605) were not fans of the club hosting PLH. The percentage of men failing to meet recommended health guidelines were as follows: physical activity, 79% (N=351/440); daily intake of fruit and vegetables, 83% (N=315/380); smoking, 28% (N=103/373); weight, 68% (N=245/358); and alcohol intake, 40% (N=112/279). 67% (N=208/310), presented with three or more risk factors for CVD, yet 69% (N=242/348) did not consider they had a health problem. Discussion A national programme of men's health promotion interventions delivered in EPL football clubs was effective in reaching target audiences. Interventions were predominantly adopted by men not meeting health guidelines. Men were well placed to receive health promotion advice and support. References White A, Holmes M (2006). #### FOOTBALL AS AN AGENT OF GENERATING SOCIAL CAPITAL

OTTESEN, L.

UNIVERSITY OF COPENHAGEN

Football as an Agent of Generating Social Capital Associate Professor Laila Ottesen, Ph.D, Department of Exercise and Sport Sciences, University of Copenhagen, lottesen@ifi.ku.dk Introduction "Football as health promotion" is a sociological study of several intervention projects with focus on sport and health. The purpose has been partly to provide knowledge about how football as a team sport can generate social capital as well as social and health related changes among the participants, and partly to examine the implementation of football as a health promotion. Methods Several video observations and qualitative (focus group) interviews with the participants are used in connection to the interventions. Results The paper is based on several interdisciplinary studies about football as health promotion carried out at the Department of Exercise and Sport Sciences at the University of Copenhagen under leadership of Associate Professor P. Krstrup and for the sociological part led by the writer of this paper. These interventions have proved that football as an activity offers significant disease prevention and health promoting potentials (Krstrup et al., 2010). Similarly the interventions have shown that the game of football and its community-forming potential contains tremendous social and networking qualities which generate social capital and work health promoting (Ottesen et al., 2010). Discussion Health promoting offers such as "Exercise on prescription" have proved only a limited effect on adherence of new exercise habits. Health interventions have to combine methods and strategies at multiple levels and have to be directed broader than just towards the individual in order to generate social changes (Ottesen et al., 2010). With a background

in the perspectives of social capital and work-life balance (Putnam et al., 2003; Hochschild 2001), the possibilities and resistance which appears among the participants in sport will be analyzed, and furthermore the paper elaborates the possibilities and resistances which appear when the projects are implemented in municipalities, local communities and sports associations. ### IS-SH10 Education, Policy and Provider Networks for Physical Activity

#### PHYSICAL ACTIVITY NETWORKS - THE VIEW FROM WITHIN

MARTIN, B.W., KAHLMEIER, S.

UNIVERSITY OF ZURICH

The multiple health effects of physical activity and sports have been well documented and physical inactivity has been recognised as an important threat to public health worldwide. However, physical activity promotion at the population level is a relatively new approach and only few countries have well-established policies and strategies in this field. In this situation, physical activity promotion networks can play an important role in providing possibilities for exchange and facilitating the activities of the different actors. The Netherlands have had one of the first national networks; based on these experiences other countries such as Switzerland have developed their own. With the growing burden of non-communicable diseases worldwide and the growing awareness of the challenges in population-wide physical activity, regional networks have developed. RAFA-PANA, the Red de Actividad Fisica de las Americas/Physical Activity Network of the Americas, HEPA Europe, the European Network for Health-Enhancing Physical Activity and the Asia Pacific Physical Activity Network have been active already for some years, the African Physical Activity Network AFPA has joined them recently. All regional structures are represented in Agita Mundo, the global physical activity promotion network, and all networks collaborate with a whole range of other organisations, including scientific societies. Out of the experiences of the last few years, requirements for the successful functioning of general physical activity promotion networks as well as task-specific structures have been identified. The opportunities offered by this structural solution will be illustrated as well as the challenges and limitations encountered by physical activity networks.

#### EUROPEAN INTEGRATION VIA EUROPEAN NETWORKING? EU-FUNDED NETWORKS HEALTH-ENHANCING PHYSICAL ACTIVITY NETWORKS: A LEGAL AND A POLITICAL SCIENCE PERSPECTIVE COMPARED

KORNBECK, J.

EUROPEAN COMMISSION

The paper will ask the question how to interpret EU funding for health-enhancing physical activity (HEPA) networks made available via sport-specific (as opposed to public health) budget lines. The expectations behind recent policy choices will be explained with reference to the development of the subject area sport and physical activity at EU level, with reference to the specific character of this area and its potential to make a contribution to the prevention of lifestyle-related health conditions caused by physical inactivity. The paper will show how the selection of nine HEPA projects for EU funding in 2009 (in anticipation of a possible future EU Sport Programme) fits into the legal framework defined by Article 165 TFEU and the role of the EU to support, coordinate or supplement the actions of the Member States. As this Treaty-based competence specifically rules out harmonisation and any other binding measures, the choice of network funding is interpreted as a soft yet useful policy making tool, comparing and contrasting a legal with a political science perspective of the role of the EU between regulation and inspiration. Drawing in particular on the Multi-Level Governance (MLG) approach, the paper will make some propositions regarding the benefits of networks as mutual learning communities and the requirements needed in selecting project proposals.

#### PHYSICAL ACTIVITY NETWORKS AND THE ROLE OF GLOBAL ADVOCACY FOR PHYSICAL ACTIVITY

BULL, F.C.

LOUGHBOROUGH UNIVERSITY/UNIVERSITY OF WESTERN AUSTRALIA

There is well established scientific evidence on the health benefits of regular physical activity in promoting health and preventing non communicable disease (NCD). This provides a solid platform for stronger commitment and national programs aimed at increasing levels of participation in most countries. Globally, NCD's account for 63% of all deaths worldwide and 80% of these occur in low and middle income countries (LMIC). There is an urgent need to scale up public health efforts, particularly in LMIC, however evidence alone has yet to translate into increased action and investment in prevention strategies. What appears missing in many countries is sufficient political commitment and high level decision making towards long term investment. For this reason, there is a need for greater advocacy work to promote the importance of physical activity, its central role in NCD prevention along side tobacco control and healthy diets, and the co benefits for other related agenda's such as environmental sustainability. Mobilizing professional networks to address this agenda is critical and recent examples of action will be explored in this presentation. In 2010 Global Advocacy for Physical Activity (GAPA) developed the Toronto Charter for Physical Activity: A global call for action to address an identified gap in suitable advocacy tools. This presentation will briefly outline the stepped approach used to develop the Toronto Charter and the process for global engagement. Progress since its launch in May 2010 as well as the development of the Investment that work for Physical Activity companion document will be shared. There is no better time and there has been no greater need for advocacy on physical activity in the lead up to the forthcoming United Nations High Level Meeting on NCD Prevention and Control in September 2011.

## Oral presentations

### OP-BN07 Sports Biomechanics 2

#### TIME-MOTION ANALYSIS OF AUSTRALIAN A-LEAGUE SOCCER WITH A FOCUS ON ACCELERATION AND DECELERATION CHARACTERISTICS

CLARK, A.C.1,2, JANSE DE JONGE, X.1, DWYER, D.1

1 UNIVERSITY OF NEWCASTLE, AUSTRALIA; 2 CENTRAL COAST MARINERS FOOTBALL CLUB, AUSTRALIA

The A-League is gaining international exposure as a high standard professional soccer league. Time-motion analysis traditionally reports total distance and velocity characteristics. The use of GPS technology allows for the detailed study of important acceleration and deceleration characteristics of elite soccer. The present study sought to complete a thorough time-motion analysis of players during A-league competition using GPS technology. Twelve professional players from one A-League team were analysed using 5Hz GPS technology during official A-League matches over two seasons resulting in 62 full matches. For time-motion analysis each half of the game was divided into three equal periods and analysed for time, distance, velocity and acceleration/deceleration. Repeated measures ANOVA was performed for total distance, distance and time spent in velocity bands and distance in acceleration/deceleration bands (low <1.11 m•s<sup>-2</sup>, moderate 1.11-2.78 m•s<sup>-2</sup>, high >2.78 m•s<sup>-2</sup>). A significant decrease in distance covered per minute was found for both the first half (from 127±18 to 120±16 m•min<sup>-1</sup>) and second half (from 122±17 to 117±18 m•min<sup>-1</sup>) and overall. Over the duration of a match a significant decline was seen in the distance of low intensity running (<3.89 m•s<sup>-1</sup>) (from 1526±179 to 1413±180 m), while an increase was seen in the time spent in low intensity running (from 846±47 to 874±43 s). There was no significant change in the distance travelled and time spent in high intensity (>3.89 m•s<sup>-1</sup>) and very high intensity running (>5.28 m•s<sup>-1</sup>). A significant reduction in the distance covered in low (from 1221±155 to 1146±152 m) and moderate (from 91±22 to 81±22 m) acceleration bands and low (from 487±62 to 451±68 m) and moderate (from 66±16 to 58±15 m) deceleration bands was found. No significant change was found in high acceleration and deceleration bands. The results indicate a progressive decline in average velocity during each half and during the overall match. In addition, a significant decline in distance covered in low intensity running and a concurrent significant increase in time spent in low intensity running, implies that players spend more time stationary and/or moving at lower velocities later in matches. Furthermore, the maintenance of high and very high intensity running throughout the match may indicate that players are implementing an effective pacing strategy in order to preserve high intensity activity. The new findings of the preservation of high acceleration distance combined with the significant decline in moderate and low acceleration distance provide further confirmation of the suggested pacing strategies that allow players to maintain their ability to accelerate maximally during crucial phases of play.

#### BIOMECHANICAL ANALYSIS OF THE BASIC BODY MOVEMENTS IN AIKIDO

FURUTANI, O.

UNIV. OF TOYAMA, FACULTY OF HUMAN DEVELOPMENT

O. Furutani<sup>1</sup>, T. Horita<sup>1</sup>, K. Hashizume<sup>1</sup> Community Sports Course, Faculty of Human Development, University of Toyama, Toyama, Japan. INTRODUCTION Aikido has been developed as a system of physical and mental training, founded by Mr. Morihei Uesiba (1883-1969) called martial arts master in early 20th century (Saito .2010). The main aim of Aikido has been considered to unify the technique, physical and mental aspects of the body, which is translated as "the Way of harmonious spirit". The basic movements in Aikido consists of tenkan (turning) (M.Ueshiba .2005). One moves in circular motion in response to the opponent and while moving spherically, one maintains center of gravity to create the stable axis of movement (K.Ueshiba .1984). The purpose of the present study was to investigate the biomechanical characteristic of the basic body movements in Aikido. METHODS Eight skilled(5-6 grade) male experts (61.4±11.5 y r ; 63.8±6.5 k g ; 169.5±4.2 c m) and 5 unskilled male (19.6±1.5 y r ; 61.3±5.6 k g ; 168.1±2.5 c m) subjects participated in this study. The subjects performed tenkan on the two force plates(KISTLER,Type2986A). The motion of the subjects was recorded by two video cameras (30 f.p.s).Three-dimensional (3D)analysis was performed by a computerized motion analysis system (FRAME DIAS4, DKH, JAPAN). Center of gravity of the body (CG)and lower limb joint kinematic variables were analyzed. RESULTS AND DISCUSSION The differences were found in the path of CG and lower limb joint kinematics between skilled and unskilled subjects in tenkan. The skilled subjects showed small change (2.9±1.4 c m) in vertical position of CG during movement as compared to unskilled subjects (6.0±3.0 c m, P<0.05). The peak velocity of the CG was higher in skilled subjects (1.39m/s) as compared to the unskilled subjects (1.14m/s, P<0.05). Skilled subjects showed shorter movement time (0.55±0.14s) as compared to the unskilled subjects (1.19±0.15s, P<0.01). In addition, force impulse of the skilled subjects were lower (283±51N • S) than the unskilled subjects (525±143N • S, P<0.01). Therefore it has been considered that Aikido experts possess well-coordinated and economical movement. REFERENCES K. Ueshiba, The Spirit of Aikido, 41, 1984, Kodansha, Tokyo, Japan. M. Ueshiba, PROGRESSIVE AIKIDO, 44-45, 2005, Kodansha, Tokyo, Japan. Y. Saito, AIKIDO TANKYU, 84-87, 2010, Shupangeijutusha, Tokyo, Japan.

#### PERFORMANCE AND KINEMATICS OF VARIOUS THROWING TECHNIQUES AND SKILL LEVELS IN TEAM-HANDBALL

WAGNER, H., PFUSTERSCHMIED, J., VON DUVILLARD, S.P., MÜLLER, E.

UNIVERSITY OF SALZBURG

PERFORMANCE AND KINEMATICS OF VARIOUS THROWING TECHNIQUES AND SKILL LEVELS IN TEAM-HANDBALL Wagner, H.1,2, Pfusterschmied, J.1,2, von Duvillard, S.P.3, Müller E.1,2 1: SSK (Salzburg, Austria), 2: CDLBS (Salzburg, Austria), 3: KESB (Idaho, USA) Introduction In team-handball competition, the players utilize various throwing techniques, whereas the standing throw with run-up and jump throw were the most applied (Wagner et al., 2008). In recent studies, it was shown that performance and kinematics in the jump throw differ depending on the skill level (Wagner et al., 2010) and that a transfer of momentum from proximal to distal and dynamic trunk and shoulder joint movements increase ball velocity in team-handball throwing (van den Tillaar and Ettema, 2009; Wagner et al., 2010). However, a study comparing different throwing techniques and skill levels in team-handball throwing is lacking. Consequently, the aim of this study was to analyze differences in performance and kinematics between the team-handball jump and standing throw with run-up in different skill levels. Methods Twenty-four participants of three different skill levels performed 10 valid jump and standing throws with run-up and were instructed to throw the ball with a maximal ball velocity into the center of a target. 3D-kinematics and ball velocity were measured using an 8 camera Vicon MX13 motion capture system, at 250 Hz. Throwing accuracy was determined by the percentage of throws that

missed the target and the mean radial error. A two-way MANOVA with the main factors throwing technique and skill level was used to calculate the differences in performance and kinematics (pelvis, trunk and shoulder rotation). Results Two-way MANOVA yielded significant effects for the factor throwing technique ( $P < 0.001$ ) and skill level ( $P < 0.001$ ). In performance, we found significant differences between throwing techniques ( $P < 0.01$ ) and skill levels ( $P < 0.001$ ) solely in the ball velocity. Additional Post-Hoc tests indicated significant differences in throwing technique ( $n=7$ ) and skill levels ( $n=8$ ) in 15 out of 36 kinematic variables. Discussion Increased ball velocity in the standing throw with run-up could be explained by a better transfer of momentum from proximal to distal. The lead leg braces the body that allows the pelvis, trunk, and throwing arm to accelerate over the braced leg. In the jump throw the missing floor contact of the lead leg demands a different strategy to accelerate the pelvis and trunk that lead to a decrease in ball velocity. However, elite and highly skilled players were able to increase angular velocity in the pelvis, trunk and shoulder rotation in both throwing techniques that lead to higher ball velocity in comparison to the low skilled players. ## THE EFFECT OF A SIMULATED 18 KM CLASSIC CROSS-COUNTRY SKIING RACE ON MAXIMAL VELOCITY AND FORCE PRODUCTION DURING DIAGONAL SKIING

OHTONEN, O., NIEMINEN, V.M., LINDINGER, S., STÖGGL, T., LINNAMO, V.

UNIVERSITY OF JYVÄSKYLÄ

THE EFFECT OF A SIMULATED 18 KM CLASSIC CROSS-COUNTRY SKIING RACE ON MAXIMAL VELOCITY AND FORCE PRODUCTION DURING DIAGONAL SKIING Ohtonen, O. 1, Nieminen, V-M. 1, Lindinger, S. 2, Stöggel, T. 2, Linnamo, V. 1 1: Neuromuscular Research Center, Department of Biology of Physical Activity, University of Jyväskylä, Finland, 2: Department of Sport Science and Kinesiology, University of Salzburg, Christian Doppler Laboratory "Biomechanics in Skiing", Austria. Introduction Both physiological (e.g. Welde et al. 2003) and biomechanical (e.g. Bilodeau et al. 1996) variables play a role in long distance cross-country skiing races. Lindinger et al. (2009) showed that diagonal roller skiing performance until exhaustion was linked to e.g. longer cycle length and greater force impulses. The aim of the present study was to examine how maximal skiing velocity and force production during diagonal skiing are affected after an 18 km simulated classic ski race on snow. Methods 7 male subjects performed an 18 km (9 x 2 km lap) simulated race in Vuokatti ski tunnel. Before and after the race, skiers performed one maximum velocity trial over a 20 m long force plate row (Vähäsöyrinki et al. 2008) using the diagonal stride. Maximum skiing velocity and differences in vertical and horizontal leg and pole forces related to body weight between pre and post tests were analyzed. Results Maximum skiing velocity decreased by  $8.5 \pm 8.1\%$  ( $P < 0.05$ ). Average vertical and horizontal leg force, and peak horizontal leg force decreased by  $5.3 \pm 3.1\%$ ,  $24.9 \pm 17.3\%$  and  $18.7 \pm 9.4\%$ , respectively (all  $P < 0.05$ ). Peak vertical pole force, impulse of vertical pole force, peak horizontal pole force and impulse of horizontal pole force decreased by  $28.1 \pm 17.6\%$ ,  $24.3 \pm 17.7\%$ ,  $25.1 \pm 23.1\%$  and  $28.6 \pm 29.1\%$ , respectively (all  $P < 0.05$ ). Peak horizontal pole force decreased the most in skiers who also had the most decrease in maximum velocity as indicated by a positive correlation ( $r = 0.93$ ,  $P < 0.05$ ) between the relative change in maximum velocity and the relative change in peak horizontal pole force. Discussion It seems that the skiers are able to maintain vertical leg forces better but the propulsive part of the leg force decreases strongly when the skiers are fatigued. Pole forces, both vertical and horizontal, decreased which emphasizes the role of the upper body in maintaining maximal skiing speed with diagonal stride. Better skiers seem to be able to maintain their skiing speed even when fatigued by maintaining the horizontal pole forces whereas for poorer skiers a decrease in horizontal pole forces may lead to decrease in maximum skiing velocity. ## THE IMPACT OF POLE PROPULSION ON KINEMATICS AND FATIGUE IN ROLLER SKI SKATING

SANDBAKK, Ø.1, HOLMBERG, H.C.2, LØKKE, T.1, ETTEMA, G.1

1: DEPARTMENT OF HUMAN MOVEMENT SCIENCE, NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY 2: SWEDISH WINTER SPORTS RESEARCH CENTRE, DEPARTMENT OF HEALTH SCIENCES, MID SWEDEN UNIVERSITY

Introduction: The G3 skating technique in cross-country skiing is performed while simultaneously employing skis and poles for propulsion. This technique may therefore be regarded as a compromise between the optimal skating push-off with the legs (comparable to speed skating) and the optimal push-off with the poles (comparable to the double poling technique). In order to understand the effect of using the poles on cycle characteristics and fatigue, the current study compared G3 skating with G3 leg-skating (without using poles for propulsion) while roller skiing on a treadmill. Methods: Seven male elite skiers performed 5-min submaximal stages at low, moderate and high speeds (8, 12 and 16 km•h<sup>-1</sup>) at a 5% incline in both techniques. Kinematics was analyzed 3-dimensionally using the Qualisys Pro Reflex system and the index of fatigue was assessed using heart rate monitoring and the Borg RPE scale. Results: Compared to G3 skating, in leg-skating cycle time and length decreased by 30% at correspondingly increased cycle rates ( $P < 0.01$ ). In association with this, the ski ground contact time and ski gliding phase were shorter in leg-skating ( $P < 0.01$ ) whereas push-off times remained constant across techniques. Ski angles with respect to the forward direction were 40% lower in leg-skating ( $P < 0.01$ ). In addition, the skiers retained constant ski angles from ski plant to ski lift-off when leg-skating, whereas ski angles increased during the push-off when skating using the poles ( $P > 0.05$ ). Maximal angles and the range of movement for the hip, knee and ankle were significantly higher in leg-skating ( $P < 0.01$ ). The legs were fully extended during the push-off phase at all speeds and techniques. When matched for heart rate and the Borg scale, skiers skied at 30% slower speeds when leg-skating ( $P < 0.01$ ). Discussion: A lower total propulsion in leg-skating leads to shorter cycle times and lengths compared to G3 skating. In order to compensate for the loss of propulsion when leg-skating, skiers increase their cycle rate and employ deeper leg positions and greater ski angles during the push-off. In association with this, the skiers kept a constant push-off time, but had shorter gliding time. All together, these aspects were related to the higher rates of fatigue when leg-skating compared to skating with poles at the same speed.

### OP-PM22 Cardiovascular: Cardiovascular Training

#### THE EFFECT OF ENDURANCE TRAINING UPON SKELETAL MUSCLE RESISTANCE VESSELS DEPENDS ON THE MUSCLE LOADING AND PLASTICITY

VINOGRADOVA, O., BORZYKH, A., KALENCHUK, V., ANDREEV-ANDRIEVSKII, A., TARASOVA, O.

**Introduction** During aerobic exercise blood flow distribution within skeletal muscles is linked to their fiber-type composition. During sub-maximal exercise blood flow to respiratory muscles may increase to higher extent than to locomotory muscles. Since shear stress is a key stimulus for alterations in muscle feed arteries, these arteries would be non-uniformly affected during endurance training (TR). To test this hypothesis we compared the effects of TR on contraction and relaxation of diaphragm (DA) and gastrocnemius muscle (GA) feed arteries in vitro. **Methods** Male Wistar rats were treadmill trained for 8 wks. The load was gradually increased, so that by the end of the 5th week rats ran 60 minutes per day at a speed 25 m/min and with incline 10 degrees. Expression of MHC isoforms and succinate dehydrogenase (SDH) was studied in single fibers by immunohistochemistry. Isometric contractile responses to noradrenaline (NA) and serotonin and relaxation to acetylcholine (ACh) in segments (2-mm long) of the arteries were studied. **Results** After 8-week endurance training maximal O<sub>2</sub> consumption in experimental animals was significantly greater than in sedentary control, and lactate threshold was shifted to the right, evidencing effectiveness of the employed training protocol. Composition and cross sectional area of either slow or fast muscle fibers in both muscles were not changed after endurance training. On the other hand in red part of gastrocnemius muscle significant increase of SDH activity was observed in both types of muscle fibers. In costal diaphragm no increase of SDH activity was observed. In controls DA as compared to GA had greater density of sympathetic innervation and higher sensitivity to NA, but not to serotonin. After TR sensitivity to NA did not change in GA, but was reduced in DA; decrease of postsynaptic sensitivity must weaken sympathetic constriction of DA during exercise. In controls dilator responses to ACh and nitroprusside in DA were also greater than in GA. After TR reactivity to ACh was not changed in DA, but prominently increased in GA, the effect was abolished by blockade of NO synthesis. Interestingly, reactivity of both arteries to SNP after TR was diminished indicating smaller sensitivity of smooth muscle to NO. **Discussion** We suggest that the training induced improvement of muscle blood supply is connected with reduced capacity for constriction in DA and with increased capacity for relaxation in GA. Differential effects of TR on DA and GA are related to basic characteristics of these arteries and their host muscles. Supported by the RFBR (grant 09-04-01701-a) and by the Program "Mechanisms of physiological functions: from molecule to behavior" of Biological Science Department, RAS.

#### BLUNTED CARDIOVASCULAR ADAPTATIONS TO INTENSE-INTERVAL COMPARED WITH ENDURANCE TRAINING

COTTER, J.D.1, PARR, E.B.1, STAVRIANEAS, S.2, GRAHAM, M.J.1, AINSLIE, P.N.3, LUCAS, S.J.E.1

*1: OU (DUNEDIN, NEW ZEALAND); 2: WU (OREGON, USA) AND 3: UBC (KELOWNA, CANADA)*

**Introduction** Much of the recent focus on adaptations to maximal-intensity interval exercise has been on energy metabolism, yet cardiovascular adaptations are also important for performance capabilities and health. The purpose of this study was to examine several cardiovascular and endurance-related functional adaptations to endurance (END) versus 30-s repeat high-intensity interval training (RHIE). We hypothesised that resting blood volume and pressure would respond similarly between regimes and sexes, and that the volume responses would relate to improvements in aerobic power and capacity. **Methods** Participants were 12 healthy but untrained adults (5 males, 7 females; age  $23 \pm 4$  y;  $VO_{2max}$   $38 \pm 5$  mL/min/kg). They were ranked within sex for  $VO_{2max}$  and assigned in randomised then alternating order to 8-wk supervised RHIE or endurance cycle ergometer training using established protocols, before a 7-wk washout and crossover. RHIE progressed from four to six 30-s intervals 3 d/wk, while END progressed from 40 to 60 min at 65%HR<sub>max</sub> 5 d/wk. Measures taken before and <3 d after training were  $VO_{2max}$ , resting blood volume (CO dilution) and arterial pressure (Finapres), and cardiovascular responses to 50-min standardised exercise (65% pretraining  $VO_{2max}$ ) and a 10-min work trial. Females were tested on d 4-10 of the menstrual cycle. Inferential analysis was via spreadsheets at [www.newstats.org](http://www.newstats.org). **Results** Increases in red cell volume were larger in END (10±9%) than in RHIE (95%CI for diff: 7±6), whereas differences for blood and plasma volumes were unclear. A 4% smaller increase in red cell volume for females was also unclear (CI: ±13%). Reductions in resting systolic, mean and diastolic pressures were clearly larger in END than RHIE. Reductions in HR at rest (END: -5; RHIE: +2 b/min) were unclear between regimes (CI: -7±8), but reductions during exercise were clearly larger in END (-21 vs -4 b/min; CI: -17±8), with unclear sex differences. Cardiac Troponin concentration responses to fixed-load and work-trial exercise were negligible. Increases in work-trial distance were larger in END (16 vs 5%; CI: 11±7), whereas increases in aerobic power were not (11 vs 16%; CI: -5±8). Changes in blood volume were moderately related to changes in exercising HR ( $r=-.50$ ,  $p=.10$ ) and aerobic power ( $r=.54$ ,  $p=.06$ ) in END, but not in RHIE. **Discussion** Whereas endurance and intense interval training seem to confer similar metabolic adaptations, the present data indicate that endurance training (for 8 weeks) is more effective in raising red cell volume, reducing resting blood pressure and exercising HR, and improving work capacity in previously untrained adults. Similar gains in aerobic power may reflect different myocardial effects.

#### PRE-PARTICIPATION SCREENING IN ELITE RUGBY UNION PLAYERS: ECG PATTERNS AND LOW FALSE POSITIVE RATES

SOMAUROO, J., GHANI, S., RAJU, H., KEMP, S., SMITH, A., SHARMA, S.

*COUNTESS OF CHESTER HOSPITAL, CHESTER; ST. GEORGES HOSPITAL, LONDON; RFU, LONDON; PREMIERSHIP RUGBY, LONDON*

**Purpose:** ECG changes in athletes are common and usually reflect structural and electrical remodelling of the heart to intensive physical training. However, abnormalities of athlete's ECG may be an expression of underlying heart disease. Recent experience of pre-participation screening (PPS) in Italian athletes demonstrates a reduction in mortality from cardiomyopathies and conduction disorders; however such practice attracts criticism due to high false positive rates. In 2010 the Premiership Rugby Union in England introduced formal PPS. **Methods:** All Premiership Rugby Union players underwent PPS with a clinical questionnaire and 12-lead ECG. ECG changes were characterised into training-related (group 1) and those not commonly related to training (group 2). Trans-thoracic echocardiogram (TTE) and other investigations were performed if questionnaire was positive or group 2 ECG changes seen. **Results:** A total of 606 players were assessed (mean age 22.9 years; range 15-37). Group 1 ECG changes included sinus bradycardia in 269 (44.4%), prolonged PR interval in 52 (8.6%), partial RBBB in 53 (8.7%), voltage criteria for LVH in 130 (21.5%) and early repolarisation in 323 (53.3%). Group 2 ECG changes included left axis deviation in 17 (2.8%), right axis deviation in 4 (0.6%), RBBB in 5 (0.8%), voltage criteria for RVH in 1 (0.2%), pro-

longed QT interval in 1 (0.2%), short PR without WPW pattern in 9 (1.5%) and abnormal T wave inversions in 15 (2.5%). Of the 606 players, 45 (7.4%) required TTE [35 (5.7%) due to ECG abnormalities; 5 (0.8%) due to family history of sudden death or cardiomyopathy; 5 (0.8%) due to symptoms]. After TTE, 34 of the 45 players were reassured. Six had abnormal changes on TTE [markedly dilated LV cavity in 3 (0.5%), mitral regurgitation in 1 (0.2%), pulmonary stenosis in 1 (0.2%), dilated aortic root in 1 (0.2%)] requiring serial surveillance. Five (0.8%) had abnormalities on TTE and/or ECG warranting further evaluation [possible ARVC in 3 (0.5%), possible in HCM 1 (0.2%), prolonged QT in 1 (0.2%)]. Further tests included exercise stress test in 5 (0.8%), 24-hour ECG in 5 (0.8%) and cardiac MRI in 3 (0.5%). None of the players exhibited a cardiac disorder warranting disqualification from sport. Conclusion: Cardiovascular evaluation of elite rugby players with a questionnaire and ECG raised no concern in 92.6% players and further 5.6% were reassured after TTE. Only 1.8% players required further tests or serial surveillance TTE. No players were disqualified. ECG patterns seen in rugby players were similar to those described in other sporting disciplines. The false positive rate on PPS with a questionnaire and ECG in an expert setting was low at 5.6% compared to 7% in the Italian experience.

## STRENGTH AND POWER TRAINING DID NOT MODIFY CARDIOVASCULAR RESPONSES TO AEROBIC EXERCISE IN ELDERLY SUBJECTS

QUEIROZ, A.C.C., KANEGUSUKU, H., CHEHUEN, M.R., COSTA, L.A.R., WALLERSTEIN, L.F., MELLO, M.T., UGRINOWITSCH, C., FORJAZ, C.L.M.

UNIVERSITY OF SÃO PAULO; FEDERAL UNIVERSITY OF SÃO PAULO

Introduction: Resistance training increases muscle strength in older adults, which has been suggested to diminish the effort necessary for the execution of physical tasks, and consequently, to reduce the cardiovascular load during exercise. This hypothesis has been proven for strength but not for aerobic stress. Therefore, this study was designed to verify if different resistance training regimens can blunt the cardiovascular load increase in response to an aerobic stimulus. Methods: Thirty-nine older adults were randomly allocated into three groups: Control (C: n=11, 63±1years), Strength Training (ST: n=13, 63±1years, 2x/week, 70-90% of 1RM), and Power Training (PT: n=15, 65±1years, 2x/week, 30-50% of 1RM, concentric phase performed as fast as possible). Before and after 16 weeks, oxygen uptake (VO<sub>2</sub>), systolic blood pressure (SBP), heart rate (HR), and rate pressure product (RPP) were evaluated during a progressive treadmill maximal cardiopulmonary exercise test. Results: Resting SBP and RPP reduced significantly and similarly from pre to post-intervention in all the groups (-7.4±1.5mmHg, -0.52±0.16 mmHg.beat/min.103, respectively, P<0.05). Maximal SBP, HR and RPP did not change throughout the study in either one of the groups. After the interventions, the slopes of the linear regressions calculated for measured VO<sub>2</sub>, HR and RPP in regard to the estimated VO<sub>2</sub> (absolute load) decreased significantly and similarly in all the experimental groups (-0.08±0.02, -10.1±2.5, -1.91±0.42, respectively, P<0.05), while the slope for the linear regression calculated between SBP and estimated VO<sub>2</sub> did not change. The slopes of the linear regressions calculated between all the cardiovascular parameters in regard to the measured VO<sub>2</sub> also did not change after the interventions. Discussion: Oppositely to what is commonly assumed, ST and PT did not reduce the metabolic cost during aerobic exercise in elderly subjects. Thus, they did not blunt submaximal and maximal increases in HR, SBP and RPP during aerobic exercise. Therefore, ST and PT did not reduce cardiovascular stress during aerobic tasks that are part of the daily activities of elderly subjects, such as sweeping the house, washing dishes, walking and so on. Financial support: FAPESP, CNPQ, CAPES and Head of the Psychopharmacology Incentive Fund Association.

## RELATIONSHIPS BETWEEN CARDIAC CHARACTERISTICS AND THE RELATIVE AEROBIC POWER IN MALE AND FEMALE ATHLETES

PAVLIK, G., MAJOR, Z., KOMKA, Z., PETREKANITS, M., KNEFFEL, Z.

SEMMELEWIS UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES

Introduction. As endurance performance markedly depends on the cardiac functions, relationships between some cardiac indices and spiroergometric parameters have been reported in our previous paper (Kneffel et al. Echocardiography, 24 901 2007) and in the papers of several other authors. In the present study relationships between the relative aerobic power, and some morphologic (left ventricular (LV) hypertrophy indicated by the LV wall thickness, internal diameter and muscle mass), functional (diastolic function indicated by the E/A ratio) and regulative (heart rate (HR), cardiac output, circumferential shortening velocity) characteristics of the athlete's heart were investigated in a large number (N=912) of young adult (age: 19-35 yr.) male and female subjects. Methods. Subjects were enrolled to four sub-groups according to their sports activity as follows: endurance athletes – ball-game-players – sprint-and-power athletes – non-athletes. Relative aerobic power was investigated on treadmill or bicycle spiroergometry, cardiac characteristics were measured by two-dimensionally guided M-mode and Doppler-echocardiography. Results. In the whole material, highly significant correlations were between the rel. aerobic power and the LV hypertrophy, E/A and the HR. In the endurance athletes and in the ball-game-players most of the cardiac parameters (rel.LV muscle mass and internal diameter in both genders, wall thickness in males, E/A and HR in females) displayed significant correlations. In the group of sprint-and-power athletes and in non-athletes a few of significant correlations (E/A and HR in sprint-and-power athletes, rel.LV muscle mass and wall thickness in non-athletes) were found only in the males. Conclusion. Endurance trained athletes (endurance athletes and ball-game-players) are supposed to have a high oxidative capacity in their muscles (slow twitch muscle fibres and an improved oxidative metabolism); the limit of the aerobic capacity and performance is the oxygen supply of the muscles which is determined by the cardiac function. The proportion of slow twitch fibres and the oxidative capacity in sprint-and-power athletes is lower; performance is already limited in the periphery.

#### RPS6 PHOSPHORYLATION MIMICS BLOOD INSULIN PROFILE WITH DIFFERENT PROTEIN INGESTION REGIMENS FOLLOWING RESISTANCE EXERCISE

ARETA, J.1, BURKE, L.2, JEACOCKE, N.2, ROSS, M.2, BROAD, E.2, PHILLIPS, S.3, MOORE, D.4, STELLINGWERFF, T.4, HAWLEY, J.1, COFFEY, V.1

1IRMIT UNIVERSITY, VICTORIA, AUSTRALIA, 2AUSTRALIAN INSTITUTE OF SPORT, CANBERRA, AUSTRALIA, 3MCMASTER UNIVERSITY, HAMILTON, CANADA, 4NESTLÉ RESEARCH CENTER, LAUSANNE, SWITZERLAND

mRNA translation is a key step in the regulation of muscle protein synthesis (MPS). Resistance exercise and nutrients both stimulate MPS, with the two having an synergistic effect on anabolic signals important for muscle hypertrophy. To date, no study has determined the interaction of manipulating nutrient availability after exercise during prolonged (12 h) recovery. Purpose: To determine the time-course of anabolic signaling during prolonged recovery from resistance exercise. Methods: 24 resistance trained men were randomly assigned to one of three groups, reporting to the laboratory after a 10-12 hr overnight fast. Immediately following leg extension exercise (4 sets × 10 reps @ 80% 1-RM, 3 min recovery) each group received whey protein in a different dosing regimen over 12h of recovery: 1) PULSE: 8 × 10 g (125 mL) every 1.5h; 2) INT: 4 × 20 g (250 mL) every 3h; and 3) BOLUS: 2 × 40 g (500 mL) every 6h. Biopsies from vastus lateralis were taken at rest and 1, 4, 6, 7 and 12 h post-exercise. Blood insulin profile and rpS6 Ser235/6 phosphorylation was measured as a marker of the nutrient response and translation initiation for MPS. Results: BOLUS increased phosphorylation of rpS6 Ser235/236 at 1h (~7 fold,  $P < .001$  compared to baseline) which with a trend to a change after 7h ( $P = .08$  compared to baseline). In contrast there were no differences in rpS6 Ser 235/236 phosphorylation with either INT or PULSE feeding protocols at any time-point compared to baseline. Blood insulin concentrations followed a similar pattern to that of the phosphorylation status of rpS6 showing two peaks at ~1h and ~7 h post exercise. Conclusion: BOLUS whey protein ingestion was associated with the greatest anabolic signal compared to the other feeding regimens. If rpS6 activity is a good predictor of muscle protein synthesis we expect that these results will correlate with FSR. Specifically, our results indicate that feeding doses of 20 and 10 g of protein fail to exert a noticeable change in this marker of translational machinery activation. This project was funded by ARC project linkage grant LP100100010.

#### EXERCISE-SPECIFIC MTOR, BUT NOT AMPK SIGNALING IN TRAINING-ACCUSTOMED INDIVIDUALS

VISSING, K.

UNIVERSITY OF AARHUS

Exercise-specific mTOR, but not AMPK signaling in training-accustomed individuals Vissing, K.1, McGee, S.L.2, Farup, J.1, Kjølhed, T.1, Vendelbo, M.H.3, Jessen, N.3. 1. Dept. of Sport Science, Aarhus University, DK-8000 Aarhus, Denmark, 2. Metabolic Research Unit, School of Medicine, Deakin University, Geelong, Australia, 3. Department of Internal Medicine and Endocrinology, Aarhus University Hospital, DK-8000 Aarhus, Denmark. Introduction An AMPK-Akt "switch" signaling mechanism has previously been suggested to explain adaptations to frequency-dependant electrical stimulation in rat muscle (1), while similar exercise-induced signaling selectivity in humans seem more equivocal (2-3). We hypothesized, that in human individuals accustomed to exercise through prior training, Akt-mTOR signaling is selectively activated by strength exercise, while AMPK signaling responses are less specific for exercise type. Methods 24 untrained individuals were divided in endurance, strength or non-exercise control groups. Exercise groups completed extended progressive training programs. Single-bout exercise trials were then conducted in the fasted state including comparison to a non-exercising control group, with blood and muscle samples collected prior to and at 0, 2.5, 5 and 22 hours post-exercise recovery to be analyzed for selected plasma substrates and hormones and for protein phosphorylation of muscle markers of AMPK and Akt-mTOR signaling. Results: endurance training (ET) producing an increase in  $\dot{V}O_{2\max}$  (~11%;  $p < 0.01$ ) and a decrease in submaximal exercise heart rate (~13%;  $p < 0.001$ ) and with strength training (ST) producing increases in knee extensor (~9%;  $p < 0.01$ ) and mean fiber cross-sectional area (~18%;  $p < 0.05$ ), respectively, and increases in peak torque (~19%;  $p < 0.001$ ) and maximal dynamic strength (~39%;  $p < 0.001$ ) of knee extensor muscle. Increased plasma levels of glucose, insulin, GH and IGF-1 and increased phosphorylated levels of muscle PAS AS160, mTOR, P70S6K and GSK-3 $\alpha$ , were observed exclusively after strength exercise ( $p < 0.05$ ). Increased phosphorylation of AMPK, HDAC5, CREB and ACC was observed after endurance exercise ( $p < 0.05$ ), but with similar trends observed after strength exercise and with no difference between exercise groups. No changes in these measures were observed in non-exercising controls. Discussion The results support that in trained individuals, downstream mTOR-signalling is selectively activated by strength exercise during late post exercise recovery, while homogeneity exists for AMPK-signaling for differentiated exercise. #### THE SUPERVILLIN POLYMORPHISM RS6481619 IS NOT ASSOCIATED WITH MAXIMAL OXYGEN UPTAKE OR ITS TRAINING RESPONSE

WILLIAMS, A.G., DAY, S.H., JOHNSON, D., MCPHEE, J.S.

MANCHESTER METROPOLITAN UNIVERSITY

THE SUPERVILLIN (SVIL) POLYMORPHISM RS6481619 IS NOT ASSOCIATED WITH MAXIMAL OXYGEN UPTAKE OR ITS TRAINING RESPONSE 1Williams A.G., 1Day S.H., 1Johnson D., 2McPhee J.S. 1Institute for Performance Research and 2Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University, UK Introduction Understanding interindividual variability in response to aerobic training holds the potential for a more individualised approach to exercise prescription. Recently, Timmons et al. (2010) identified 11 single nucleotide polymorphisms (SNPs) that collectively accounted for 23% of the variance in the gains in maximal oxygen uptake in the HERITAGE Family study (Bouchard et al. 1999). Most of these polymorphisms have not previously been associated with exercise responses and thus replication is needed. Here we analyse the potential association between one of those polymorphisms, the supervillin (SVIL) SNP rs6481619, and data derived from McPhee et al. (2009). Method McPhee et al. (2009) obtained one-leg cycling peak oxygen uptake and two-leg cycling maximal oxygen uptake in 61 previously sedentary women before and after a six-week aerobic cycle training programme. DNA was extracted from 200  $\mu$ L whole blood using spin columns (Qiagen, Crawley, UK). Genotyping was performed via

real-time PCR using a Chromo4 machine (BioRad, Hemel Hempstead, UK) and a custom Taqman® SNP genotyping assay (Applied Biosystems, Warrington, UK). Data were analysed using ANCOVA, with body mass and physical activity as covariates. Results One-leg cycling peak oxygen uptake increased from 1.9 L/min to 2.1 L/min and two-leg cycling maximal oxygen uptake increased from 2.4 L/min to 2.7 L/min (both  $P < 0.0005$ ). No significant associations were observed between the SVIL rs6481619 SNP (AA=32, AC=25, CC=4) and any oxygen uptake data ( $0.15 \leq P \leq 0.99$ ). In particular, whether treated as 3 separate genotype groups ( $P = 0.808$ ) or as A-allele homozygotes vs. C-allele carriers ( $P = 0.536$ ), there was clearly no association between genotype and the response of maximal oxygen uptake to training – i.e. the phenotype used by Timmons et al. Discussion The SVIL rs6481619 SNP accounts for 4% of the observed variance in the Timmons et al. study. Very recent work by Bouchard et al., using precisely the same phenotype data as Timmons et al. (but different methods to identify candidate genes), also fails to replicate the SVIL data. In that context, it is less surprising that we fail to replicate the Timmons et al. observation in an independent cohort with different training intensity and volume. ### IS THERE A DOSE-RESPONSE EFFECT OF A DUAL DA/NA REUPTAKE INHIBITOR ON PERFORMANCE AND THERMOREGULATION IN THE HEAT?

ROELANDS, B., CORDERY, P., WATSON, P., DECOSTER, S., DEBASTE, E., MEEUSEN, R.

VRUE UNIVERSITEIT BRUSSEL

Introduction Bupropion, a dopamine/noradrenaline (DA/NA) reuptake inhibitor has previously shown to possess both ergogenic and thermogenic properties (Watson et al, 2005). It appears that bupropion (2x300mg) enabled subjects to maintain a higher power output with the same perception of effort and thermal stress while obtaining significantly higher core temperatures. Despite this ergogenic effect and the potentially high risk for developing heat illness, bupropion is not a prohibited substance. Furthermore, it is not known if lower doses (50 and 75% of the maximal daily dose of 300mg) exert the same effects during exercise in high ambient temperature. Methods Ten healthy trained male cyclists (age  $25 \pm 4$  y;  $W_{max}$   $351 \pm 27$  W;  $VO_{2max}$   $63.5 \pm 6$  ml/min/kg) completed four experimental trials in  $30^{\circ}\text{C}$  in a double blind-randomized crossover design. Subjects ingested either placebo (pla; 300 mg) or bupropion (300 mg =bup100; 225 mg = bup75 or 150 mg = bup50) on the evening before and the morning of the trials. Subjects cycled for 60min at 55% $W_{max}$ , immediately followed by a time trial (approx. 30min) to measure performance. Statistical analysis was performed with a 2-factor (drugxtime) repeated measures ANOVA, paired samples t-tests were used to identify pair-wise differences. The significance level was set at  $p < 0.05$ . Results In the placebo trial subjects took  $35.7 \pm 6.7$  min to complete the time trial while in the bup50 trial this was  $33.7 \pm 3.4$  min ( $p = 0.375$ ); in the bup75 trial  $33.4 \pm 3.4$  min ( $p = 0.247$ ); bup100:  $33.1 \pm 3.7$  min ( $p = 0.316$ ). No differences between the bupropion trials were observed ( $p > 0.05$ ). Core temperature was significantly higher in the bup100 trial at the end of exercise ( $p = 0.035$ ) compared to the placebo trial. No differences in ratings of perceived exertion and thermal sensation were detected ( $p > 0.05$ ). Discussion In contrast to the previous study, no statistical significance could be shown for performance, despite a 2 to 2.6 min or 5 to 7% better performance in the bupropion trials. Furthermore, no difference between the doses of bupropion were observed, indicating that even the lowest dose (2x150 mg) resulted in the same effects on performance. Core temperature rose significantly after administration of the highest bupropion dose. This is an effect that was also observed in our previous study and that is caused by the increased metabolic heat production resulting from the maintenance of a higher power output. ### SKELETAL MUSCLE SIGNALLING IN RESPONSE TO SPRINT EXERCISE: SEX DIFFERENCES?

FUENTES, T., GUERRA, B., PONCE-GONZÁLEZ, J.G., MORALES-ÁLAMO, D., GUADALUPE-GRAU, A., OLMEDILLAS, H., RODRÍGUEZ-GARCÍA, L., FEJOO, D., PÉREZ, I., MARTÍNEZ, P., CALBET, J.A.L.

UNIVERSITY OF LAS PALMAS DE GRAN CANARIA

Introduction. Sprint exercise leads to the activation of several signalling cascades, particularly those involved in the regulation of metabolism and the response to cellular stress in the skeletal muscle. Despite differences between men and women in both the metabolic response to endurance and sprint exercise no single study has determined whether a sex dimorphism in skeletal muscle signalling response to sprint exercise exists in humans. Purpose. To determine if there a sex dimorphism in the AMPK, MAPK/ERK and STAT3 muscle signalling pathways in response to 30s all-out sprint test (Wingate test). Methods. Seventeen men and ten women performed a 30-s Wingate test. Muscle biopsies were taken before, immediately after the exercise and at 30 and 120 minutes during the recovery period. Results. Thr172-AMPK $\alpha$ , ACC $\beta$  Ser221, Thy705-STAT3, Thy202/Thy204-ERK1/2 and Thy180/Thy182-p38MAPK phosphorylation responses to sprint exercise were similar in men and women. Thr172-AMPK $\alpha$  phosphorylation was enhanced fourfold 30 min after the sprint exercise in males and females ( $P < 0.01$ ). The ACC $\beta$  Ser221 phosphorylation was enhanced by about threefold just after the sprint test exercise and 30 min into the recovery period in males and females ( $P < 0.01$ ). Thy705-STAT3 phosphorylation was increased two hours after the Wingate test compared to the value observed right after the end of the exercise ( $P < 0.05$ ) and 30 min after the Wingate test there was a 2.5-fold increase in Thy202/Thy204-ERK1/2 phosphorylation, compared to both the pre-exercise and to the value observed right after the Wingate test (both,  $P < 0.05$ ). Conclusion. The muscle signalling response to a single bout of sprint exercise mediated by AMPK, ACC, STAT3, ERK and p38MAPK is essentially similar in men and women. Marked increases in AMPK, ACC, STAT3, and ERK phosphorylation were observed after a single 30s all-out sprint (Wingate test) in the vastus lateralis. Supported by grants from FUNCIS 10/07 and Ministerio de Educación y Ciencia, Spain (DEP2010-21866).

#### CROSSTALK BETWEEN THE EXERCISE-INDUCED MECHANICAL HYPOALGESIA AND ISOKINETIC MUSCLE STRENGTH

PENCHEVA, N., STOILOV, A., GRANCHARSKA, K.

*SOUTH-WEST UNIVERSITY*

**CROSSTALK BETWEEN THE EXERCISE-INDUCED MECHANICAL HYPOALGESIA AND ISOKINETIC MUSCLE STRENGTH** Pencheva, N.I., Stoilov, A. 2, Grancharska, K. 1: Department of Sports and Kinesiotherapy and 2: Department of Physics of SOUTH-WEST UNIVERSITY (Blagoevgrad, Bulgaria) **Introduction** The exercise-induced hypoalgesia (EIH) is a controversial issue and further research is warranted. The aim of this study was: - to compare pain-pressure threshold (PTT) at rest of gastrocnemius-soleus muscle (GS) between dominant and non-dominant lower leg or between lateral and medial part of GS belly; - to assess the degree of EIH in loaded (GS) and unloaded (b. brachii; BB) limb; and - to correlate PPT or EIH with muscle strength. **Methods** The study included 19 right-handed, right-legged, male volunteers (median age: 21 years, range 18-23). Hand-held pressure algometer (Somedic AB) was used to evaluate the PTT (kPa/cm<sup>2</sup>). The pressure (increase rate of 50 kPa/s) was applied to left and right lower leg on both lateral or medial part of the GS belly and to left and right BB, before and 15 min after treadmill test to exhaustion. The elevation of the PTT after exercise was a measure for the degree of EIH. To define subject's maximal ankle (plantar/dorsal flexion; speed: 30 o/s) or knee (flexion/extension; speed: 60 o/s) muscle strength, an isokinetic dynamometer (Biodex System 4 Pro) was used. **Results** The medial part of the GS muscle was more sensitive to pressure (PTT, kPa/cm<sup>2</sup>: 350±25-right side; 350±24-left side) as compared with the lateral (430±18 and 390±19, respectively), but only the right lateral part was less sensitive as compared to the left one. The EIH (kPa/cm<sup>2</sup>) was maximal for the lateral part of right GS (150.2±17.39) and was more pronounced in comparison with unloaded limb (right BB: 63.5±15.8). The EIH correlated ( $p<0.05$ ) to ankle muscle strength (plantar flexion, 117.8±8.7 NM;  $r=0.77$ ) and knee muscle strength (flexion, 121.3±6.7 NM,  $r=0.69$ ; extension, 239.5±11.8 NM,  $r=0.54$ ). **Discussion** The differences in PPT's between lateral and medial part of GS found in the present study, correspond to suggestions (Polianskis et al., 2001) for different nociceptor density in functionally diverse locations of a muscle. The EIH is not localized to the exercising body part. Central pain inhibitory mechanisms probably mediate the EIH (Koltyn, 2000; Drury et al., 2004; Pencheva and Petrova, 2005), but the greatest decrease in PPT occurs in the exercising limb. The correlation between the EIH with isokinetic muscle strength found in this study suggests that the endogenous modulation of pain perception following exercise improves muscle strength. **References** Drury DG, Stuempfle K, Shannon R, Miller J (2004). #### GREATER PERIPHERAL FORCE PRODUCTION ABILITIES AND NOT GREATER CENTRAL DRIVE EXPLAIN SUPERIOR CYCLE TIME TRIAL PERFORMANCE

RENFREE, A., WEST, J., CORBETT, M., RHODEN, C.

*UNIVERSITY OF WORCESTER*

**Introduction** Compensatory neuromuscular activity has been demonstrated to occur in response to impaired muscular force production during fatiguing exercise (Bundle et al 2006). However, to our knowledge no study has compared neuromuscular activity during self paced exercise tasks of differing levels of performance. This study therefore compares power output and neuromuscular activity during the fastest and slowest of two 20km cycle time trials. **Methods** One female and six male well trained participants ( $31 \pm 11$  years) who were currently active in competitive road cycling performed two 20km time trials using their own bicycles mounted on the Kingcycle ergometer rig. Instantaneous power output and surface iEMG measured from the vastus lateralis, biceps femoris, and tibialis anterior over a 10s period were recorded at 0.5km intervals. iEMG data was subsequently normalised against MVC for each muscle group. Mean power and iEMG data were calculated for each 5km segment of the fastest and slowest trials performed, and a Two Way ANOVA for repeated measures was used to assess differences between trials. **Results** Three participants achieved their fastest time in the first trial performed, and four in the second. Mean time to complete fastest and slowest trials was  $1796 \pm 154$ s and  $1872 \pm 208$ s respectively. Power output was significantly higher ( $P<0.01$ ) in every individual 5km segment of the fastest overall trials, whilst iEMG activity was greater ( $P<0.05$ ) in every individual segment of the slowest overall trials. **Discussion** The similar shape of the power profiles during fastest and slowest trials suggest a high degree of regulation of pacing and that differences in performance were not the result of premature onset of fatigue during the slowest trials. However, the greater neuromuscular activity in conjunction with the lower muscular power output indicates that peripheral force production abilities were somehow compromised during the slower trials. Although the exact nature of this impairment is unknown, the results of this study indicate that differences in performance between two self paced time trials result from variation in peripheral physiological status and not from variation in central motor drive. **References** Bundle, M.W., Ernst, C.L., Bellizzi, M.J., Wright, S., Weyand, P.G. (2006). American Journal of Physiology – Regulatory, Integrative and Comparative Physiology, 291(5), 1457-1464.

#### LARGER BILATERAL FORCE DEFICIT IN PROXIMAL THAN DISTAL JOINTS MIGHT BE LINKED TO DIFFERENCES IN INTER-HEMISPHERIC COMMUNICATION

AUNE, T.K., AUNE, M.A., ETTEMA, G., VEREIJEN, B.

*NORD TRONDELAG UNIVERSITY COLLEGE*

**Introduction** The term bilateral force deficit (BFD) is used to describe that maximal muscle force is lower during simultaneous contraction of muscles bilaterally compared to the sum of forces generated unilaterally. The physiological explanations of BFD are mainly based on theory of neural inhibition, and there is mounting evidence for a higher order of inhibition related to the interaction of the primary motor cortex (M1) of the two hemispheres when performing concurrently bilateral contractions. These interhemispheric inhibitory interactions might decrease neural drive to the activated muscles. Based on the morphological and functional differences between proximal and distal joints the purpose of this study was to explore eventually differences in BFD in proximal and distal joints in the upper extremities/arms. **Method** Ten volunteer male ( $n=5$ ) and female ( $n=5$ ) sport science students participated in the experiment. The subjects underwent two days of testing. The subjects were tested in two unilateral conditions and the bilateral condition in constrained single-joint maximal voluntary contraction (MVC) in isometric flexion of the shoulder and index finger. **Results** The results showed a significant BFD for

shoulder flexion (20.51%), while there was a relatively small and non significant BFD for index finger flexion (5.22%). Discussion These results indicate that the commissural fibers in corpus callosum preserving interhemispheric communication have an inhibitory effect for proximal muscles, while distal muscles are less inhibited. The significant difference in BFD between proximal and distal muscles might be explained by the high number of commissural fibers connecting the motor cortex areas for proximal joints compared to distal joints. It is concluded that the commissural fibers in corpus callosum preserving interhemispheric communication in general might have an inhibiting effect on bimanual motor tasks. References Brodal, P. #### IS-BN03 Musculoskeletal Modelling for Assessing Loading and Risk of Injury

##### THE ROLE OF MUSCLE FORCES IN JOINT LOADING AND INTRA-ARTICULAR LOAD DISTRIBUTION: EXPERIMENTAL RESULTS AND IMPACT ON MODELLING

BRÜGGEMANN, G.

GERMAN SPORT UNIVERSITY COLOGNE

In human movement studies it is common to calculate the net joint moments of the proximal joint of a body segment using an inverse dynamic approach. More detailed models distribute the net moments and net forces acting on a given joint to muscle forces, bone-to-bone forces and ligament forces. Such models use a number of assumptions e.g. the muscle moment arm, muscles' line of action, take additional information into account (e.g. muscle activation) and quite often use static optimization with a more or less randomly chosen cost function to solve the mathematically underdetermined problem. Finite element models can probably estimate the intra-articular stress and stress distribution but such models are strongly depend on information on the material properties of the elements and the force applied to the joint through muscle forces, inertial forces, axial and shear forces. Direct pressure distribution measurements have been applied in ex-vivo studies to joints of the human leg and especially to the talocrural joint, the patello-femoral joint and the tibio-femoral joint. Potthast et al. (2008) showed in a systematic approach using a pneumatic loading simulator on fresh frozen cadaveric legs the strong effect of the application of muscle forces to the talocrural joint. The muscle forces and their distribution have been shown to build the dominant determinants of intra-articular joint and biological tissue loading. The data demonstrated extreme individual results. Recent data demonstrated the role the muscles play in the tibio-femoral joint. The study used a pneumatically driven knee simulator in an ex-vivo experiment and allowed an inside view into changes in intra-articular loading patterns related to joint alignment (varus, valgus) and muscle forces of thigh and shank. Depending on the muscle forces applied the centre of intra-articular pressure moved up to 12 mm in medio-lateral and 5 mm in anterior-posterior directions. The effect of different quadriceps loading patterns on the patello-femoral contact pressure during simulated weight bearing knee flexion was recently reported by Wünschel et al. (2011). The impact of more medial or lateral applied quadriceps loading to the pressure distribution between patella and trochlea and especially the centre of contact pressure was clearly demonstrated. The ex-vivo data explore the dominant role the muscle forces play for intra-articular joint loading and therefore joint tissue loading. A more detailed inspection of the results allows a significant inside view into the variability of intra-articular loading patterns in different subjects and the high individuality of results. These finding should have a major impact on modelling especially if individualized estimates of intra-articular or tissue loading are the purpose of research. ##### KNEE MODELLING AND IN-VIVO CHANGES WITH CONTRACTION: IMPLICATIONS FOR ESTIMATING JOINT FORCES AND LOADING

BALTZOPOULOS, V.

MANCHESTER METROPOLITAN UNIVERSITY

Human movement is the result of muscle moments (muscle force x moment arm) applied around the joint axes of rotation. Since the muscle and tendon operate in series, the mechanical properties of tendons and any changes in moment arms will affect muscle length, velocity and, therefore, force output and the muscle moment applied to the joint. In addition to muscle length and force changes during dynamic activities, moment arms and lines of action of muscles and tendons also change with contraction (Tsaopoulos et al., 2007a). Although moment arms cannot be easily predicted from anthropometric characteristics in adults (Tsaopoulos et al., 2007b; O'Brien et al. 2009) and there are significant differences in the estimates of moment arm length when using different joint rotation centre definitions, in the knee for example (Tsaopoulos et al., 2009), it is well recognized that contraction-specific parameters are required for the realistic estimation of muscle and joint forces in musculoskeletal modelling and simulation applications. We have recently calculated tibiofemoral knee joint forces during dynamic isokinetic concentric knee extension and the differences between resting-state and contracting-state measurements of moments arms and lines of tendon action lead to overestimated compressive and shear forces when using the resting-state parameters throughout the joint range of motion. The overestimation of the maximum compressive force when using resting-state mechanical parameter values was ~418 N (5.8%) or ~0.6 times body weight (BW) with a shift of the average maximum force joint position from 45 to 30 deg of knee flexion. The maximum shear force was overestimated by ~1120 N (158%) or 1.6 BW when using resting-state parameters. Inflated tibiofemoral forces would over-estimate loading of the knee joint and risk of injury during dynamic activities involving knee extension. This review of our work on muscle-tendon and joint function shows that there are important in-vivo interactions, which have significant implications for performance, measurement of dynamic strength, and estimation of loading in the musculoskeletal system using modern modelling and simulation techniques. ## RELATIVE INFLUENCE OF REALISTIC SEGMENTAL MOTION AND JOINT MODELLING ON

LAKE, M.

LIVERPOOL JOHN MOORES UNIVERSITY

RELATIVE INFLUENCE OF REALISTIC SEGMENTAL MOTION AND JOINT MODELLING ON LOWER LIMB LOADING DURING RUNNING AND SPRINTING Lake, M. John Moores University, Liverpool, U.K. Background The contribution of segmental accelerations to joint kinetic calculations during locomotion has often been underestimated and there are several data collection issues to address before utilising the inverse dynamics technique to determine joint kinetics for movements that have some high frequency characteristics. We have previously explored non-invasive methods to adequately track and then capture lower limb segmental movement transients (Digby et al., 2005) and more recently have examined their influence on joint kinetic calculations (e.g. Smith and Lake, 2007). This review summarises some of the important methodological factors to consider when attempting to record joint motion and loading during running and sprinting. Realistic lower limb motion transients and joint axis modelling Information regarding the typical frequency content of segmental motions during running and sprinting is limited in the literature, but there are indications from bone pin studies that tibial motion has frequencies up to 30-40 Hz. By maintaining those frequencies in the data we have been successful in matching our non-invasive estimates of movement transients to similar measures using bone pins. There is a dual consideration for the measurement of the transients non-invasively: 1) that the marker or accelerometry mounting system on the skin is likely to track fast underlying bone motion; 2) that the transient motion is captured adequately using appropriate sampling rates and filter cut-off frequencies. Using those precautions we have measured peak movement transients that are more than double those previously documented (e.g. peak internal rotation velocity of the tibia). The modelling of lower limb joint axes and the accuracy of moment arm lengths typically has a larger influence on joint kinetic calculations than accurate segmental accelerations. However, we have found that for some joints during sprinting the movement transients can have a similar and opposite influence on joint moments and powers to those observed when manipulating joint axis definitions. Conclusion Few studies have attempted to justify their non-invasive approaches to measure fast lower limb movements during running and, in some cases, it is likely that there may be a substantial underestimation of movement transients. A more realistic consideration of both movement transients and joint axes are required before interpreting joint kinetic data during the stance phase of running and sprinting. ## MODELLING INDIVIDUAL-SPECIFIC NEUROMUSCULAR AND MORPHOLOGIC CONTRIBUTIONS TO KNEE INJURY: MOVING BEYOND HOMOGENEOUS PREVENTION

MCLEAN, S.

UNIVERSITY OF MICHIGAN

In spite of knee joint and particularly ACL injury mechanisms increasingly viewed as multi-factorial, few injury prevention efforts extend beyond an isolated neuromuscular focus. This limited approach has stemmed primarily from the fact that neuromuscular factors can be readily modified through common training principles. Being largely viewed as non-modifiable, knee joint morphologies have typically been ignored within the prevention model. With such factors directly impacting knee joint mechanics and resultant ACL loading, however, we contend that their neglect drastically compromises prevention success. A precise understanding of the integrative contributions of individual-specific neuromuscular and morphologic factors to knee joint injury risk thus seems critical. The inherent complexities associated with assessing combined neuromuscular and morphologic contributions to knee injury render in vivo experimental-based methods virtually impossible. Our own work has been driven by the notion that the application of innovative modeling techniques may circumvent this issue. We have previously utilized valid subject-specific model landing simulations to examine the effects of realistic neuromuscular perturbations on 3D knee loading (McLean et al., 2003). With these models, we have identified high-risk individual-specific landing neuromechanical profiles (McLean et al., 2004) and subsequently elucidated explicit training adaptations that may act to reduce this risk (McLean et al., 2009). The finite element (FE) modeling method is a powerful and versatile modeling tool capable of reproducing highly complex joint tissue geometries and the mechanical behavior of constituent materials at discrete points throughout a system. With this in mind, we have developed finite element modeling techniques that reliably simulate knee joint and resultant ACL load states during high-impact landings as a function of explicit specimen specific morphologies (e.g., posterior tibial slope angle and ACL laxity) (McLean et al., 2010). We now initiate innovative surrogate modeling methods that couple forward dynamic and structurally relevant FE models to successfully predict the knee joint and ligamentous response. Through these novel efforts, we aim to establish a non-invasive clinical risk screening tool that targets and ultimately counters knee injuries based on individual-specific neuromechanical and joint factors. We agree developing models of this type represents a substantial and perhaps currently insurmountable computational challenge. The potential for reducing catastrophic knee injuries and their long-term sequelae, however, suggests such efforts are both warranted and vital. References 1. McLean SG, Su, A, van den Bogert, AJ. #### DIFFERENT CHANGES IN OXIDATIVE STRESS AND NO BIODISPONIBILITY DURING 24 HOURS IN HYPOBARIC VS NORMOBARIC HYPOXIA

FAISS, R.1,2, JAGDEEP, S.2, PIALOUX, V.3, SARTORI, C.4, FAES, C.3, PRAZ, M.2, DÉRIAZ, O.2, MILLET, G.P.1

1: ISSUL, FBM (LAUSANNE, SWITZERLAND), 2: IRR (SION, SWITZERLAND), 3: CRIS (LYON 1, FRANCE), 4: CHUV (LAUSANNE, SWITZERLAND)

**Introduction** Slight differences in physiological responses at rest have been reported between hypobaric hypoxia (HH) and normobaric hypoxia (NH) during short exposure (4). It has been also suggested that hypobaria per se might influence the nitric oxide (NO) regulation (1) and that NO influences the physiological differences between HH and NH (2). In addition, oxidative stress is known to decrease the NO bioavailability in the vasculature (5). To date, comparison of HH vs NH physiological responses during moderate exercise, NO end-products and oxidative stress markers over a long period (24 h) was not reported yet. **Methods** Ten male subjects were randomly exposed for 24 h to actual (HH) or simulated (NH) high-altitude (3000m). Pre- and every 8h, plasma levels of oxidative stress (i.e. MDA, AOPP), antioxidant power (FRAP) and peroxynitrite activity (nitrotyrosine), exhaled NO [exNO] and blood nitrate and nitrite [NOx] were measured at rest and oxygen arterial saturation (SpO<sub>2</sub>), heart rate (HR) and gas exchanges during a 6-min cycling exercise at 50% of peak power output. Results exNO decreased ( $p < 0.05$ ) in HH (-10%, -35% and -21% after 1h, 16h and 24h) but remained stable in NH. Similarly, NOx decreased over 24h in HH (-36%,  $p < 0.05$ ) but was stable in NH. In opposition, AOPP increased more ( $p < 0.05$ ) in HH (+120%, +116% and +260% after 1h, 16h and 24h) than in NH (+13%, +23% and +88%). The other oxidative stress markers did not change either in HH or in NH. During exercise, minute ventilation and tidal volume were lower in HH compared to NH after 8h and 16h ( $p < 0.05$ ). SpO<sub>2</sub>, HR, oxygen consumption, breathing frequency, end tidal O<sub>2</sub> pressure and heart rate showed similar adaptations in HH and NH. **Discussion** This study reports the time course of adaptations in oxidative stress and physiological responses to moderate exercise throughout a 24h period in HH compared to NH. The exercise-induced increase in ventilation was lesser in HH than NH and was associated with a decrease in NO biodisponibility in HH as already observed (1). Furthermore, the concomitant increase in AOPP in HH suggests that oxidative stress might inhibit NO as it was previously demonstrated (3). However it remains unclear if the decreased NO bioavailability and the increased oxidative stress are involved in the lower ventilatory adaptations to hypoxia observed in HH. **References** Hemmingsson T, Linnarsson D (2009) *Respir Physiol Neurobiol* 169:74-77. **Introduction** Intensive physical activity is closely related to the production of free radicals, which play an important role as mediators of skeletal muscle damage. This study examined the effects of Astaxanthin (Asx) supplementation on oxidative and enzymatic exercise stress markers in elite young soccer players. Evaluations were made after 90 days of regular training activity and supplementation. **Methods** 32 male soccer players (age  $17.72 \pm 0.76$  years) participated in this study. Subjects were randomly assigned in a double-blind fashion to astaxanthin (Asx) and placebo (P) group. Asx group was supplemented with 4 mg of Asx. Blood was obtained before and after 2 hours training, at the end of observational period. The biomarkers of oxidative stress taken in consideration were total antioxidative status (TAS), superoxide-dismutase (SOD), superoxide anion (O<sub>2</sub><sup>-</sup>) and advanced oxidation protein products (AOPP). Serum activity of creatine-kinase (CK), lactate-dehydrogenase (LDH) and aspartate-aminotransferase (AST) were also measured. Results TAS decreased after the training in both groups, but this change reached statistical significance only in P group ( $p < 0.01$ ), which indicates that Asx supplementation could support antioxidant defense mechanism. A trend for increased serum SOD was observed in both groups following training, with higher SOD activity in Asx group compared to P group. As a result of training, AOPP and O<sub>2</sub><sup>-</sup> concentrations increased in P group, while there was a decrease in these parameters in Asx group. These changes did not reach statistical significance. Post-exercise elevations above resting values was observed for CK and AST in the P group ( $p < 0.01$ ), while remained practically unchanged in Asx group. We observed significant increase in LDH activity in both groups after the training ( $p < 0.01$  for both groups). **Discussion** Antioxidant activity of Asx can have potential benefits in protection of non-enzymatic (TAS) defense mechanism from free radical production. Asx supplementation may help in neutralizing O<sub>2</sub><sup>-</sup> and reducing protein oxidation during exercise. Asx reduced post-training increment of CK and AST, which may suggest that the muscular damage was reduced. Based on our findings, supplementation with astaxanthin might be beneficial strategy in improving sport recovery and performance. Tsakiris S, Parthimos T, Tsakiris T, Parthimos N, Schulps K. #### LEAD ACETATE, AND OXIDANT/ANTIOXIDANT, INFLAMMATORY AND NEUROTHROPHIC-MARKERS: NEURO AND CARDIO-PROTECTIVE EFFECTS OF EXERCISE TRAINING AND CURCUMIN

HOSSEINZADEH, M., DABIDI-ROSHAN, V., HOSEINZADEH, S., JOLAZADEH, T., MAHJOB, S.

UNI. OF MAZANDARAN

**Introduction** Lead is one of the most important metals that pollute the natural environment due to man's impact. The toxicity of many heavy metals is due to their ability to cause oxidative damage to tissues. Health effects of exposure to air pollution have been indicated by previous studies (Bharat et al. 2009, Boris et al. 2008, Chuang et al. 2007). We investigated the neuro and cardio-protective effects of exercise training and/or curcumin on lead acetate induced damage in rats homogenized tissues. **Methods** Forty rats were randomly divided into 5 groups: (1) lead acetate (Pb), (2) curcumin+Pb, (3) endurance training+Pb, (4) training+curcumin+Pb, (5) sham-operated groups. The rats in the 3 and 4 groups experienced the treadmill running of 15 to 22 m/min for 25 to 64 minutes, 5 times a week for 8 weeks. The 1 to 4 groups received lead acetate (20 mg/kg), the sham-operated group received curcumin solvent (ethyl oleat), and the 2

and 4 groups received curcumin solution (30 mg/kg) intraperitoneally, 3 times a week for 8 weeks. Results The two-way ANOVA analyses indicated, Lead administration resulted in significant increases in Metallothionein-3 (MT-III), high-sensitive C-reactive protein (hs-CRP), creatine kinase-MB (CK-MB), malondialdehyde (MDA), and low-density lipoprotein (LDL), but significantly decreased brain-derived neurotrophic factor (BDNF), glutathione peroxidase (GPx), Total Antioxidant Capacity (TAC), and high-density lipoprotein (HDL) levels. However, treadmill running and/or curcumin supplementation resulted in a significant decrease in hs-CRP, CK-MB, MDA, and LDL levels and significantly increased BDNF, GPx, TAC, and HDL levels. Moreover, there was an inhibitory effect of training+curcumin on chronically lead acetate administration in the hippocampus MT-III levels, as compared to other groups. Discussion The present study demonstrates the restorative potential of curcumin and exercise training by reversing lead-induced oxidative damage in brain and heart. Treatment by curcumin and exercise training restored these damages and tended to normalize biomarkers, suggesting a reversal of lead-induced toxicity, and confirming the free radical scavenging property of curcumin (Bharat et al. 2009). This result provides a rationale for an inhibitory role of herbaceous antioxidant supplementation and aerobic regular exercise in the attenuation of lead-induced neuro and cardiotoxicity. ## EFFECTS OF ASTAXANTHIN SUPPLEMENTATION ON SPORTS PERFORMANCE IN YOUNG ELITE SOCCER PLAYERS

RADIOJEVIC, N.1, DIKIC, N.1, BARALIC, I.2, DJORDJEVIC, B.2, ANDJELKOVIC, M.1, VUJIC, S.1, TOTIC, S.3

1:SPORTS MEDICINE ASSOCIATION OF SERBIA (BELGRADE, SERBIA), 2:INSTITUTE FOR BROMATOLOGY, FACULTY OF PHARMACY (BELGRADE, SERBIA), 3:FACULTY OF ORGANIZATIONAL SCIENCES (BELGRADE, SERBIA)

Introduction Oxidative stress is a condition in which the delicate balance existing between pro-oxidant (free radicals) production and antioxidant defense system is changed in favor of free radical expression. Astaxanthin (Asx), a red carotenoid pigment, is a biological antioxidant that occurs naturally in a wide variety of living organisms. The aim of this study was to determine the effects of Asx supplementation on sports performance in young elite soccer players. Methods Sixty healthy young (age 17.7±0.7) soccer players have participated in this double blind placebo controlled study during three months. The intervention group received 4 mg Asx capsules daily. We monitored ergospirometry parameters (VO<sub>2</sub>max, RQ, VE, HRmax, HRrecovery, time to exhaustion, maximal speed). Also, we have analyzed blood biochemical (ALT, AST, CK, LDH, Iron, Ferritin, Cho, HDL, LDL, Tg, Gly, Tp, TBIL, urea, creatinine) and hematological (WBC, RBC, PLT, Hgb, Hct, MCV) parameters before and after training session. Before starting the dietary supplementation, baseline values for each of the subjects were obtained. All tests were repeated after 90 days of supplementation. Results Any significant changes in ergospirometry parameters between groups were not observed among the values before and after 90 days of administration period. In Asx group, however, there were significant improvement in maximal speed (18/18.5 km/h) and time to exhaustion (9.7/10 min) before and after 90 days of supplementation period (p<0.05). Significant elevation of CK level registered in P group after training session 90 days after supplementation (p<0.05), was not observed in Asx group. There were no significant effects of Asx supplementation on the biochemical and hematological parameters between groups. Discussion The present study suggests that Astaxanthin may stabilize muscle cells membranes and reduce muscular fatigue. Based on our findings, supplementation of Astaxanthin could improve endurance that may lead to better sports performance. Further studies need to evaluate mechanisms behind the increased endurance. Sports performance benefits from taking natural astaxanthin characterized by visual acuity and muscle fatigue improvements in humans. *Journal of Clinical Therapeutics & Medicines* 2002; 18 (9): 1085-1100.

## REDOX STATUS REGULATION OF INTRACELLULAR SIGNALING PATHWAYS FOLLOWING EXERCISE-INDUCED MUSCLE DAMAGE

FATOUROS, I., MICHAILIDIS, Y., TERZIS, G., KARAGOUNIS, L., JAMURTAS, A.Z., SPENGOS, K., CHATZINIKOLAOU, A., SAKE-LIOU, A., MANDALIDIS, D., ATHANASOPOULOS, S., MANTA, P., METHENITIS, S., RUSSELL, A.P.

DEMOCRITUS UNIVERSITY OF THRACE

Introduction Exercise-induced muscle damage (EIMD) generates reactive oxygen species (ROS) thereby inducing oxidative stress in skeletal muscle which in turn elevates muscle's antioxidant defense systems (Margonis et al., 2007). Although several oxidative-stress-sensitive signal transduction pathways, such as those of NF-κB, MAPK, and Akt/mTOR, have been shown to activate gene expression of numerous enzymes and proteins that are essential for cellular redox homeostasis, there is limited information regarding the effects of redox status on the regulation of these pathways following EIMD (Ji, 2008). Therefore, the aim of this study was to determine the responses of redox-sensitive pathways in human skeletal muscle during the inflammatory and healing phases associated with EIMD. Methods Ten healthy men received either placebo or N-acetylcysteine (NAC, 20 mg/kg/d) following a strenuous eccentric exercise protocol (20 sets, 15 repetitions/set) on an isokinetic dynamometer in a counterbalanced, double-blind design. In each trial, blood was collected and muscle strength was measured at baseline, immediately post-exercise as well as 2h post-exercise and daily for the next 8 days. In each trial, muscle biopsies from vastus lateralis were collected at baseline, 2h post-exercise as well as 2 and 8 days within recovery. Results Eccentric exercise induced marked muscle damage (determined microscopically and biochemically), muscle soreness (increased DOMS), intense inflammatory response (increased creatine kinase, CRP, cytokines, adhesion molecules), performance deterioration (at 60 and 180 o/sec), and an upregulation of AKT, mTOR, p70S6K, rpS6, and NF-κB phosphorylation for 3 days within recovery. Inflammation subsided, performance improved and muscle healing was evident 8 days post-exercise. NAC administration attenuated muscle damage, inflammatory response and strength losses within 2 days post-exercise but resulted in lower satellite cell activation and strength gains 8 days within recovery compared to placebo. NAC ingestion resulted in an attenuation of AKT, mTOR, p70S6K, rpS6, and NF-κB phosphorylation 8d post-exercise. Discussion The results of the present study suggest that redox status regulation may be essential for muscle's adaptive response during the inflammatory and healing phases associated with EIMD as previously shown (Aoi et al., 2004). It appears that although antioxidant supplementation may limit muscle damage and inflammation, it may also hamper muscle's regenerative capability. ## THE COMBINED INTAKE OF ALPHA -KETOGLUTARIC ACID AND 5-HYDROXYMETHYLFURFURAL DOES NOT PREVENT THE HYPOXIA ASSOCIATED PERFORMANCE DECREMENT

GATTERER, H., PHILIPPE, M., MAIRER, K., WILLE, M., BURTSCHER, M.

UNIVERSITY INNSBRUCK

**Introduction** Hypoxia is known to decrease aerobic exercise performance. The main cause is the reduced oxygen availability at altitude (1) but also the oxidative stress induced by hypoxia has been suggested to decrease performance (2). Accordingly, Subudhi et al. found improved power output at the ventilatory threshold during acute exercise in hypoxia when the oxidative stress was reduced by antioxidant (AO) supplementation (3). It could be speculated that also the combined intake of alpha -ketoglutaric acid (alpha-KG) and 5-hydroxymethylfurfural (5-HMF) which was shown to reduce oxidative stress and to increase VO<sub>2</sub>max and Wattmax in patients admitted for lung resection (4) could prevent the hypoxia associated performance decrement. **Methods** 12 healthy, regularly active men performed two incremental cycle ergometer tests to exhaustion (the first under normoxia and the second under hypoxia at a simulated altitude of 4300m). Maximal oxygen uptake (VO<sub>2</sub>max), maximal power output (Wattmax), the power output at the ventilatory threshold (VT) (first systematic increase of the VE/VO<sub>2</sub>) and the lactate threshold (LT) (4mmol/L) were determined. The VO<sub>2</sub>max values of the test in normoxia were used to randomly assign participants to either a placebo group (PG, n=6) or an alpha-KG and 5-HMF supplementation (SG, n=6) group in a double-blind fashion. **Results** Compared to normoxia a significant reduced VO<sub>2</sub>max (PG -12.0±3.6, SG -10.6±3.1 ml/min/kg), Wattmax (PG -50.7±16.9, SG -61.0±26.3 W) and power output at the VT (PG -57.3±38.6, SG -62.8±33.0 W) and LT (PG -45.0±18.4, SG -35.0±27.9 W) was found under hypoxia in both groups (p<0.05). No differences were found for these decrements between groups. **Discussion** Although we used a comparable "dose" of AO as Subudhi et al. did, the present results do not support their outcomes. Subudhi et al. found a reduction in the hypoxia associated performance decrement (power output at VT) after AO ingestion (3). An explanation may be that in the present investigation the AO supplementation did not increase the antioxidative capacity of the subjects. Supplementation in the present investigation started only 48h before the hypoxia test, whereas Subudhi et al. supplemented for 3 weeks (3). The present results indicate that short term ingestion of AO before going to high altitude has no effect on the hypoxia associated performance decrement. **References** (1) Burtcher et al. ## THE IMPACT OF OBESITY ON DEVELOPMENTAL COORDINATION DISORDERS IN ADOLESCENCE

WAGNER, M.1, KASTNER, J.2, PETERMANN, F.2, JEKAUC, D.3, WORTH, A.1, BÖS, K.4

1 UNIVERSITY OF EDUCATION SCHWÄBISCH GEMÜND (GERMANY), 2 UNIVERSITY OF BREMEN (GERMANY), 3 UNIVERSITY OF KONSTANZ (GERMANY), 4 KARLSRUHE INSTITUTE OF TECHNOLOGY (GERMANY)

**Introduction:** Developmental Coordination Disorders (DCD) as well as overweight and obesity are of increasing importance in the study of human growth as both indications are associated with a number of comorbidities and increasing prevalence rates. This study sought to determine the impact of obesity on DCD in adolescence. Therefore, we assumed: (i) there is an impact of obesity on DCD in adolescence as we expect obese adolescents to show a higher DCD-risk in comparison to normal-weight adolescents; (ii) the impact of obesity on DCD is task specific as we expect the higher DCD-risk of obese adolescents in comparison to normal-weight adolescents to be more pronounced in gross than in fine motor tasks; (iii) the impact of obesity on gross motor DCD is gender-specific as we expect the higher risk of obese adolescents for gross motor DCD in comparison to their normal-weight peers to be more pronounced in male than in female adolescents. **Methods:** At the beginning of a stationary rehabilitation, 43 boys and 36 girls aged 11 to 16 years (mean: 14.02; SD: 1.29) were assessed with the Movement Assessment Battery for Children 2. The results were compared with 92 normal-weight controls. Logistic regressions were used to test hypotheses. **Results:** Results made it clear that (i) obese adolescents do have a 8.73 (CI(95%) 2.46-30.95) higher DCD-risk in comparison to their normal-weight peers; (ii) the impact of obesity on DCD is more pronounced in gross than in fine motor tasks as obese adolescents show a 4.77 (CI(95%) 1.69-13.51) higher gross motor DCD-risk whereas the increased risk of fine motor DCD is 3.68 (CI(95%) 1.47-9.21); (iii) the impact of obesity on gross-motor DCD is only significant in boys (OR: 15.82; CI(95%) 1.94-128.82). **Conclusion:** Our results suggest that obesity could be a detrimental factor in the consolidation of gross motor DCD especially in boys. However, due to the cross-sectional design of the study, final empirical evidence is still lacking. **References:** Wagner, M., Kastner, J., Petermann, F., Jekauc, D., Worth, A. & BöS, K. (in prep.). ## EFFECTS OF TRAINING ON BALANCE PERFORMANCE UNDER DT-CONDITIONS

WOLLESEN, B., VOELCKER-REHAGE, C., MATTES, K.

UNIVERSITY OF HAMBURG, JACOBS UNIVERSITY BREMEN, UNIVERSITY OF HAMBURG

**Introduction** Most daily activities require the management of sensori-motor tasks while simultaneously processing external information: for example, holding a conversation while opening a container or crossing a street while observing traffic flow (dual-task performance). A review has shown, that older adults perform more poorly than younger adults when simultaneously engaged in cognitive and sensori-motor tasks (Wollacott & Shumway-Cook, 2002). In daily life situations this is associated with reduced balance performance and an increased fall risk. This systematic review investigated if older adults benefit from training interventions in dual-task (DT) situations. Training effects were analysed with regard to the training programme and task conditions (e.g. standing, walking, complexity of secondary cognitive task). **Methods** Literature was systematically searched via OVIDsp (Medline, EMBASE, PsycINFO). DT studies were included by the following criteria: (1) investigation of at least one motor task, (2) assessment of DT performance outcomes, (3) conduction of an intervention, and (4) investigation of older adults in an experimental-control group designs or an old-young comparisons. Results Eleven studies met all inclusion criteria. Studies differed in sample size, training duration, investigated motor and cognitive tasks. Four types of interventions were identified: (1) general single task (ST) motor training, (2) specific ST motor training, (3) general DT training, and (4) task-related (specific) DT training. Nearly all types of training improved motor performance under DT- conditions for standing and walking tasks. The secondary tasks differed in complexity and examined cognitive functions e.g. processing speed, controlled or visuospatial processes and executive functions (following Colcombe & Kramer, 2003). A Meta- Analysis of the training effects could not be processed because of the

differences in methodological quality. Most benefits seem to be reached by a specific DT training in comparison to a general ST training. Conclusions Motor and cognitive DT performance can be improved by performance related exercises. To reach beneficial effects, the training intervention should include a certain level of exercise load such as rising difficulties, appropriate intensity and duration, a certain level of task specificity, and variable task prioritisation. To provide transfer into everyday situations we suppose that the intervention needs to build up rather general task managing strategies. Future research should focus on transfer of training effects into everyday situations and dose-response-relationships. References Colcombe SJ & Kramer AF. ## **FATIGUE INDUCED CHANGES IN STATIC AND DYNAMIC POSTURAL CONTROL IN ATHLETES WITH PREVIOUS ANKLE INJURY**

STEIB, S., ZECH, A., HENTSCHKE, C., PFEIFER, K.

UNIVERSITY OF ERLANGEN-NUREMBERG

**Introduction:** Neuromuscular impairments, such as proprioceptive deficits and decreased balance performance (static and dynamic postural control) have been demonstrated following ankle injury (Wikstrom et al., 2009). This may contribute to an increased re-injury risk in team athletes after return to competition. Although most (re)injuries occur in the last minutes of a game (Hawkins & Fuller, 1999), little is known about fatigue-induced changes of sensorimotor control in athletes who suffered from an ankle sprain in the past. The aim of this study was to investigate bilateral, fatigue-induced alterations of static and dynamic balance in athletes with a history of ankle injury. **Methods:** 31 athletes, 15 with a previous ankle sprain (9 males, 6 females, age:  $22.67 \pm 2.72$  years, height:  $176.27 \pm 8.88$  cm, mass:  $70.93 \pm 8.10$  kg) and 16 healthy control subjects (11 males, 5 females, age:  $25.88 \pm 2.66$  years, height:  $176.13 \pm 8.65$  cm, mass:  $69.38 \pm 10.17$  kg) were tested in two experimental sessions: (1) Center of pressure sway velocity (vCOP) in single-leg-stance, 'time to stabilisation' (TTS) after a unilateral jump-landing task and (2) mean reach distance in the 'star excursion balance test' (SEBT) were assessed for both legs before and immediately after a fatiguing treadmill exercise (TRF). To compare fatigue induced performance of injured with non-injured legs a two factorial linear mixed model was specified for each of the main outcomes. 'Fatigue' and 'injury' were included as fixed factors nested in the random individual's factor. **Results:** In non-fatigued condition, athletes with a history of ankle injury showed significant impairments in vCOP and SEBT ( $p < 0.05$ ) whereas TTS was similar between both groups. Significant fatigue effects were found in both legs of injured and non-injured athletes for SEBT, vCOP and TTS ( $p < 0.05$ ). There was a significant fatigue-by-injury interaction for TTS ( $p < 0.001$ ). Post hoc analysis revealed a significantly greater increase of TTS in athletes with a history of ankle injuries. **Discussion:** Both groups showed significant changes in static and dynamic postural control following a fatiguing running exercise. In the jump stabilizing task, fatigue-effects were most prominent on the injured leg. To our knowledge, this is the first study showing that dynamic postural control of subjects with a history of ankle injury is more affected by fatigue compared to healthy athletes. Further studies with larger sample size are needed to confirm these results. **References:** Wikstrom EA, Naik S, Lodha N, Cauraugh JH (2009). *Med Sci Sports Exerc.* 41(6), 1287-1295. ## **EFFECTS OF A PROPRIOCEPTIVE TRAINING PROGRAM WITH CROSSOVER ON BALANCE CONTROL IN POSTMENOPAUSAL SUBJECTS**

BENVENUTI, P.1, BOTTI, F.M.2, BISCARINI, A.2, PANICHI, R.2, BRUNETTI, O.2, ALGIERI, M.2, BERTIATO, F.1, PETTOROSSO, V.E.2

1: UNIVERSITY OF VERONA (ITALY), 2: UNIVERSITY OF PERUGIA (ITALY)

**Introduction** Ageing is associated with a progressive loss of balance control and an increased risk of falling. This is a relevant problem especially in postmenopausal osteoporotic women due to the major risk of fractures. Physical training has been indicated to attenuate the natural decay of postural control. However, most of the machines used for training are designed for enhancing muscle force, but not specifically for increasing proprioceptive function and balance control. In this study, balance control was examined by using a new machine "CROSSOVER Technogym" (CO), with which body balance is continuously challenged by working out in multilateral planes as skating movement. **Methods** To evidence the effects of CO on balance, we recruited two groups (10 subjects each) of postmenopausal voluntary healthy women (aged 55-69) assigned to train with a stationary bike (SB) and CO, respectively. Test sessions were performed 7 days and 1 day before training onset, as well as 5 and 12 weeks after training onset. Balance was assessed as center of foot pressure velocity (CFPv) in stance tests with eyes open (EO) and closed (EC). Explosive force was also evaluated as jump height in standardized squat jumps. Heart rate (HR) and mechanical power during the training sessions were recorded. ANOVA and post-hoc analysis were performed for statistical significance. **Results** Both CFPv in EC and "Romberg quotients" (RQ) between EC and EO CFPv were significantly reduced in CO subjects, while this was not observed in SB subjects. The effect lasted several weeks after the end of training. In CO group CFPv decreased from  $1.67 \pm 0.39$  cm/sec to  $1.46 \pm 0.22$  cm/sec in EC condition, and RQ from  $1.22 \pm 0.14$  to  $1.06 \pm 0.1$ . Conversely no differences between the groups were observed concerning explosive power enhancement and HR reduction. **Discussion** The reduction of CFPv and RQ clearly indicates an improvement of balance in the elder subjects who underwent the CO training program. This was not observed in the group trained with stationary bike, although the effects on force and heart rate were similar in SB and CO groups. Therefore, we suggest that CO training specifically improves balance, possibly increasing the efficacy of the motor control through the enhancement of the proprioceptive input.

## **THE EFFECT OF FUNCTIONAL CIRCUIT TRAINING ON FUNCTION, SELF-REPORTED BALANCE AND HEALTH STATUS**

GINÉ-GARRIGA, M., GUERRA, M., MARTIN-BORRÀS, C., UNNITHAN, V.B.

FPCEE BLANQUERNA. UNIVERSITAT RAMON LLULL

**INTRODUCTION.** The concept of frailty has long been associated with advancing age but only recently has it been specifically defined as a medical syndrome. Physical frailty has been regarded as a precursor state to disability and dependence on others for daily activities. Frail individuals are considered to be the group of patients that presents the most complex and challenging problems to health care professionals. The purpose of this study was to evaluate whether a 12-week functional circuit training program (FCT) could reduce functional decline, and improve self-reported balance and health status in a group of physically frail community-dwelling older individuals. **METHODS.** Fifty-one individuals, 83.98 (2.89) years old, were considered frail and tested at week 0 and randomly assigned into two groups (intervention group, IG = 26, control group, CG = 25); forty-one were assessed at week 12 (IG = 22, CG = 19). IG underwent a structured 12-week FCT program, which focused on a combination of functional balance and lower body strength-based exercises. Measures of

function (Barthel Index), and self-reported balance (Activities-specific Balance Confidence scale) and health status (SF-12) were assessed at week 0 and 12. An ANCOVA was performed and week 12 measures were covaried for week 0 measures. RESULTS. Function measures in IG participants showed significant ( $p<0.05$ ) improvements relative to those in the CG. The mean score (SD) in Barthel index assessment of participants in the IG and CG groups were 78.23 (.88) and 69.15 (.95), respectively in week 12 measures. Significant ( $p<0.05$ ) improvements were also demonstrated for the other outcome measures. The mean units (SD) in physical function assessed with the SF-12 questionnaire in the IG and CG groups were 40.86 (1.05) and 31.59 (1.13), respectively in week 12 measures ( $p=0.001$ ). DISCUSSION. In summary, our findings indicate that our intervention improves function, and self-reported balance and health status, leading to a reduction in functional limitations.

### PROMOTING BALANCE AND STRENGTH IN THE MIDDLE-AGED WORKFORCE

GRANACHER, U.1, MUEHLBAUER, T.1, WICK, C.2, RUECK, N.2, ESPOSITO, C.2, ROTH, R.2, ZAHNER, L.2

1: FRIEDRICH-SCHILLER-UNIVERSITY JENA, 2: UNIVERSITY OF BASEL

**Introduction** The prevalence of sustaining fall-related injuries is high in the middle-aged workforce (Kemmlert and Lundholm, 2001). Deficits in postural control (i.e., increased postural sway, reduced gait velocity) and muscle strength (i.e., decreased strength and especially power) represent important fall-risk factors (Onambele et al., 2006). The objective of this study was to examine the impact of balance and strength training conducted at the worksite followed by detraining on measures of postural control and muscle strength/power in the middle-aged workforce. **Methods** Thirty-two adults (9 females, 23 males) with sedentary office work participated in this study and were assigned to an intervention ( $n=17$ , age:  $56\pm 4$  years, mass:  $75\pm 8$  kg, height:  $174\pm 9$  cm) or a control group ( $n=15$ , age:  $56\pm 3$  years, mass:  $82\pm 12$  kg, height:  $175\pm 8$  cm). The intervention group participated in 8 weeks of progressive balance and strength training conducted at the worksite (three times per day for 8 minutes each, 5 days per week), followed by 8 weeks of detraining. Pre, post, and follow-up testings included the measurement of (a) total centre of pressure (CoP) displacements during one-legged standing on a balance platform, (b) gait velocity during a 12-m-walk at preferred speed, (c) peak isometric/isokinetic torque and rate of torque development (RTD) of the plantar flexors on an isokinetic device, and (d) counter-movement jumping height on a force platform. **Results** A 2 (group: intervention, control)  $\times$  3 (test: pre, post, follow-up) analysis of variance with repeated measures on test revealed significant improvements in CoP displacements ( $p<0.01$ , +11% from pre to post testing), gait velocity ( $p<0.05$ , +3%), peak isometric ( $p<0.05$ , +19%) and isokinetic ( $p<0.05$ , +17%) torque, RTD ( $p<0.01$ , +37%), and jumping height ( $p<0.05$ , +4%). During detraining, balance variables further improved (+4-7% from post to follow-up testing), whereas strength variables deteriorated (-4-24%). **Discussion** Results of the study illustrate that a short-term balance and strength training conducted at the worksite on a daily basis represents a feasible and safe training modality that produced marked improvements in variables of static and dynamic balance as well as maximal and explosive strength in the middle-aged workforce. Given that the training regimen was able to counter important intrinsic fall-risk factors (i.e., deficits in postural control and strength), it seems plausible to argue that this worksite training program could have a fall-preventive effect. **References** Kemmlert K, Lundholm L. (2001). *Appl Ergon*, 32(2), 149-53 Onambele GL, Narici MV, Maganaris CN. (2006). *J Appl Physiol*, 100(6), 2048-2056

### OP-PM45 Muscle Activity 2

#### DYNAMIC MUSCLE CONTRACTIONS INDUCED BY HIGH FREQUENCY STIMULATION ARE INFLUENCED BY K<sup>+</sup> AND LACTIC ACID IN ISOLATED RAT SOLEUS MUSCLES

OVERGAARD, K.1, PEDERSEN, K.K.1, NIELSEN, O.B.2

UNIVERSITY OF AARHUS

**Introduction** During intense activation muscles may receive input of very high frequency from the nervous system (Christie & Kamen, 2006). The ability of the muscles to react functionally to these high frequencies is crucial for the rate of force development (RFD) and for maximal power (Pmax) development. Under intense activation muscle excitability and contractility may also be influenced by increased extracellular K<sup>+</sup> ([K<sup>+</sup>]<sub>o</sub>) and accumulation of lactic acid (LA). Here we investigated the influence of [K<sup>+</sup>]<sub>o</sub> and LA on the RFD and Pmax in muscles stimulated at high frequency. **Methods** Soleus muscles isolated from 4 wk old Wistar rats were incubated in standard K.R. buffer at 30°C initially containing 4 mM K<sup>+</sup> and equilibrated with 95% O<sub>2</sub>/5% CO<sub>2</sub> (pH 7.4). For measurement of power muscles were mounted on a force/length controlled dynamometer (305B, Aurora inc., Canada) at Lo. Muscles were stimulated every 10 min with 0.5-1.5 sec pulse trains at 60 Hz or 300 Hz to obtain tetanic activation. Contraction velocities were recorded at a number of different force levels from 5-90% of isometric force. Force-velocity curves were constructed by fitting to the Hill equation and Pmax was calculated. For measurements of isometric tetanic force and RFD muscles were mounted isometrically and stimulated as described above, RFD was defined as the force developed during the first 30 ms of contraction. During the experiments [K<sup>+</sup>]<sub>o</sub> was increased from 4 to 8 mM and subsequently 10 mM LA was added. N was 8-10 in all experiments. **Results** Tetanic force was equal at 300 and 60 Hz ( $42\pm 2$  vs  $43\pm 2$  g,  $p>0.05$ ). However both Pmax and RFD were larger at 300 Hz than at 60 Hz ( $231\pm 19$  vs  $189\pm 15$  g $\times$ mm/s and  $16.0\pm 0.4$  vs  $10.1\pm 0.7$  g/30 ms, respectively (both  $p<0.05$ ). At 60 Hz, incubation at 8 mM K<sup>+</sup> significantly reduced force and Pmax by 11 and 13 % respectively, whereas RFD was increased by 15 %. Subsequent addition of 10 mM LA at 8 mM K<sup>+</sup> had no significant effect on any of the contractile parameters. At 300 Hz, however, incubation at 8 mM K<sup>+</sup> led to larger reductions in force, Pmax and RFD (31, 32 and 26 % respectively), and significant recoveries of 16, 7 and 19 %, respectively, were seen when 10 mM LA was added. **Discussion** The results illustrate that optimal dynamic muscle function is achieved at higher stimulation frequencies than those needed to achieve maximal isometric force. Furthermore, the depressing effects of K<sup>+</sup> and protective effects of LA on force, power and RFD are more pronounced at high frequencies indicating that regulation of muscle excitability is very important for muscle function during high frequency input. **References** Christie A & Kamen G. ## COMPARISON BETWEEN ALTERNATING AND PULSED CURRENT ELECTRICAL MUSCLE STIMULATION FOR ACUTE PHYSIOLOGICAL RESPONSES

ALDAYEL, A., JUBEAU, M., MCGUIGAN, M., NOSAKA, K.

KING SAUD UNIVERSITY

**Introduction** Several types of electrical muscle stimulation (EMS) are used in rehabilitation and sport training, and one of the factors to determine the types is waveform. The most commonly used EMS waveforms are alternating current (AC) and pulsed current (PC). Some studies showed that alternating current EMS induced more muscle fatigue than pulsed current (1,2). However, physiological differences between AC and PC EMS are not necessarily clear. This study compared AC and PC EMS for torque output, muscle oxygenation, skin temperature, blood lactate, hormonal responses, and skeletal muscle damage markers. **Methods** Twelve healthy men (23-48 y) received AC EMS (2.5 kHz delivered at 75 Hz, 400  $\mu$ s) for the knee extensors of one leg and PC EMS (75 Hz, 400  $\mu$ s) for the other leg to induce 40 isometric contractions (on-off ratio 5-15 s) at the knee joint angle of 100° (0°: full extension) separated by 2 weeks in a randomised, counterbalanced order. The current amplitude was consistently increased to maximally tolerable level, and the torque and perceived intensity were recorded. Changes in tissue oxygenation index ( $\Delta$ TOI) and total hemoglobin volume of vastus lateralis and medialis muscles were assessed by a near-infrared spectroscopy. Skin temperature (Tsk) of the stimulated knee extensors were measured before, during and for 30 min after EMS. Blood lactate, growth hormone, testosterone, insulin-like growth factor 1, testosterone, and cortisol were measured before, during, immediately after, and 15, 30, 45 and 60 min after EMS. Maximal voluntary isometric contraction torque, muscle soreness with a 100-mm visual analogue scale and plasma creatine kinase activity were measured before and 1, 24, 48, 72 and 96 h after EMS. Changes in these variables were compared between AC and PC by a two-way repeated measures ANOVA. **Results** No significant differences between AC and PC were evident for changes in the peak torque induced during EMS, but the torque during each isometric contraction was less stable for AC than PC. The changes in Tsk, lactate, hormones, muscle damage markers were not significantly different between AC and PC. The decreases in  $\Delta$ TOI amplitude during contraction phases were significantly ( $P < 0.05$ ) greater for PC than AC. **Discussion** These results suggest that the acute effects of AC and PC EMS on the stimulated muscle and systemic responses are similar; however, muscle oxygenation was more affected in AC, which was likely due to greater muscle fatigue in the AC compared with the PC. **References** 1. ## BICEPS BRACHII MUSCLE OXYGEN DEMAND DURING ELECTRICALLY EVOKED AND VOLUNTARY SUSTAINED ISOMETRIC CONTRACTIONS

MUTHALIB, M.1,2, JUBEAU, M.3, MILLET, G.Y.3, FERRARI, M.4, KERR, G.1, NOSAKA, K.2

1: QUEENSLAND UNIV. TECHNOLOGY (AUSTRALIA) 2: EDITH COWAN UNIV. (AUSTRALIA) 3: JEAN MONNET UNIV. (FRANCE) 4: UNIV. L'AQUILA (ITALY)

**Introduction** We have shown that decreases in biceps brachii (BB) oxygenation (measured by near-infrared spectroscopy, NIRS), during intermittent (1s contraction/1s rest) isometric contractions (ISO) of the elbow flexors induced by electrical muscle stimulation (EMS) were greater to those during voluntary contractions (VOL) when both were performed at the same force level, but similar when both were performed at the respective maximal intensity (I). Considering that sustained ISO (e.g., 10s) is more metabolically demanding than intermittent 1s contractions, this study compared changes in BB oxygenation and total haemoglobin volume (tHb) during and after a 10s sustained ISO of the elbow flexors evoked by EMS generating 30% of maximal voluntary ISO (MVC) and VOL at the same torque level (30%MVC) as well as MVC level. **Methods** Eight healthy men (23-33 y) undertook EMS and VOL with the same arm on an isokinetic dynamometer with an elbow joint angle of 90°. The BB and brachioradialis muscles were stimulated via surface electrodes at 30 Hz to induce a 10s ISO targeting 30% of pre-determined MVC. After a 100s rest, the subjects performed a 10s VOL ISO at the same torque level as that of EMS followed 90s later by a 10s MVC. Torque and changes in BB oxygenation (tissue oxygenation index, TOI) and tHb (measured by Hamamatsu NIRO-200) during and after each contraction were compared between EMS and VOL. **Results** When EMS was compared to VOL at the same torque level, decreases in TOI and tHb from baseline were greater ( $P < 0.05$ ) and recovery of TOI to baseline was slower ( $P < 0.05$ ) for EMS than VOL. However, when EMS was compared with VOL at MVC level, changes in TOI and tHb parameters during and after the contraction were similar, despite the 65% lower torque for EMS than VOL. **Discussion** At the same torque level, the greater TOI and tHb changes in EMS than VOL suggest that BB O<sub>2</sub> demand in the investigated muscle volume was greater for EMS than VOL; this was likely due to lower activation of muscle fibres during submaximal VOL. The similar TOI and tHb changes between EMS and VOL at MVC level indicate that the BB O<sub>2</sub> demand was similar between the two conditions. Thus, it seems likely that muscle fibres at least under the NIRS probe were similarly activated during EMS and VOL at MVC, despite the spatially fixed and temporally synchronous activation manner in EMS (2). The difference in the torque output between EMS and VOL at MVC seems to be due to the greater involvement of all elbow flexor and stabilizer muscles to force production in VOL than EMS. **References** 1. ## EFFECTS OF DYNAMIC ELECTROMYOSTIMULATION OF THE LEG MUSCLE CHAIN ON ISOMETRIC AND ISOINERTIAL STRENGTH PARAMETERS AND SPRINT PERFORMANCE

DOERMANN, U., HOUBEN, P., ZIADI, S., NOWAK, S., WIRTZ, N., KLEINOEDER, H., MESTER, J.

GERMAN SPORT UNIVERSITY COLOGNE

**Introduction:** Linear and nonlinear sprints are basic abilities in many sports. Electromyostimulation (EMS) is known as a potential training method on strength and power. Although two studies reveal an improvement of sprint performance by static EMS (Billot et al. 2010; Brocherie et al. 2005), there are no data for possible effects of dynamic EMS training. This method seems advantageous because it integrates neuromuscular coordination comparable to motor tasks. The aim of this study was to investigate the effects of EMS supported dynamic training forms on strength, power and sprint performance. **Methods:** 14 strength trained subjects ( $21.3 \pm 2.6$  yrs;  $178.0 \pm 9.9$  cm;  $70.5 \pm 10.6$  kg) were randomized in an EMS (EMS-G) and a free weight group (FW-G). The training period lasted 4 weeks (2x/week). Squats and lunges were the exercises for both groups (3 sets, 10 rep., 1 min rest). The computer given speed (DigiMax) for a single repetition was 2s con, 1s iso and 2s ecc at a range of motion of 90-170°. The difference between the groups was given in the application of an additional weight (10-repetition maximum) in contrast to EMS (individually 70% intensity; impulse: frequency 85Hz, width 350 $\mu$ s, type bipolar/rectangle; duty cycle 6/4) during the exercises. The EMS surface electrodes (miha bodytec) were placed around the muscle belly of the calves, thighs and at the buttocks. The pre- and post-test were conducted before and after the training period. The re-test followed 2 weeks of regeneration. The strength diagnostics were carried out with a Leg-Extension, a Leg-Curl and a Leg-Press (gym80; 3 isometric

and 6 isoinertial tests with 40% and 60% additional load). Sprint abilities were tested by a 30m sprint (standing + flying start) and a t-run measured by light barriers (Sportronic). Results: Sign. increases of maximal isometric force ( $F_{max}$ ) and isoinertial power ( $P_{max}$ ) for both training groups were shown at Leg-Press:  $F_{max}$  improved by 30% for the FW-G and by 22% for the EMS-G (re-test).  $P_{max}$  with 60% additional load increased for both groups in the post-test (12% FW-G; 12% EMS-G) and in the re-test (17% FW-G; 11% EMS-G) ( $p < 0.05$ ). The 10m sprint time decreased significantly for the EMS-G (-3%) during the 30m sprint (standing start). No sign. results were given for the FW-G. Both groups showed a significantly higher performance for the t-run (15% FW-G; 18% EMS-G). There were no sign. differences between the groups ( $p < 0.05$ ). Conclusion: Dynamic EMS as well as free weight training both enhance strength and power of the leg muscle chain and sprint performance. There are no specific effects between the groups. Thus dynamic EMS (individually 70% intensity) offers comparable effects without using additional loads in technically challenging exercises such as the squat. Brocherie et al. ## NEUROMUSCULAR ADAPTATIONS INDUCED BY CONSTANT AND VARIABLE FREQUENCY STIMULATION

PAPAIOORDANIDOU, M., BILLOT, M., VARRAY, A., MARTIN, A.

UNIVERSITY MONTPELLIER 1

Rapid fatigue development is one of the major limitations of Electrical Stimulation (ES) clinical applications. Research has been focused on identifying the ES protocol that would minimise this rapid fatigue onset. Constant and variable frequency trains (CFTs, VFTs) have been compared in terms of fatigue entailment. Results are equivocal, since some authors report greater muscle fatigue following VFTs (Binder-Macleod and Russ, 1999) while others demonstrate no differences (Thomas et al, 2003) or even decreased muscle fatigue compared with CFTs (Bickel et al, 2003). No study has been focused on the nature of the fatigue developed under these two stimulation paradigms. The aim of the present study was to compare the fatigue developed by these two patterns of stimulation both quantitatively and qualitatively. Ten healthy males received the two ES regimes, which were randomly assigned to the lower limbs. ES was applied over the triceps surae and protocols consisted of 450 trains (167ms on/500ms off, 30Hz) at an intensity evoking 30% of Maximal Voluntary Contraction (MVC). A doublet (100Hz) was used in the beginning of each train for the VFTs protocol. Torque and electromyographic activity of the soleus muscle were continuously recorded. Neuromuscular tests were performed before and immediately after each ES protocol. Changes in muscle characteristics (excitability and contractile properties) were evaluated by analysis of the muscle compound action potential (Mwave) and associated twitch torque (PI), while the RMS/M was used to assess neural drive to the exercising muscle. All parameters were obtained during rest, maximal and submaximal (30% MVC) contractions. MVC significantly decreased after the two protocols ( $P < 0.05$ ), giving evidence of similar neuromuscular fatigue development. M-wave (at rest and superimposed to maximal and submaximal contractions) significantly decreased after both ES protocols ( $P < 0.01$ ), demonstrating alterations in muscle excitability, while the associated mechanical response showed no significant changes. The twitch mechanical response elicited at the intensity evoking 30% MVC significantly decreased after both protocols ( $P < 0.001$ ), giving evidence of altered contractile properties of the motor units solicited during the ES protocols. RMS/M values obtained at submaximal contraction tended to increase compared to pre values ( $P = 0.08$ ), suggesting enhanced neural drive to the exercising muscle. The two ES patterns gave rise to equivalent neuromuscular fatigue development. This fatigue was the result of adaptations taking place at a peripheral level while neural command was increased to cope with the peripheral alterations of the muscle capacity to generate force. The present results do not give evidence of an advantage of one ES pattern over the other in terms of neuromuscular fatigue development. ## THE PHYSIOLOGICAL EFFECTS OF LOW-INTENSITY NEUROMUSCULAR ELECTRICAL STIMULATION ON SHORT-TERM RECOVERY FROM SUPRA-MAXIMAL EXERCISE BOUTS IN TRI-ATHLETES.

MALONE, J.K.

UNIVERSITY COLLEGE DUBLIN

The physiological effects of low-intensity neuromuscular electrical stimulation (NMES) on short-term recovery from supra-maximal exercise bouts in tri-athletes. 1Malone JK, 1Coughlan GF, 1Crowe L, 2Gissane GC, 1Caulfield B. 1Stim XDP Research Group, Institute for Sport & Health, University College Dublin, Dublin 4, Ireland. 2St Mary's University College, Strawberry Hill, Twickenham, Middlesex, England. Introduction Inadequate recovery from high-intensity exercise bouts can limit sporting performance [1]. Previous research using various recovery intervention protocols have generally found positive results compared to passive recovery [2,3]. A recent study showed that NMES during recovery lowered blood lactate (Bla) compared to passive recovery [4]. The aim of this study was to determine the acute effects of NMES on Bla and performance parameters in trained male tri-athletes. Methods On three separate days, 13 trained male tri-athletes ( $31 \pm 5$  yrs;  $182.8 \pm 6.9$  cm;  $78.1 \pm 8.4$  kg) performed six 30 sec Wingate tests (30WanT) on a cycle ergometer. Each session consisted of 3 x 30WanT (bouts 1-3) interspersed by 4 min recovery (80 Watts @ 80 rev.min<sup>-1</sup>), followed by a randomly assigned 30 min recovery intervention of either: i) passive (seated), ii) active (cycling @ 30% V02max) or iii) NMES (1 Hz / 500  $\mu$ s - ON:OFF 2:6 s). The 3 x 30WanT bouts were then repeated (bouts 4-6) and compared to bouts 1-3 for peak power (PP), mean power (MP) and fatigue index (FI). Bla and heart rate (HR) were recorded at designated time points throughout. Data were analysed using repeated measures ANOVA with Tukey's HSD post hoc test. Results Bla decreased significantly faster during the active recovery intervention compared to both the NMES and passive interventions ( $P < 0.05$ ). There were no significant differences between interventions for PP ( $P = 0.710$ ), MP ( $P = 0.928$ ) and FI ( $P = 0.814$ ) when the post intervention bouts (4-6) were compared to the pre intervention bouts (1-3). Discussion NMES during recovery was not more effective than active, or surprisingly, passive recovery for improving subsequent performance. Despite Bla clearing at a significantly faster rate for the active recovery intervention, PP, MP or FI did not improve significantly compared to NMES and passive. This supports the belief that lactate is not a major cause of muscle fatigue [1]. In conclusion, NMES does not appear to be more effective than traditional methods for enhancing recovery. #### HEART RATE AND PERCEIVED EXERTION RESPONSES TO THREE TYPES OF LOW-VOLUME, HIGH-INTENSITY EXERCISE: PILOT DATA FROM PROJECT FFAB

TAYLOR, K.L.1, AZEVEDO, L.1, BOCK, S.2, BATTERHAM, A.M.1

1 TEESIDE UNIVERSITY, 2 DURHAM UNIVERSITY

HEART RATE AND PERCEIVED EXERTION RESPONSES TO THREE TYPES OF LOW-VOLUME, HIGH-INTENSITY EXERCISE: PILOT DATA FROM PROJECT FFAB (FUN FAST ACTIVITY BLASTS) Taylor, K. L. 1, Azevedo, L.1, Bock, S. 2, Batterham, A. M. 1. 1Teesside University (Middlesbrough, UK). 2Durham University, UK. Introduction Project FFAB (Fun Fast Activity Blasts) is a controlled before and after study of the effects of low-volume, high-intensity exercise on a variety of health outcomes in adolescents (13-15 yrs). Notwithstanding the substantial benefits reported, the exercise modes utilised in recent work (e.g., stationary cycling and running; Burgomaster et al., 2005 and Tjønnå et al., 2009) might not form engaging and sustainable interventions in an adolescent population. A preliminary in-depth qualitative study within Project FFAB indicated a preference for exercise challenges related to boxing, dance, and soccer. The aim of this pilot study was to assess heart rate and perceived exertion responses to three prototype prescriptions of low-volume high-intensity exercise based on these activities. Methods Participants (24 females, 13.6 ± 0.5 years; mean ± SD) took part in three sessions (one boxing-based, one dance-based, and one soccer-related) and were encouraged to perform 45 s of maximal effort exercise followed by 90 s rest. This was repeated four times per session. Heart rate (HR) was measured using Polar RS400 monitors and the Polar Team2 system (Polar Electro, Kempele, Finland). Participants recorded their overall rating of perceived exertion (RPE) using a pictorial OMNI scale (Robertson, 2004). Results The participants' average maximum HR values were 200 ± 19bpm, 200 ± 16 bpm and 200 ± 11 bpm (mean ± SD) for boxing-, dance-, and soccer-related activities, respectively. These equate to ~96% of the participants' age-predicted maximum heart rate. The overall RPE average was 5.4 ± 1.8. Discussion The observed maximum HR values and % maximum heart rate confirm that each exercise challenge was high-intensity. It is plausible that if such activities were to be integrated within an intervention, health benefits might accrue similar to those reported in previous work (e.g., Whyte et al., 2010; Tjønnå et al., 2009). The average RPE value of 5.4 indicates the participants described the sessions as between "somewhat easy" and "somewhat hard". This was unexpected and, given the high maximum HR values, warrants further investigation. The findings from this pilot work inform the design of a 10-week school-based high-intensity training intervention for adolescents in Project FFAB. #### EFFECTS OF CARDIOLOCOMOTOR INTERACTIONS ON THE SPECTRUM OF HEART RATE VARIABILITY DURING RUNNING

DI MICHELE, R., MERNI, F.

UNIVERSITY OF BOLOGNA

EFFECTS OF CARDIOLOCOMOTOR INTERACTIONS ON THE SPECTRUM OF HEART RATE VARIABILITY DURING RUNNING Di Michele, R.1, Merni, F.1 1: Department of Histology, Embryology, and Applied Biology, University of Bologna (Italy) Introduction During cycling and running, the locomotor rhythm can modulate the heart rate (HR), although the characteristics of cardiocomotor coupling are different in the two exercise modes (Nomura et al., 2003). Furthermore, it was recently demonstrated that in cycling the interactions between the locomotor and heart rhythms result in a new heart rate variability (HRV) spectral component corresponding to pedalling frequency (Blain et al., 2009). This study aimed to analyse the spectrum of the RR signal collected during an incremental running test, in order to individuate the frequency and magnitude of spectral components originating from cardiocomotor interactions. Methods On a grass field, nineteen male soccer players performed an exhaustive running test, with speed starting at 8.5 km/h and increasing by 0.5 km/h every minute. During the test, self-selected stride rate (SR) and RR periods were measured. A Short-time Fourier transform was applied to the RR series to estimate the power spectra. Results In all the subjects, the analysis of time-varying spectra allowed to detect two spectral frequency components related to SR. The first component (F1) was at a frequency of one half the SR (1.2 to 1.6 Hz), whereas the frequency of the second component (F2) equalled the absolute value of the SR-HR difference (0 to 0.8 Hz). At 80, 90, and 100% of maximum HR, the magnitude of F1 was 19.2 ± 10.2, 17.8 ± 9.3, and 15.0 ± 8.2 % of total high-frequency power (HF, >0.15 Hz). At the same intensities, F2 represented 19.6 ± 13.4, 16.6 ± 9.5, and 13.2 ± 7.4 % of HF. Discussion The presence of F1 confirmed what observed in cycling (Blain et al., 2009), i.e. a spectral component corresponding to the main locomotor rhythm that represents a significant portion of HF power and appears even when the cardiac and locomotor rates are not synchronous. The mechanism underlying F1 is probably the modulation of venous return by limb muscles contraction. The main finding of this study is however the appearance of the F2 component. F2 could have links with the relationship between the instantaneous RR variation and the phase of the cardiac cycle in which the vastus lateralis contraction occurs (Nomura et al., 2006). Finally, the presence of F2 in the same frequency ranges of the low frequency and the respiratory components could lead to overestimate the spectral power relative to those components, requiring caution when interpreting the frequency analysis of HRV collected during running. #### ADAPTING WORKLOAD IMPROVES THE USE OF HEART RATE RECOVERY AS A MONITORING TOOL

LAMBERTS, R.P.1, MASKELL, S.1, BORRESEN, J.2, LAMBERT, M.I.1

1: UCT/MRC RESEARCH UNIT FOR EXERCISE SCIENCE AND SPORTS MEDICINE, DEPARTMENT OF HUMAN BIOLOGY, UNIVERSITY OF CAPE TOWN, SOUTH AFRICA, 2: DISCOVERY VITALITY, JOHANNESBURG, SOUTH AFRICA

Introduction Heart rate after a standardized exercise test varies with a change in training status (Borresen and Lambert, 2007; Buchheit et al., 2008; Lamberts et al., 2009) possibly compromising the accuracy of measuring changes in heart rate recovery (HRR). Therefore the aim of this study was to determine if a change in exercise intensity would result in a change in HRR and its associated typical error of measurement. The practical aim of this study was to determine the range of exercise intensity following which HRR is relatively stable and can therefore be used as an accurate monitoring tool Methods Thirty-one subjects were recruited for this study and asked to perform four

submaximal running tests (HIMS). Based on the heart rate after the first HIMS, and with the aim to achieve heart rates in between 85-90% of heart rate maximum (HRmax), subjects were allocated to either group SAME (85-90% of HRmax (n=9)) - completing four identical HIMS (starting speed 7.2 km•h<sup>-1</sup>), group FASTER (< 85% HRmax (n=10)) completing two standard and two faster HIMS (starting speed 8.6 km•h<sup>-1</sup>) or to group SLOWER (> 90% HRmax (n=12)) completing two standard and two slower HIMS (starting speed 6.0 km•h<sup>-1</sup>) on alternating days. Results Adapting the HIMS resulted in the HRmax of SLOWER at the end of the HIMS decreasing from 94% HRmax to 89% HRmax (p = 0.000136), while HRmax increased from 82% HRmax to 88% HRmax in the FASTER group (p = 0.000136). There were no changes in absolute HRR at the end of the HIMS in either of these groups. However, improved coefficient of variation (CV) and lower typical errors of measurement (TEM) were found in both the SLOWER and FASTER group (SLOWER: CV 11 ± 7 to 5 ± 3% (p = 0.025), TEM 6 to 3 beats; FASTER: CV 11 ± 7 to 4 ± 3% (p = 0.048), TEM 7 to 3 beats) when the HIMS protocol was adapted. Discussion This study shows that although no changes in absolute HRR occurred with a change in exercise intensity, the capacity to detect meaningful changes improved significantly when the exercise intensity of the HIMS protocol was adapted. The highest sensitivity to detect meaningful changes on a day-to-day basis occurred at exercise intensities ranging from 86 to 93% of HRmax. To ensure the highest level of sensitivity in detecting meaningful changes in HRR, submaximal testing protocol should be adapted when ≤ 85% or ≥ 94% of HRmax is reached. ## IS THE ESTIMATING MAXIMUM HEART RATE EQUATION VALID TO PRESCRIBE EXERCISE SPORT TRAINING IN CHILDREN AND YOUTH?

COLANTONIO, E.

UNIVERSIDADE FEDERAL DE SÃO PAULO

IS THE ESTIMATING MAXIMUM HEART RATE EQUATION VALID TO PRESCRIBE EXERCISE SPORT TRAINING IN CHILDREN AND YOUTH? Colantonio, E.I, Lima, J.R.P.2, Kiss, M.A.P.D.M.3 1: Universidade Federal de São Paulo (São Paulo, Brazil), 2: Universidade Federal de Juiz de Fora (Juiz de Fora, Brazil), 3: Universidade de São Paulo (São Paulo, Brazil) Introduction Estimation of HRmax has been largely based on formula HRmax= 220-age (Eq n°1). This equation is used in textbooks without citation of original research, even so formula and related concepts are included in Sports Medicine examinations, Exercise Physiology, and Fitness. Therefore, the aim of this study was to compare the HRmax predicted by formula and HRmax measured during exercise test, performed to exhaustion, in a large range of age group, according to gender and training level. Methods Sample was composed by 145 subjects (74 female and 69 male), ranging from 7 to 17 yr, divided into pupils (non-trained) and swimmers (trained). VO2peak values were obtained by VO2000 – Medgraphics® gas analysis system, Inbrasport® ATL treadmill using an incremental adapted Bruce protocol. Rest and exercise HR was monitored by the Ergo PC 13 Micromed® electrocardiograph. HRmax was also estimated by formula Eq n° 1. Data were analysed with general linear model. Results Mean and standard deviation of difference between predicted HRmax and measured HRmax, according to gender and training level were: female non trained 23.85 ± 13.61; female trained 25.76 ± 13.87; male non trained 27.94 ± 15.80; male trained 24.06 ± 15.23; total non trained 26.23 ± 14.95; total trained 24.90 ± 14.49 bpm. Linear normal model agreement results were: age: p=0.001, coefficient (-1.76), confidence interval [-2.54 ; -0.98]; gender: p=0.969, coefficient (-), confidence interval [-], training level: p=0.342, coefficient (-), confidence interval [-]; gender and training level interaction: p=0.454, coefficient (-), confidence interval [-], respectively. Discussion Both gender cross-sectional (Tanaka et al, 2001) or longitudinal data (Gellish et al, 2007) provide statistical evidence that the commonly accepted prediction of HRmax by Eq n°1 is biased for adults; HRmax is overestimated, both gender, under 40 yr and underestimated HRmax for those older 40 yr. In present study difference between HRmax predicted and HRmax measured decreased 1.76 units by year, in total 7-17 yr age-group. Conclusion It can be concluded that prediction of HRmax based on Eq n°1 overestimated measured HRmax during a lab maximal incremental test in children and youths. In addition, the gender and training level were not related with the HRmax, independently if HRmax was predicted or measured. Thus, the HRmax=220-age is not recommended for exercise training prescription, in special for children and youths. References Gellish RL., et al. (2007) Med Sci Sports Exerc, 39:822-9. ## DOES HEART RATE FEEDBACK INFLUENCE RATINGS OF PERCEIVED EFFORT AND PERFORMANCE TIME DURING COMPETITIVE CYCLING?

CHRISTIE, C., PENGELLY, R.

RHODES UNIVERSITY

Introduction It has been shown that for cycling time trials lasting longer than 10 minutes, an even pacing strategy is fastest. This is despite the fact that even experienced cyclists start at a high work rate and then taper off despite similar, or even increased, perceived effort. Further, many athletes use heart rate monitors to gauge their pace even though their use has been questioned. Thus, the aim of this study was to establish whether constant heart rate feedback would result in an altered pacing strategy during cycling TT performance. Methods Seven trained cyclists were required to complete two 40 km Time Trials. During each of these, heart rate was continuously measured although with one condition, heart rate feedback (HRF) was provided while during the other condition, no heart rate feedback (NHRF) was given. Cycling speed, 'central' and 'local' perceived effort were measured at 10 km intervals. Results Although cyclists maintained the same average speed during both conditions (mean of 44 km/h), they were initially more cautious during the HRF condition with pace remaining relatively constant during the first 30 km. In contrast, during the NHRF condition speed gradually increased in the first 10 km and then stabilised until the 30 km mark. After 30 km, in both conditions, speed increased exponentially and significantly to a final speed of 47 km/h and 46 km/h for the HRF condition and the NHRF condition respectively. The cyclists completed the HRF condition 20 s faster than the NHRF condition; a finding which was not significant. There were no difference in heart rates; a mean heart rate of 158 b/min (NHRF) and 160 b/min (HRF). However, the cyclists perceived less effort during the NHRF condition but only at the 10 km mark; a finding which was significant. After this, perceptions of effort were similar. Discussion Overall, heart rate, perceptual and performance responses were similar during both conditions. Further, athletes were able to accurately perceive work effort despite receiving no heart rate feedback. However, the 20 s faster TT when heart rate feedback was given, is an important finding. This may have been due to the fact that during the NHRF condition, heart rate did not dictate pace and the cyclists thus started out at a faster pace and then realised that this could not be maintained. They then used their internal feed forward control mechanism to reduce speed in order to ensure adequate provision for the end spurt. This more variable pacing strategy during the NHRF condition may have resulted in the 20 s slower total time.

This is supported by previous findings which have shown that a more even distribution of work rate is the fastest even though most athletes don't follow this.

#### CHANGES IN RECURRENT INHIBITION DURING MAXIMAL VOLUNTARY ANISOMETRIC CONTRACTION

DUCLAY, J., AMARANTINI, D., MARTIN, A.

UNIVERSITY OF TOULOUSE, UPS

**Introduction** As recently reported by Duchateau and Enoka (2008), the specific modulation of the activation signal during lengthening contractions could involve both supraspinal and spinal mechanisms. Different researchers have highlighted that this specific neural drive, observed for lengthening contractions, mostly acts at the spinal level (Duclay et al. 2005; Gruber et al. 2009). Both pre and post-synaptic inhibitory mechanisms appear to be involved in the modulation of the activation signal during lengthening compared with shortening maximal voluntary contraction (MVC). This study was designed to investigate the relative contribution of post synaptic inhibitory mechanisms to the neural modulations observed for lengthening contraction by evaluating changes in recurrent inhibition during anisometric MVC. **Methods** Experiments were performed on 9 healthy men. Maximal H-reflexes (Hmax) and M-waves (Mmax) were evoked in Soleus (SOL) at an ankle angle of 90° during shortening and lengthening MVC. During MVC, maximal H-reflex with no direct M-wave response was also recorded as reference H-reflex (H1). The paired H reflex technique proposed by Hultborn and Pierrot Deseilligny (1979) was used to record test H reflex (H') to assess recurrent inhibition. The Hmax/Mmax and H'/H1 ratios were computed to investigate changes in spinal excitability and in recurrent inhibition respectively. SOL electromyographic (EMG) activity were quantified with root mean square (RMS) values of the EMG signal and normalized to the corresponding maximal M-wave (Mmax). **Results** The results indicate that the amplitudes of H' and H1 were by 34,4% and 19,5% lower during lengthening than during shortening MVC, respectively. Both SOL Hmax/Mmax and H'/H1 ratios were smaller ( $P < 0.05$ ) during lengthening MVCs ( $0.46 \pm 0.07$  and  $0.49 \pm 0.10$ , respectively) compared with shortening MVCs ( $0.59 \pm 0.05$  and  $0.64 \pm 0.10$ , respectively), despite similar RMS values of SOL EMG for all contraction types ( $P > 0.05$ ). **Discussion** Although the test reflex may be less sensitive to inhibitory mechanisms than the reference H-reflex (Hultborn and Pierrot-Deseilligny, 1979), the larger decrease in H' than in H1 during lengthening compared with shortening MVCs indicates a change in post synaptic inhibition. At comparable levels of SOL EMG activity, the decrease found in both Hmax/Mmax and H'/H1 ratios suggests that the reduction of the spinal excitability during lengthening MVC can, at least partly, be linked to an increase in recurrent inhibition. **References** Duclay J, Martin A (2005). **Introduction** The quantification of the mechanical load on internal biological structures during physical activity in daily life and recreational activity is a prerequisite for understanding injury and overload mechanisms and for controlling that physical activity. The purpose of this study is the quantification of mechanical load acting on the lower limb of the pregnant woman. **Methods** Biomechanical data were collected in laboratory, using 2 force-platforms (Kistler AG, Winterthur, Switzerland) and a high resolution optoelectronic system with 10 cameras of high speed (Oqus3 Qualisys AB) at 200Hz, providing three-dimensional data. Kinematic and kinetic analysis by inverse-dynamics, were obtained with Visual3D software. The task consisted of walking at a comfortable speed. Three measures were collected at the beginning of the 2nd trimester-B2T ( $13.0 \pm 1.8$  weeks), at the beginning of the 3rd trimester-B3T ( $27.0 \pm 1.3$  weeks), and at the end of the 3rd trimester-E3T ( $37.1 \pm 1.2$  weeks). 4 pregnant women participated in B2T, 5 in B3T and 6 in E3T, in a crossover longitudinal study. **Results** Comfortable speed decreased from 1.22m/s in B2T through 1.17m/s in B3T, until 1.11m/s in E3T. Stride width increased from 0.108m in B2T through 0.117m in B3T, until 0.124m in E3T. Stride length decreased from 1.29m in B2T through 1.26m in B3T, until 1.22m in E3T. Duration of the gait cycle increased from 1.06s in B2T through 1.08s in B3T, until 1.10s in E3T. Ground reaction forces (GRF) tend to decrease maximum peak in vertical component and have higher anterior and medial forces. Ankle moment of forces tends to decrease through pregnancy and, knee and hip moment of forces tend to increase from B2T to E3T. Power seems to decrease in all lower joints during pregnancy. **Discussion** On average, throughout pregnancy, temporal and spatial parameters have changed (Falola et al., 2009; Wu et al., 2002; Wu et al., 2004; Wu et al., 2008), allowing the pregnant women fit to morphological and physiological changes (Guyton & Hall, 1997). The sagittal range of motion, GRF and joint reaction forces on both lower limb joints shows small but significant differences among trimesters (Foti, et al., 2000; Lymbery and Gilleard, 2005). The results of the present work in progress will be useful to develop recommendations for pregnancy specific exercise programs, for pain prevention and to improve the biomechanical models. **References** Falola, J. #### MUSCLE COORDINATION AND OVERALL EFFICIENCY IN CYCLING

BLAKE, O.

SIMON FRASER UNIVERSITY

**MUSCLE COORDINATION AND OVERALL EFFICIENCY IN CYCLING** Blake, OM.1; Champoux, Y.2; Wakeling, JM.1 1: Simon Fraser University, Canada 2: VelUS, University of Sherbrooke, Canada **INTRODUCTION** Cycling utilizes muscle coordination to apply force to the pedals. Some coordination patterns produce maximal power while some are more efficient. Variations in muscle coordination are reflected in the metabolic costs (Bigland-Ritchie et al., 1976) and mechanical power output and therefore should be apparent in the overall mechanical
